Flexion contractures of the hip or knee are seen in patients with amputations of the lower extremity. This complication must be avoided so that the patient can ambulate with a prosthetic device. Proper positioning and active range-of-motion exercises help prevent this complication.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

A client who had an elective below-the-knee amputation reports pain in the part of his leg that was amputated. What is the nurse's best response to his pain?

- A. "The pain will go away in a few days or so."
- B. "That's phantom limb pain and every amputee has that."
- C. "On a scale of 0 to 10, how would you rate your pain?"
- D. "The pain is not real, so we don't treat it."

Health Promotion and Maintenance

The typical patient undergoing elective amputation is a middle-aged or older man with diabetes and a lengthy history of smoking. He most likely has not cared for his feet properly, which has resulted in a nonhealing, infected foot ulcer and possibly gangrene. Therefore adherence to the disease management plan may help prevent the need for later amputation. Lifestyle habits like maintaining a healthy weight, regular exercise, and avoiding smoking can help prevent chronic diseases like diabetes and poor blood circulation.

The second largest group who have amputations comprise young men who have motorcycle or other vehicular crashes or who are injured by industrial equipment or by combat or accidents in war. These men may either experience a traumatic amputation or undergo a surgical amputation because of a severe crushing injury and massive soft-tissue damage. Teach young male adults the importance of taking safety

precautions to prevent injury at work and to avoid speeding or driving while drinking alcohol. An increasing number of young women also tend to speed and drive while drinking, which endangers themselves and others around them.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

Monitor neurovascular status in the affected extremity that will be amputated. When the patient has peripheral vascular disease, also check circulation in both legs. Assess skin color, temperature, sensation, and pulses in both affected and unaffected extremities. Capillary refill can be difficult to determine in the older adult related to thickened and opaque nails. In this situation, the skin near the nail bed can be used (see [Chart 54-3](#)). Capillary refill may not be as reliable as other indicators. Observe and document any discoloration of the skin, edema, ulcerations, presence of necrosis, and hair distribution on the lower extremities.

Psychosocial Assessment

People react differently to the loss of a body part. Be aware that an amputation of a portion of one finger, especially the thumb, can be traumatic to the patient. The thumb is needed for hand activities. Therefore the loss must not be underestimated. Patients undergoing amputation face a complete, permanent loss. Evaluate their psychological preparation for a planned amputation, and expect them to go through the grieving process. Adjustment to a traumatic, unexpected amputation is often more difficult than accepting a planned one. The young patient may be bitter, hostile, and depressed. In addition to loss of a body part, the patient may lose a job, the ability to participate in favorite recreational activities, or a social relationship if other people cannot accept the body change.

The patient has an altered self-concept. The physical alteration that results from an amputation affects body image and self-esteem. For example, a patient may think that an intimate relationship with a partner is no longer possible. An older adult may feel a loss of independence. Assess the patient's feelings about himself or herself to identify areas in which he or she needs emotional support. Refer the patient to the certified hospital chaplain, other spiritual leader, or social worker if he or she is hospitalized. Counseling resources are also available in the community.

Attempt to determine the patient's willingness and motivation to withstand prolonged rehabilitation after the amputation. Asking questions about how he or she has dealt with previous life crises can provide clues. Adjustment to the amputation and rehabilitation is less difficult if the patient is willing to make needed changes.

In addition to assessing the patient's psychosocial status, assess the family's reaction to the surgery or trauma. Their response usually correlates directly with the patient's progress during recovery and rehabilitation. Expect the family to grieve for the loss, and they must be allowed to adjust to the change.

Assess the patient's and family's coping abilities, and help them identify personal strengths and weaknesses. Assess the

patient's religious, spiritual, and cultural beliefs. Certain groups require that the amputated body part be stored for later burial with the rest of the body or be buried immediately. Other cultural customs and rituals may apply depending on the group with which the patient associates.

Diagnostic Assessment

The surgeon determines which tests are performed to assess for viability of the limb based on blood flow. A large number of noninvasive techniques are available for this evaluation. For complete accuracy, the health care provider does not rely on any single test.

One procedure is measurement of segmental limb blood pressures, which can also be used by the nurse at the bedside. In this test, an **ankle-brachial index (ABI)** is calculated by dividing ankle systolic pressure by brachial systolic pressure. A normal ABI is 1 or higher.

Blood flow in an extremity can also be assessed by other noninvasive tests, including Doppler ultrasonography or laser Doppler flowmetry and transcutaneous oxygen pressure (TcPO₂). The ultrasonography and laser Doppler measure the speed of blood flow in the limb. The TcPO₂ measures oxygen pressure to indicate blood flow in the limb and has proved reliable for predicting healing.

INTERVENTIONS

A traumatic amputation requires rapid emergency care to possibly save the severed body part for reattachment and prevent hemorrhage.

Emergency Care: Traumatic Amputation

For a person who has a traumatic amputation in the community, first call 911. Assess the patient for airway or breathing problems. Examine the amputation site, and apply direct pressure with layers of dry gauze or other cloth, using clean gloves if available. Many nurses carry gloves and first aid kits for this type of emergency. Elevate the extremity above the patient's heart to decrease the bleeding. Do not remove the dressing to prevent dislodging the clot.

The fingers are the most likely part to be amputated and replanted. The current recommendation for prehospital care is to wrap the completely severed finger in dry sterile gauze (if available) or a clean cloth. Put the finger in a watertight, sealed plastic bag. *Place the bag in ice water, never directly on ice, at 1 part ice and 3 parts water* (Laskowski-Jones, 2006). Avoid contact between the finger and the water to prevent tissue damage. Do not remove any semidetached parts of the digit. Be sure that the part goes with the patient to the hospital.

Collaborative Care for the Patient with an Amputation

Patient care depends on the type and location of the amputation. For example, an above-the-knee amputation (AKA) has the potential for more postoperative complications than does a partial foot amputation. Regardless of where the amputation occurs, collaborate with the rehabilitation therapists to improve ambulation and/or enable the patient to be independent in ADLs. For many amputations, prostheses can be used to substitute for the missing body part.

Patients undergoing lower extremity amputation today are not confined to a wheelchair. Advancements in the design of

prosthetics have enabled them to become independent. Therefore complications from extended bedrest are not common, even for older adults.

Assessing Tissue Perfusion and Managing Pain. *The nurse's primary focus is to monitor for signs indicating that there is sufficient tissue perfusion but no hemorrhage.* The skin flap at the end of the residual (remaining) limb should be pink in a light-skinned person and not discolored (lighter or darker than other skin pigmentation) in a dark-skinned patient. The area should be warm but not hot. Assess the closest proximal pulse for presence and strength, and compare it with that in the other extremity. If the patient has bilateral vascular disease, however, comparison of limbs may not be an accurate way of measuring blood flow. Use a Doppler device to determine if the affected side is being perfused.

All patients experience pain as a result of either a traumatic or surgical (elective) amputation. Some patients also report pain in the missing body part, often called **phantom limb pain (PLP)**. Be sure to determine which type the patient has, because they are managed very differently.

! NURSING SAFETY PRIORITY

Action Alert

If the patient reports PLP, recognize that the pain is real and should be managed promptly and completely! It is not therapeutic to remind the patient that the limb cannot be hurting because it is missing. To prevent increased pain, handle the residual limb carefully when assessing the site or changing the dressing.

Opioid analgesics are not as effective for PLP as they are for residual limb pain. IV infusions of calcitonin (Miacalcin, Calcimar) during the week after amputation can reduce phantom limb pain. The health care provider prescribes other drugs on the basis of the type of PLP the patient experiences. For instance, beta-blocking agents such as propranolol (Inderal, Apo-Propranolol ♣, Detensol ♣) are used for constant, dull, burning pain. Antiepileptic drugs such as carbamazepine (Tegretol) and gabapentin (Neurontin) may be used for knifelike or sharp burning pain. Antispasmodics such as baclofen (Lioresal) may be prescribed for muscle spasms or cramping. Some patients improve with antidepressant drugs.

Teach patients about other modalities for managing PLP, including:

- Ultrasound therapy
- Massage
- Heat
- Biofeedback
- Relaxation therapy
- Hypnosis
- Psychotherapy

Most of these modalities are described in **Chapters 2 or 5**. Incorporate them into the plan of care if agreeable with the patient by collaborating with specialists who are trained to perform them. For example, physical therapists often use massage, heat, transcutaneous electrical nerve stimulation (TENS), and ultrasound therapy for pain control. Collaborate with the certified hospital chaplain to provide emotional support or a social worker or psychologist to provide psychotherapy, as needed.

Preventing Infection

The surgeon typically prescribes a broad-spectrum prophylactic antibiotic immediately before elective surgery. These may be continued in patients with traumatic amputations or those who have open wounds on the residual limb. The initial pressure dressing and drains are usually removed by the surgeon 48 to 72 hours after surgery. Inspect the incision or wound for signs of infection. Record the appearance, amount, and odor of drainage, if present. The surgeon may want the incision open to air until staples or sutures are removed or may want the residual limb to have a continuous soft or rigid dressing made of fiberglass. A soft dressing is secured by an elastic bandage wrapped firmly around the residual limb.

Promoting Mobility and Preparing for Prosthesis

Collaborate with the physical therapist to begin exercises as soon as possible after surgery. If the amputation is planned, the therapist may work with the patient before surgery to start muscle-strengthening exercises and evaluate the need for ambulatory aids, such as crutches. If the patient can practice with these devices before surgery, learning how to ambulate after surgery is much easier.

For patients with AKAs or BKAs, teach range-of-motion (ROM) exercises for prevention of flexion contractures, particularly of the hip and knee. A trapeze and an overhead frame aid in strengthening the arms and allow the patient to move independently in bed. Teach the patient how to perform range-of-motion exercises. Be sure to turn the patient every 2 hours, or teach the patient to turn independently. Move the patient slowly to prevent muscle spasms (Pullen, 2010).

A firm mattress is essential for preventing contractures with a leg amputation. Assist the patient into a prone position every 3 to 4 hours for 20- to 30-minute periods if tolerated and not contraindicated. This position may be uncomfortable initially but is necessary to prevent hip flexion contractures. Instruct the patient to pull the residual limb close to the other leg and contract the gluteal muscles of the buttocks for muscle strengthening. After staples are removed, the physical therapist may begin resistive exercises, which should also be done at home.

For above- and below-the-knee amputations, teach the patient how to push the residual limb down toward the bed while supporting it on a soft pillow at first. Then instruct him or her to continue this activity using a firmer pillow and then progress to a harder surface. This activity helps prepare the residual limb for prosthesis and reduces the incidence of phantom limb pain and sensation (Pullen, 2010).

Elevation of a lower-leg residual limb on a pillow while the patient is in a supine position is controversial. Some practitioners advocate avoiding this practice at all times because it promotes hip or knee flexion contracture. Others allow elevation for the first 24 to 48 hours to reduce swelling and subsequent discomfort. Inspect the residual limb daily to ensure that it lies completely flat on the bed.

Before an elective amputation, the patient often sees a certified prosthetist-orthotist (CPO) so that planning can begin for the postoperative period. Arrangements for replacing an arm part are especially important so that the patient can achieve self-management. Some patients are fitted with a temporary prosthesis at the time of surgery. Others, particularly older patients with vascular disease, are fitted after the residual limb has healed.

FIG. 54-12 A common method of wrapping an amputation stump. *Top*, Wrapping for above-knee amputation. *Bottom*, Wrapping for below-knee amputation.

The patient being fitted for a leg prosthesis should bring a sturdy pair of shoes to the fitting. The prosthesis will be adjusted to that heel height.

Several devices help shape and shrink the residual limb in preparation for the prosthesis. Rigid, removable dressings are preferred because they decrease edema, protect and shape the limb, and allow easy access to the wound for inspection. The Jobst air splint, a plastic inflatable device, is sometimes used for this purpose. One of its disadvantages is air leakage and loss of compression. Wrapping with elastic bandages can also be effective in reducing edema, shrinking the limb, and holding the wound dressing in place.

For wrapping to be effective, reapply the bandages every 4 to 6 hours or more often if they become loose. *Figure-eight wrapping prevents restriction of blood flow. Decrease the tightness of the bandages while wrapping in a distal-to-proximal direction.* After wrapping, anchor the bandages to the highest joint, such as above the knee for BKAs (Fig. 54-12).

The design of and materials for prostheses have improved dramatically over the years. Computer-assisted design and manufacturing (CAD-CAM) is used for a custom fit. One of the most important developments in lower extremity prosthetics is the ankle-foot prosthesis, such as the Flex-Foot for more active amputees.

Promoting Body Image and Lifestyle Adaptation

The patient often experiences feelings of inadequacy as a result of losing a body part, especially the older adult who was in poor health before surgery and men who are often the main providers for their families. If possible, arrange for him or her to meet with a rehabilitated amputee who is about the same age as the patient.

Use of the word *stump* for referring to the remaining portion of the limb (residual limb) continues to be controversial. Patients have reported feeling as if they were part of

a tree when the term was used. However, some rehabilitation specialists who routinely work with amputees believe the term is appropriate because it forces the patient to realize what has happened and promotes adjustment to the amputation. *Assess the patient to determine what term he or she prefers.*

Assess the patient's verbal and nonverbal references to the affected area. Some patients behave euphorically (extremely happy) and seem to have accepted the loss. *Do not jump to the conclusion that acceptance has occurred.* Ask the patient to describe his or her feelings about changes in body image and self-esteem. He or she may verbalize acceptance but refuse to look at the area during a dressing change. This inconsistent behavior is not unusual and should be documented and shared with other health care team members.

A patient who seems to adjust to the amputation during hospitalization may realize that it is difficult to cope with the loss after discharge from the hospital. Teach the patient and family about available resources and support from organizations such as the Amputee Coalition of America (ACA) (www.amputee-coalition.org) and the National Amputation Foundation (NAF) (www.nationalamputation.org). The NAF was originally started for veterans but has since expanded to offer services to civilians.

With advancements in prostheses and surgical techniques, most patients can return to their jobs and other activities. Professional athletes who use prostheses are often quite successful in sports. Patients with amputations ski, hike, golf, bowl, and participate in other physically demanding activities. Many amputees participate actively in organized and recreational sports.

If a job or career change is necessary, collaborate with a social worker or vocational rehabilitation specialist to evaluate the patient's skills. A supportive family or significant other is important for the adjustment to this change. The patient may also think that an intimate relationship is no longer

possible because of physical changes. Discuss sexuality issues with the patient and his or her partner as needed. Professional assistance from a sex therapist, intimacy coach, or psychologist may be needed.

Help the patient and family set realistic desired outcomes and take one day at a time. Help them recognize personal strengths. If the desired outcomes are not realistic, frustration and disappointment may decrease motivation during rehabilitation. Basic principles of rehabilitation are discussed in Chapter 8.

Community-Based Care

The patient is discharged directly to home or to a skilled facility or rehabilitation facility, depending on the extent of the amputation. When rehabilitation is not feasible as in the debilitated or demented older adult, he or she may be discharged to a long-term care facility. Coordinate this transfer with the case manager or discharge planner to ensure continuity of care.

At home, the patient with a leg amputation needs to have enough room to use a wheelchair if the prosthesis is not yet available. He or she must be able to use toileting facilities and have access to areas necessary for self-management, such as the kitchen. Structural home modifications may be required before the patient goes home.

After the sutures or staples are removed, the patient begins residual limb care. A home care nurse may be needed to teach the patient and/or family how to care for the limb and the prosthesis if it is available (Chart 54-7). The limb should be rewrapped three times a day with an elastic bandage applied in a figure-eight manner (see Fig. 54-12). For many patients, a shrinker stocking or sock is easier to apply. After the limb is healed, it is cleaned each day with the rest of the body during bathing with soap and water. Teach the patient and/

or family to inspect it every day for signs of inflammation or skin breakdown.

COMPLEX REGIONAL PAIN SYNDROME

Pathophysiology

Complex regional pain syndrome (CRPS), formerly called **reflex sympathetic dystrophy (RSD)** and **causalgia**, is a poorly understood dysfunction of the central and peripheral nervous systems that leads to severe, chronic pain. Genetic factors may play a role in the development of this devastating complication. CRPS most often results from fractures or other traumatic musculoskeletal injury and commonly occurs in the feet and hands. In some cases, specific nerve injuries are present, but in others, no injury can be identified. A triad of clinical manifestations is present, including abnormalities of the autonomic nervous system (changes in color, temperature, and sensitivity of skin over the affected area, excessive sweating, edema), motor symptoms (paresis, muscle spasms, loss of function), and sensory symptoms (intense burning pain that becomes intractable [unrelenting]).

Over time, spotty and diffuse osteoporosis can be seen on x-ray examination. Timing of diagnosis is important because the syndrome is more difficult to treat when diagnosed in the later stages.

PATIENT-CENTERED COLLABORATIVE CARE

The first priority of management is pain relief. Little research has been done to demonstrate the best practices for caring for a patient with CRPS (Hsu, 2009). Therefore a combination of interventions is used. Nurses play an important role in patient management, which includes drug therapy and a variety of nonpharmacologic modalities. Many classes of drugs may be used to manage the intense pain. These include topical analgesics, antiepileptic drugs, antidepressants, corticosteroids, bisphosphonates, and analgesics. Chapter 5 discusses pain management in detail.

In collaboration with the physical and occupational therapists, assist in maintaining adequate range of motion (ROM) and function. The skin of a patient with CRPS tends to alternate between warm, swollen, and red to cool, clammy, and bluish. Skin care needs to be gentle with minimal stimulation.

Peripheral or spinal cord neurostimulation using an external or internal implanted device delivers electrical pulses to block pain from getting to the brain where pain is perceived. The external or acupuncture method requires weekly sessions or a short-term continuous trial before the device is surgically implanted. Complications of implantable neurostimulators include spinal cord damage from hematoma or edema formation or other neurologic dysfunction.

A chemical sympathetic nerve block may be used. This procedure can be done by an IV infusion of phentolamine, a drug that blocks sympathetic receptors, or by injecting an anesthetic agent next to the spine to block sympathetic nerves.

Minimally invasive surgical **sympathectomy**, or cutting of the sympathetic nerve branches via endoscopy through a small axillary incision, may be required. Topical skin adhesive is used to close the very small incision. The patient

! NURSING SAFETY PRIORITY

Action Alert

Collaborate with the prosthetist to teach the patient about prosthesis care after amputation to ensure its reliability and proper function. These devices are custom made, taking into account the patient's level of amputation, lifestyle, and occupation. Proper teaching regarding correct cleansing of the socket and inserts, wearing the correct liners, assessing shoe wear, and a schedule of follow-up care is essential before discharge. This information may need to be reviewed by the home care nurse.

CHART 54-7 HOME CARE ASSESSMENT

The Patient with a Lower Extremity Amputation in the Home

- Assess the residual limb for:
 - Adequate circulation
 - Infection
 - Healing
 - Flexion contracture
 - Dressing/elastic wrap
- Assess the patient's ability to perform ADLs in the home.
- Evaluate the patient's ability to use ambulatory aids and to care for the prosthetic device (if available).
- Assess the patient's nutritional status.
- Assess the patient's ability to cope with body image change.

is discharged to home a few hours later with a follow-up examination the next day with the health care provider. Usual activities can resume a few days later.

Assist the patient in coping with CRPS because it often has a profound psychological effect. A referral for psychological counseling or psychotherapy may be indicated. The Reflex Sympathetic Dystrophy Syndrome Association (RSDSA) (www.rsds.org) and National Pain Association (www.nationalpainassociation.org) are available to help patients and their families organize or locate support groups and other resources.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse is concerned that a client who had an open reduction, internal fixation of his tibia and fibula is at risk for complex regional pain syndrome. What assessment findings at the affected area are common when a client has this complication? **Select all that apply.**

- A. Dull, aching pain
- B. Decrease in sweating
- C. Muscle spasms
- D. Skin discoloration
- E. Paresis
- F. Edema

SPORTS-RELATED INJURIES

In addition to the bone and muscle problems already discussed, trauma can cause cartilage, ligament, and tendon injury. Many musculoskeletal injuries are the result of playing sports (professional and recreational) or doing other strenuous physical activities. The popularity of all-terrain vehicles (ATVs) and skateboarding has increased injuries in younger patients. Sports injuries have become so common that large metropolitan hospitals have sports medicine clinics and physicians who specialize in this field.

Although the specific types of injury are numerous, this chapter includes only the most common ones seen in a hospital or ambulatory care setting. The principles of injury to one part of the body are similar to those of other sports injuries. For example, a tendon rupture in a knee is cared for in the same manner as a tendon rupture in the wrist. [Chart 54-8](#) lists general emergency measures for sports-related injuries. All patients require frequent neurovascular monitoring.

Because the knee is most often injured, it is discussed as a typical example of other areas of the body. Trauma to the

knee results in **internal derangement**, a broad term for disturbances of an injured knee joint. When surgery is required to resolve the problem, most surgeons prefer to perform the procedure through an arthroscope when possible. A description of arthroscopy is presented in [Chapter 53](#).

KNEE INJURIES: PATELLOFEMORAL PAIN SYNDROME

Patellofemoral pain syndrome (PFPS) is the most common diagnosis in patients who have knee pain. It occurs most often in people who are runners or who overuse their knee joints. For that reason, it is sometimes referred to as “runner’s knee.” Patients with this problem describe pain as being behind or around their patella (knee cap) in one or both knees. Swelling is not common although stiffness may be present, especially when the knee is flexed.

Management usually involves rest, physical therapy, bracing or splinting, and mild analgesics. For patients who have pain lasting for more than 12 months, arthroscopic surgery is performed.

KNEE INJURIES: MENISCUS

Pathophysiology

There are two semilunar cartilaginous structures, or menisci, in the knee joint: the medial meniscus and the lateral meniscus. These pads act as shock absorbers, but they can tear. Tearing is usually a result of twisting the leg when the knee is flexed and the foot is placed firmly on the ground. The medial meniscus is much more likely to tear than the lateral meniscus because it is less mobile. Internal rotation causes a tear in the medial meniscus. External rotation causes a tear in the lateral meniscus.

Tears can be anterior or posterior, longitudinal or transverse. In the medial meniscus, a longitudinal tear, or “bucket handle” injury, often causes the knee to lock (i.e., the torn cartilage jams between the femur and the tibia and prevents extension of the knee). Surgery is often required for this type of injury. In transverse tears, the knee does not lock and surgery may not be required.

PATIENT-CENTERED COLLABORATIVE CARE

The patient with a torn meniscus typically has pain, swelling, and tenderness in the knee. A clicking or snapping sound can often be heard when the knee is moved.

A common diagnostic technique is the **McMurray test**. The examiner flexes and rotates the knee and then presses on the medial aspect while slowly extending the leg. The test result is positive if clicking is palpated or heard. A negative finding, however, does not rule out a tear.

For a locked knee, the treatment may be manipulation followed by splinting or casting for 3 to 6 weeks. If the problem recurs, a partial or total **meniscectomy** is performed. An *open* meniscectomy requires a surgical incision for removal of all or part of the meniscus and is rarely performed. Most surgeons prefer to remove only the affected portion during a *closed* meniscectomy, which can be done through an arthroscope as a same-day surgical procedure. As described in [Chapter 53](#), an arthroscope is a metal tubular

CHART 54-8 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of Patients with Sports-Related Injuries

- Do not move the victim until spinal cord injury is ascertained (see [Chapter 45](#) for assessment of spinal cord injury).
- Rest the injured part; immobilize the joint above and below the injury by applying a splint if needed.
- Apply ice intermittently for the first 24 to 48 hours (heat may be used thereafter).
- Elevate the affected limb to decrease swelling.
- Use compression for the first 24 to 48 hours (e.g., elastic wrap).
- Always assume the area is fractured until x-ray studies are done.
- Assess neurovascular status in the area distal to the injury.

FIG. 54-13 A knee immobilizer.

instrument used for examination or surgery of joints. One or more small incisions (less than $\frac{1}{4}$ -inch [0.6-cm] long) are made in the knee for insertion of the arthroscope. The surgeon threads a cutting device through the arthroscope for removal of the torn cartilage while the knee is irrigated. The surgeon may use a laser during the procedure, depending on the type and severity of the injury. A bulky pressure dressing is applied after the procedure, and the affected leg is wrapped in elastic bandages.

As for any postoperative patient, check the surgical dressing for bleeding and monitor vital signs after the patient is admitted to the same-day surgical unit. Perform neurovascular checks as outlined in [Chart 54-3](#), usually every hour for the first few hours and then every 4 hours. Teach the patient and family what signs and symptoms to watch for after surgery and when to notify the health care provider.

The patient begins exercises immediately after surgery to strengthen the leg, prevent venous thromboembolism, and reduce swelling. Quadriceps setting, in which the patient straightens the leg while pushing the knee against the bed, is done in sets of 10 or more. Straight-leg raises are also performed. Range-of-motion (ROM) exercises are usually not started for several days.

To prevent bending the affected knee, the physician may request a knee immobilizer, such as the one shown in [Fig. 54-13](#). Elevate the leg on one or two pillows according to the physician's preference, and apply ice to reduce postoperative swelling. Full weight bearing is restricted for several weeks, depending on the amount of cartilage removed. The patient is usually discharged from the hospital with crutches in less than 23 hours.

KNEE INJURIES: LIGAMENTS

The cruciate and collateral ligaments in the knee are predisposed to injury, often from sports or vehicular crashes. The anterior cruciate ligament (ACL) is the most commonly torn

ligament in the knee. Athletes often get these injuries during skiing, skating, or gymnastics. Women have ACL tears more often than men, possibly related to hormonal influences, biomechanical factors, and anatomic differences. Proper athletic shoes and learning how to land when jumping can help prevent this injury.

When the ACL is torn, the patient feels a snap and the knee gives way because of ACL laxity. Within hours, the knee is swollen, stiff, and painful. Examination by the health care provider shows positive ligament laxity. The diagnosis of an ACL tear is best confirmed by magnetic resonance imaging (MRI).

Treatment may be nonsurgical or surgical, depending on the severity of the injury and the activity of the patient. Exercises, bracing, and limits on activities while the ligament heals may be sufficient. If medical management is not effective or the tear is severe, surgery may be needed.

The surgeon repairs the tear by reattaching the torn portions of the ligament through arthroscopy. The leg is placed in a brace or immobilizer. If the ligament cannot be repaired, reconstructive surgery may be performed with autologous grafts. A ligament from another part of the body is used to replace the torn knee ligament. Another option is artificial knee implants such as the GORE-TEX ligament.

Complete healing of knee ligaments after surgery can take 6 to 9 months or longer. These patients may use a continuous passive motion (CPM) machine at home. Teach the patient how to use and care for the machine. CPM use is discussed with the postoperative care of the total knee patient in [Chapter 20](#).

OTHER INJURIES

CARPAL TUNNEL SYNDROME

Pathophysiology

Carpal tunnel syndrome (CTS) is a common condition in which the median nerve in the wrist becomes compressed, causing pain and numbness. The carpal tunnel is a rigid canal that lies between the carpal bones and a fibrous tissue sheet. A group of tendons surrounds the synovium and shares space with the median nerve in the carpal tunnel. When the synovium becomes swollen or thickened, this nerve is compressed.

The median nerve supplies motor, sensory, and autonomic function for the first three fingers of the hand and the palmar aspect of the fourth (ring) finger. Because the median nerve is close to other structures, wrist flexion causes nerve impingement, and extension causes increased pressure in the lower portion of the carpal tunnel.

CTS usually presents as a chronic problem. Acute cases are rare. Excessive hand exercise, edema or hemorrhage into the carpal tunnel, or thrombosis of the median artery can lead to acute CTS. *Patients with hand burns or a Colles' fracture of the wrist are particularly at risk for this problem.* In most cases, the cause may not result in nerve deficit for years.

CTS is also a common complication of certain metabolic and connective tissue diseases. For example, **synovitis** (inflammation of the synovium) occurs in patients with rheumatoid arthritis (RA). The hypertrophied synovium compresses the median nerve. In other chronic disorders such as diabetes mellitus, inadequate blood supply can

CHART 54-9 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Health Promotion Activities to Prevent Carpal Tunnel Syndrome

- Become familiar with federal and state laws regarding workplace requirements to prevent repetitive stress injuries such as carpal tunnel syndrome (CTS).
- When using equipment or computer workstations that can contribute to developing CTS, assess that they are ergonomically appropriate, including:
 - Specially designed wrist rest devices
 - Geometrically designed computer keyboards
 - Chair height that allows good posture
- Take regular short breaks away from activities that cause repetitive stress, such as computers.
- Stretch fingers and wrists frequently during work hours.
- Stay as relaxed as possible when using equipment that causes repetitive stress.

cause median nerve neuropathy or dysfunction, resulting in CTS.

CTS is the most *common* type of **repetitive stress injury (RSI)**. RSIs are the fastest growing type of occupational injury. People whose jobs require repetitive hand activities such as pinching or grasping during wrist flexion (e.g., factory workers, computer operators, jackhammer operators) are predisposed to CTS. It can also result from overuse in sports activities such as golf, tennis, or racquetball.

In a few cases, CTS may be a familial or congenital problem that manifests in adulthood. Space-occupying growths such as ganglia, tophi, and lipomas can also result in nerve compression.

Women, especially those older than 50 years, are much more likely than men to experience CTS, most likely due to the higher prevalence of diseases such as RA in women. The problem most often affects the dominant hand but can occur in both hands simultaneously. CTS is beginning to be found in children and adolescents as a result of the increased use of computers in everyday life.

Health Promotion and Maintenance

Most businesses recognize the hazards of repetitive motion as a primary cause of occupational injury and disability. Both men and women in the labor force are experiencing increasing numbers of RSIs. Occupational health nurses have played an important role in ergonomic assessments and in the development of ergonomically designed furniture and various aids to decrease CTS and other musculoskeletal injuries.

U.S. federal and state legislation has been passed to ensure that all businesses, including health care organizations (HCOs), provide *ergonomically appropriate workstations* for their employees (Occupational Safety and Health Administration). The Joint Commission also requires that hospitals and other HCOs provide a safe work environment for all staff. In Canada, each province requires the work setting to have joint health and safety committees in which employees are actively involved in setting safety standards (Canadian Centre for Occupational Health and Safety). **Chart 54-9** lists best practices for preventing CTS in the health care setting.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

A medical diagnosis is often made based on the patient's history and report of hand pain and numbness and without further assessment. Ask about the nature, intensity, and location of the pain. Patients often state that the pain is worse at night as a result of flexion or direct pressure during sleep. The pain may radiate to the arm, shoulder and neck, or chest.

In addition to reports of numbness, patients with carpal tunnel syndrome (CTS) may also have **paresthesia** (painful tingling). *Sensory* changes usually occur weeks or months before *motor* manifestations.

The health care provider performs several tests for abnormal sensory findings. Phalen's wrist test, sometimes called **Phalen's maneuver**, produces paresthesia in the median nerve distribution (palmar side of the thumb, index and middle fingers, and half of the ring finger) within 60 seconds due to increased internal carpal pressure. The patient is asked to relax the wrist into flexion or to place the back of the hands together and flex both wrists at the same time. The Phalen's test is positive in most patients with CTS.

The same sensation can be created by tapping lightly over the area of the median nerve in the wrist (**Tinel's sign**). If the test is unsuccessful, a blood pressure cuff can be placed on the upper arm and inflated to the patient's systolic pressure (tourniquet). This often causes pain and tingling.

The newest pain-provoking diagnostic test being used is the Okutsu position test. The patient is asked to place the hands in a palm-to-palm position with thumbs extended. Then he or she is asked to move the wrist toward the radial side as far as it can be done and hold that position for 1 minute. Pain and tingling occur more often than from the Tinel's and Phalen's tests.

Motor changes in carpal tunnel syndrome (CTS) begin with a weak pinch, clumsiness, and difficulty with fine movements. These changes progress to muscle weakness and wasting, which can impair self-management. If desired, test for pinching ability and ask the patient to perform a fine-movement task, such as threading a needle. Strenuous hand activity worsens the pain and numbness.

In addition to inspecting for muscle atrophy and task performance, observe the wrist for swelling. Gently palpate the area and note any unusual findings. Autonomic changes may be evidenced by skin discoloration, nail changes (e.g., brittleness), and increased or decreased hand sweating.

When a definitive diagnosis is uncertain, the health care provider may request routine x-rays, electromyography (EMG) and nerve conduction studies (NCS), and/or ultrasonography. MRI is generally not very helpful in diagnosis. NCS testing reveals nerve dysfunction before muscle atrophy is observed. An ultrasound scan may be done to view the cause of the problem. The most common finding is an enlarged median nerve within the carpal tunnel.

INTERVENTIONS

The health care provider uses conservative measures before surgical intervention. However, CTS can recur with either type of treatment. Management depends on the patient, but established best practices have not been determined (Uchiyama et al., 2010).

Nonsurgical Management

Aggressive drug therapy and immobilization of the wrist are the major components of nonsurgical management. Teach the patient the importance of these modalities in the hope of preventing surgical intervention.

NSAIDs are the most commonly prescribed drugs for the relief of pain and inflammation, if present. In addition to or instead of systemic medications, the physician may inject corticosteroids directly into the carpal tunnel. If the patient responds to the injection, several additional weekly or monthly injections are given. Teach him or her to take NSAIDs with or after meals to reduce gastric irritation.

A splint or hand brace may be used to immobilize the wrist during the day, during the night, or both. Many patients experience temporary relief with these devices. The occupational therapist places the wrist in the neutral position or in slight extension.

Laser or ultrasound therapy may also be helpful. Some patients report fewer symptoms after beginning yoga or other exercise routine.

Surgical Management

Surgery is necessary in about half of patients with CTS. Surgery can relieve the pressure on the median nerve by providing nerve decompression. Major surgical complications are rare after CTS surgery. In some cases, however, CTS recurs months to years after surgery.

The nurse in the physician's office or same-day surgical center reinforces the teaching provided by the surgeon regarding the nature of the surgery. Postoperative care is reviewed so the patient knows what to expect. [Chapter 16](#) describes general preoperative care in detail.

Whatever the cause of nerve compression, the surgeon removes it either by cutting or by the newer laser technique. The two most common surgeries are the open carpal tunnel release (OCTR) and the newer endoscopic carpal tunnel release (ECTR). When CTS is a complication of rheumatoid arthritis, a [synovectomy](#) (removal of excess synovium) through a small inner-wrist incision may resolve the problem. Removal of a space-occupying growth, if present, also decompresses the nerve. A recent systematic review showed that surgical treatment seems to be more effective than conservative measures over the long term. However, there was no evidence that one type of procedure, open or endoscopic, was more effective than the other (Huisstede et al., 2010).

ECTR, the endoscopic technique, is a common alternative to OCTR, the open technique. The surgeon makes a very small incision (less than $\frac{1}{2}$ inch [1.2 cm]) through which the endoscope is inserted. The surgeon then uses special instruments, which may include a laser, to free the trapped median nerve. Although ECTR is less invasive and costs less than the open procedure, the patient may have a longer period of postoperative pain and numbness compared with recovery from OCTR.

After surgery, monitor vital signs and check the dressing carefully for drainage and tightness. If ECTR has been performed, the dressing is very small. The surgeon may require that the patient's affected hand and arm be elevated above heart level for several days to reduce postoperative swelling. Check the neurovascular status of the fingers every hour during the immediate postoperative period, and encourage the patient to move them frequently. Offer pain medication

and assure him or her that a prescription for analgesics will be provided before discharge.

Hand movements, including lifting heavy objects, may be restricted for 4 to 6 weeks after surgery. The patient can expect weakness and discomfort for weeks or perhaps months. Teach him or her to report any changes in neurovascular status, including increased pain and numbness, to the surgeon's office immediately.

Remind the patient and family that the surgical procedure might not be a cure. For instance, synovitis may recur with rheumatoid arthritis and may recompress the median nerve. Multiple surgeries and other treatments are common with CTS.

The patient may need assistance with self-management activities during recovery. Ensure that assistance in the home is available before discharge; this is usually provided by the family or significant others.

TENDINOPATHY AND JOINT DISLOCATION

Other injuries can affect any synovial joint. The nursing management of each of these is similar to the collaborative care previously discussed for knee injuries. One of the most common injuries seen in general and sports medicine is Achilles tendon–related injuries (tendinopathy). *Rupture of the Achilles tendon* is common in adults who participate in strenuous sports or in women who wear high heels regularly. It can also occur after taking fluoroquinolone antibiotics, such as levofloxacin (Levoquin) and ciprofloxacin (Cipro) (Barry, 2010).

In the older adult, quadriceps tendon rupture may occur from a fall down several steps. Most cases of Achilles tendinopathy can be treated with RICE (see [Chart 54-8](#)):

- **Rest**
- **Ice**
- **Compression**
- **Elevation**

Some evidence supports the use of NSAIDs, and changes in activity and shoes may be helpful (Chang et al., 2010). Ultrasound treatments may also be effective.

For severe damage and as a last resort, the tendon is surgically repaired and the leg is immobilized in a cast or brace for at least 6 to 8 weeks. If the tendon is beyond repair, a [tendon transplant](#) (also known as *tendon reconstruction*) may be performed. A tendon is removed from one part of the body and transplanted to the affected area, or a cadaver donor is used.

[Dislocation of a joint](#) occurs when the ends of two or more bones are moved away from each other. If the dislocation is not complete, the joint is partially dislocated, or [subluxed](#). It can occur in any diarthrodial (synovial) joint but is most common in the shoulder, hip, knee, and fingers. This injury is usually the result of trauma but can be congenital or pathologic and can result from joint disease, such as arthritis.

The typical manifestations of dislocation are:

- Pain
- Immobility
- Alteration in contour of the joint
- Deviation in length of the extremity
- Rotation of the extremity

The health care provider performs a closed reduction of the joint and moves the joint surfaces back into their normal

anatomic position. The patient requires light anesthetic or moderate sedation. The joint is immobilized by a cast, splint, brace, or immobilizer until healing occurs.

Recurrent dislocations are common in the knee and shoulder. For this problem, the joint may be fixed with wires or other device to prevent further displacement. A cast, splint, or traction is applied for 3 to 6 weeks.

STRAINS AND SPRAINS

A **strain** is excessive stretching of a muscle or tendon when it is weak or unstable. Strains are sometimes referred to as *muscle pulls*. Falls, lifting a heavy item, and exercise often cause this injury.

Strains are classified according to their severity:

- A first-degree (mild) strain causes mild inflammation but little bleeding. Swelling, ecchymosis (bruising), and tenderness are usually present.
- A second-degree (moderate) strain involves tearing of the muscle or tendon fibers without complete disruption. Muscle function may be impaired.
- A third-degree (severe) strain involves a ruptured muscle or tendon with separation of muscle from muscle, tendon from muscle, or tendon from bone.

Severe pain and disability result from severe strains.

Management usually involves cold and heat applications, exercise, and activity limitations. The health care provider may prescribe anti-inflammatory drugs to decrease inflammation and pain. Muscle relaxants may also be used. In third-degree strains, surgical repair of the ruptured muscle or tendon may be needed.

A **sprain** is excessive stretching of a ligament. Twisting motions from a fall or sports activity typically cause the injury. Sprains are also classified according to severity. Pain and swelling result from ligament injuries. The treatment for *mild (first-degree)* sprains includes RICE (see [Chart 54-8](#)).

Second-degree sprains require immobilization, such as elastic bandage and an air stirrup ankle brace or splint, and partial weight bearing while the tear heals. For severe ligament damage (*third-degree* sprain), immobilization for 4 to

6 weeks is necessary. Arthroscopic surgery may be done, particularly for chronic joint instability.

ROTATOR CUFF INJURIES

The musculotendinous, or rotator, cuff of the shoulder functions to stabilize the head of the humerus in the glenoid cavity during shoulder abduction. Young adults usually sustain a tear of the cuff by substantial trauma, such as may occur during a fall, while throwing a ball, or with heavy lifting. Older adults tend to have small tears related to aging, repetitive motions, or falls, and the tears are usually painless.

The patient with a torn rotator cuff has shoulder pain and cannot easily abduct the arm at the shoulder. When the arm is abducted, he or she usually drops the arm because abduction cannot be maintained (drop arm test). Pain is more intense at night and with overhead activities. Partial-thickness tears are more painful than full-thickness tears, but full-thickness tears result in more weakness and loss of function. Muscle atrophy is commonly seen. Diagnosis is confirmed with x-rays, MRI, ultrasonography, and/or CT scans.

The health care provider usually treats the patient with partial-thickness tears conservatively with NSAIDs, intermittent steroid injections, physical therapy, and activity limitations while the tear heals. Physical therapy treatments may include ultrasound, electrical stimulation, ice, and heat ([Smith & Smith, 2010](#)).

For patients who do not respond to conservative treatment in 3 to 6 months or for those who have a complete (full-thickness) tear, the surgeon repairs the cuff using open, mini-open, or arthroscopic procedures. After surgery, the affected arm is usually immobilized for several weeks. Pendulum exercises are started on the third or fourth postoperative day and progress to active exercises in about 2 weeks. If the surgery is extensive, the patient's arm may be immobilized for a longer time before exercises begin. Patients then begin outpatient rehabilitation in the occupational therapy department. Teach them that they may not have full function for several months.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient has impaired mobility and sensation as a result of acute musculoskeletal trauma?

- Extremity swelling, bleeding, bruising, shortening, malalignment, and/or rotation
- Report of severe pain
- Break in skin integrity
- Report of decreased or unusual sensation in extremity
- Inability or decreased ability to move extremity
- Difficulty breathing (rib trauma)
- Severe kyphosis (compression fractures)

What should you INTERPRET and how should you RESPOND to a patient with impaired mobility and sensation as a result of acute musculoskeletal trauma?

Perform and interpret focused physical assessment findings, including:

- ABC (airway, breathing, circulation) ability
- Pain intensity and quality
- Vital signs
- Neurovascular assessment (“circ check”)

Respond:

- First, establish ABCs if problem exists.
- If skin is not intact, cover wound with dry, sterile dressing, if available; use clean cloth as an option. Apply pressure to proximal pulse if patient is bleeding; for traumatic amputation, apply direct pressure to the residual body part.
- Implement measures to prevent hypovolemic shock if patient is bleeding, including lying patient flat, keeping him or her warm, and elevating the bleeding part.

NURSING CONCEPT REVIEW—cont'd

- Splint the extremity (in community setting) to prevent movement and further damage.
- If in hospital setting, assist health care provider in splinting.
- Provide pain control interventions by drug therapy as soon as possible.
- Provide emotional assurance for the patient by being present and comforting.

On what should you REFLECT?

- Monitor the patient's response to pain control interventions.
- Think about what else you could do to prevent complications.
- Determine what health teaching will be needed, depending on the treatment that is provided (e.g., surgery, cast).

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with physical and occupational therapists for care of patients with extremity fractures.
- Collaborate with the prosthetist, physical and occupational therapists, psychologist, and sex therapist or intimacy coach for care of patients with amputations.
- Several community organizations, such as the Amputee Coalition of America, are available to help patients and their families cope with the loss of a body part.
- Use strict aseptic technique when caring for wounds in patients with compound fractures to help prevent infection; give antibiotic therapy as prescribed.
- Assess the risk for and implement interventions to prevent complications of immobility in patients having musculoskeletal injury or surgery (e.g., pressure ulcers, venous thromboembolism [VTE]).

Health Promotion and Maintenance

- Teach patients and their family members and significant others how to care for casts or traction at home.
- Reinforce teaching for ambulating with crutches, walkers, or canes.
- Provide special care for older adults with hip fractures, including preventing heel pressure ulcers and promoting early ambulation to prevent complications of immobility.
- Teach exercises to patients with leg amputation to prevent hip flexion contractures.

Psychosocial Integrity

- Be aware that patients with severe musculoskeletal trauma may have a prolonged hospitalization and recovery period.
- For patients with severe trauma or amputation, assess coping skills and encourage verbalization.
- Recognize that the patient having an amputation may need to adjust to an altered lifestyle; however, new custom prosthetics improve mobility.

- Help the patient with an amputation or other musculoskeletal trauma and family to set realistic expected outcomes and take one day at a time.

Physiological Integrity

- Be aware that open fractures cause a higher risk for infection than do closed fractures.
- Assess patients with fractures for complications, such as VTE, infection, and acute compartment syndrome.
- Recognize that fat embolism syndrome is different from pulmonary (blood clot) embolism as outlined in [Chart 54-2](#).
- Provide emergency care of the patient with a fracture as described in [Chart 54-4](#).
- Identify the patient at risk for acute compartment syndrome; loosen bandages, or request that the patient's cast be cut if neurovascular compromise is noted.
- As a priority, assess neurovascular status frequently in patients with musculoskeletal injury, traction, or cast as described in [Chart 54-3](#).
- Provide appropriate cast care, depending on the type of cast (plaster or synthetic); check for pressure necrosis under the cast by feeling for heat, assessing the patient's pain level, and smelling the cast for an unpleasant odor.
- Provide pin care for patients with skeletal traction or external fixation; assess for manifestations of infection at the pin sites.
- Provide postoperative care for the patient having a fracture repair, including promoting mobility and monitoring for complications of immobility.
- Provide care for patients having a vertebroplasty or kyphoplasty as described in [Chart 54-6](#).
- Observe for hemorrhage and infection in the patient having an amputation.
- Postoperatively, assess for and promptly manage phantom limb pain in the patient who has an amputation; collaborate with specialists to incorporate complementary and alternative therapies into the patient's plan of care.
- Provide emergency care for patients with a sports-related injury as outlined in [Chart 54-8](#).

CONCEPT OVERVIEW

Nutrition, Metabolism, and Bowel Elimination

Why do we eat, and how are nutrition, metabolism, and bowel elimination related? Within the human body, as in all living systems, energy is required to perform any function. The word *metabolism* means to change or transform. Humans transform the energy stored within food into the types of energy needed to make the body work.

As shown in Fig. 1, *nutrition* involves ingesting many types of foods that contain proteins, carbohydrates, fats, vitamins, and minerals. Once inside the GI tract, the processes of digestion break down food into its basic elements, which then are absorbed into the blood and delivered to cells. Through metabolism, cells convert these basic elements into chemical energy, mostly adenosine triphosphate (ATP). Different cells then use metabolism to further transform ATP into heat energy, mechanical energy, chemical energy, and electrical energy. The transformation of chemical energy into other types of energy within the human body is *irreversible*. It is lost from the body in the form of heat and work. Thus bringing food into the body on a daily basis is important in meeting the human needs of nutrition and metabolism.

Heat energy helps maintain the core body temperature at or near 98.6° F—the ideal temperature for important physiologic reactions. When environmental temperatures are low, more food is needed to maintain body temperature. When environmental temperatures are high, less food is needed to maintain body temperature. Therefore, in general,

more calories need to be consumed per day in the winter than in the summer.

Mechanical energy is used for cell and tissue movement, cell shape changes, and whole body movement. *Electrical energy* generates the action potentials that allow nerves to transmit impulses and muscles to contract. *Chemical energy* is used to drive every chemical reaction in the body. As long as it remains alive, the body continuously needs to change food into these different energies.

Bowel elimination is the way the body rids itself of those food components that cannot be absorbed into the blood and converted into energy, such as fiber and cellulose. If these components remained in the GI tract, they would soon fill it to the point that no nutrients could be ingested.

Consider Fig. 1 as representing the entire nutrition, metabolism, and bowel elimination of a person throughout his or her lifetime. The energy ingested in the form of food exactly matches the energy transformed by metabolism and is used for all the different types of internal and external “work” of the body. When this ideal situation exists, the person always has the right amount of nutrients and neither stores excess nutrients nor breaks down body tissues to use for energy.

FIG. 1

In Fig. 2, the person is not ingesting enough nutrients to meet metabolic energy needs. As a result, the different types of work are less efficient and the person metabolizes his or her own body tissues to provide needed energy. If this situation continues, it will lead to death.

FIG. 2

In Fig. 3, the person is ingesting more nutrients than are needed to meet energy needs. As a result, these extra energy compounds are converted first into glycogen and eventually into fat. Although fat represents stored energy, excessive fat can harm the body. In addition, when food is ingested to excess, metabolism and work energies are not increased. Only heat and bowel elimination increase.

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Assess patients for complications of diagnostic tests.
2. Prioritize post-test care for patients having endoscopic procedures.

Health Promotion and Maintenance

3. Identify factors that place patients at risk for GI problems.
4. Teach pre-test and post-test care for diagnostic GI testing to patients and families.

Psychosocial Integrity

5. Identify general psychological responses to GI health problems.

Physiological Integrity

6. Briefly review the anatomy and physiology of the GI system.
7. Describe GI system changes associated with aging.
8. Perform a GI history using selected Gordon's Functional Health Patterns.
9. Perform focused physical assessment for patients with suspected or actual GI health problems.
10. Explain and interpret common laboratory tests for a patient with a GI health problem.

FIG. 55-1 The gastrointestinal system (GI tract) can be thought of as a tube (with necessary structures) extending from the mouth to the anus for a 25-foot length. The structure of this tube (*shown enlarged*) is basically the same throughout its length.

The GI system includes the GI tract (alimentary canal), consisting of the mouth, esophagus, stomach, small and large intestines, and rectum. The salivary glands, liver, gallbladder, and pancreas secrete substances into this tract to form the GI system (Fig. 55-1). The main function of the GI tract, with the aid of organs such as the pancreas and the liver, is the *digestion* of food to meet the body's *nutritional* needs and the *elimination* of waste resulting from digestion. Adequate nutrition is required for proper functioning of the body's organs and other cells (see the Concept Overview). The GI tract is susceptible to many health problems, including structural or mechanical alterations, impaired motility, infection, and cancer.

ANATOMY AND PHYSIOLOGY REVIEW

Overview of the Gastrointestinal System

Structure

The GI tract is a hollow muscular tube surrounded by four tissue layers. The **lumen**, or inner wall, of the GI tract consists of four layers: mucosa, submucosa, muscularis, and serosa. The *mucosa*, the innermost layer, includes a thin layer of

smooth muscle and specialized exocrine gland cells. It is surrounded by the submucosa, which is made up of connective tissue. The *submucosa* layer is surrounded by the muscularis. The *muscularis* is composed of both circular and longitudinal smooth muscles, which work to keep contents moving through the tract. The outermost layer, the *serosa*, is composed of connective tissue. Although the GI tract is continuous from the mouth to the anus, it is divided into specialized regions. The mouth, pharynx, esophagus, stomach, and small and large intestines each perform a specific function. In addition, the secretions of the salivary, gastric, and intestinal glands; liver; and pancreas empty into the GI tract to aid digestion.

Function

The functions of the GI tract include secretion, digestion, absorption, motility, and elimination. Food and fluids are ingested, swallowed, and propelled along the lumen of the GI tract to the anus for elimination. The smooth muscles contract to move food from the mouth to the anus. Before food can be absorbed, it must be broken down to a liquid, called **chyme**. **Digestion** is the mechanical and chemical process in which complex foodstuffs are broken down into simpler forms that can be used by the body. During digestion, the stomach

secretes hydrochloric acid, the liver secretes bile, and digestive enzymes are released from accessory organs, aiding in food breakdown. After the digestive process is complete, absorption takes place. **Absorption** is carried out as the nutrients produced by digestion move from the lumen of the GI tract into the body's circulatory system for uptake by individual cells.

Oral Cavity

The oral cavity (mouth) includes the buccal mucosa, lips, tongue, hard palate, soft palate, teeth, and salivary glands. The buccal mucosa is the mucous membrane lining the inside of the mouth. The tongue is involved in speech, taste, and **mastication** (chewing). Small projections called *papillae* cover the tongue and provide a roughened surface, permitting the movement of food in the mouth during chewing. The hard palate and the soft palate together form the roof of the mouth.

Adults have 32 permanent teeth: 16 each in upper and lower arches. The different types of teeth function to prepare food for digestion by cutting, tearing, crushing, or grinding the food. Swallowing begins after food is taken into the mouth and chewed. Saliva is secreted in response to the presence of food in the mouth and begins to soften the food. Saliva contains mucin and an enzyme called *salivary amylase* (also known as *ptyalin*), which begins the breakdown of carbohydrates.

Esophagus

The esophagus is a muscular canal that extends from the pharynx (throat) to the stomach and passes through the center of the diaphragm. Its primary function is to move food and fluids from the pharynx to the stomach. At the upper end of the esophagus is a sphincter referred to as the **upper esophageal sphincter (UES)**. When at rest, the UES is closed to prevent air into the esophagus during respiration. The portion of the esophagus just above the gastroesophageal (GE) junction is referred to as the **lower esophageal sphincter (LES)**. When at rest, the LES is normally closed to prevent reflux of gastric contents into the esophagus. If the LES does not work properly, gastroesophageal reflux disease (GERD) can develop (see Chapter 57).

Stomach

The stomach is located in the midline and left upper quadrant (LUQ) of the abdomen and has four anatomic regions. The *cardia* is the narrow portion of the stomach that is below the gastroesophageal (GE) junction. The *fundus* is the area nearest to the cardia. The main area of the stomach is referred to as the *body* or *corpus*. The *antrum* (pylorus) is the distal (lower) portion of the stomach and is separated from the duodenum by the pyloric sphincter. Both ends of the stomach are guarded by sphincters (cardiac and pyloric), which aid in the transport of food through the GI tract and prevent backflow.

Smooth muscle cells that line the stomach are responsible for gastric motility. The stomach is also richly innervated with intrinsic and extrinsic nerves. **Parietal cells** lining the wall of the stomach secrete hydrochloric acid, whereas chief cells secrete pepsinogen (a precursor to pepsin, a digestive enzyme). Parietal cells also produce **intrinsic factor**, a substance that aids in the absorption of vitamin B₁₂. Absence of the intrinsic factor causes pernicious anemia.

After ingestion of food, the stomach functions as a food reservoir where the digestive process begins, using

mechanical movements and chemical secretions. The stomach mixes or churns the food, breaking apart the large food molecules and mixing them with gastric secretions to form chyme, which then empties into the duodenum. The *intestinal phase* begins as the chyme passes from the stomach into the duodenum, causing distention. It is assisted by secretin, a hormone that inhibits further acid production and decreases gastric motility.

Pancreas

The pancreas is a fish-shaped gland that lies behind the stomach and extends horizontally from the duodenal C-loop to the spleen. The pancreas is divided into portions known as the *head*, the *body*, and the *tail* (Fig. 55-2).

Two major cellular bodies (exocrine and endocrine) within the pancreas have separate functions. The *exocrine* part is about 80% of the organ and consists of cells that secrete enzymes needed for digestion of carbohydrates, fats, and proteins (trypsin, chymotrypsin, amylase, and lipase). The *endocrine* part of the pancreas is made up of the islets of Langerhans, with alpha cells producing glucagon and beta cells producing insulin. These hormones produced are essential in the regulation of *metabolism*. Chapter 67 describes the endocrine function of the pancreas in detail.

Liver and Gallbladder

The *liver* is the largest organ in the body (other than skin) and is located mainly in the right upper quadrant (RUQ) of the abdomen. The right and left hepatic ducts transport bile from the liver. It receives its blood supply from the hepatic artery and portal vein, resulting in about 1500 mL of blood flow through the liver every minute.

The *liver* performs more than 400 functions in three major categories: storage, protection, and metabolism. It *stores* many minerals and vitamins, such as iron, magnesium, and the fat-soluble vitamins A, D, E, and K.

The *protective* function of the liver involves phagocytic **Kupffer cells**, which are part of the body's reticuloendothelial system. They engulf harmful bacteria and anemic red blood cells. The liver also detoxifies potentially harmful compounds (e.g., drugs, chemicals, alcohol). Therefore the risk for drug toxicity increases with aging because of decreased liver function.

The liver functions in the *metabolism* of proteins considered vital for human survival. It breaks down amino acids to remove ammonia, which is then converted to urea and is excreted via the kidneys. In addition, it synthesizes several plasma proteins, including albumin, prothrombin, and fibrinogen. The liver's role in carbohydrate metabolism involves storing and releasing glycogen as the body's energy requirements change. The organ also synthesizes, breaks down, and temporarily stores fatty acids and triglycerides.

The liver forms and continually secretes bile, which is essential for the breakdown of fat. The secretion of bile increases in response to gastrin, secretin, and cholecystokinin. Bile is secreted into small ducts that empty into the common bile duct and into the duodenum at the sphincter of Oddi. However, if the sphincter is closed, the bile goes to the gallbladder for storage.

The *gallbladder* is a pear-shaped, bulbous sac that is located underneath the liver. It is drained by the cystic duct, which joins with the hepatic duct from the liver to form the

FIG. 55-2 The anatomy of the pancreas, the liver, and the gallbladder.

common bile duct (CBD). The gallbladder collects, concentrates, and stores the bile that has come from the liver. It releases the bile into the duodenum via the CBD when fat is present.

Small Intestine

The small intestine is the longest and most convoluted portion of the digestive tract, measuring 16 to 19 feet (5 to 6 m) in length in an adult. It is composed of three different regions: duodenum, jejunum, and ileum. The *duodenum* is the first 12 inches (30 cm) of the small intestine and is attached to the distal end of the pylorus. The common bile duct and pancreatic duct join to form the ampulla of Vater, emptying into the duodenum at the duodenal papilla. This papillary opening is surrounded by muscle known as the **sphincter of Oddi**. The 8-foot (2.5-m) portion of the small intestine that follows the sphincter of Oddi is the *jejunum*. The last 8 to 12 feet (2.5 to 4 m) of the small intestine is called the *ileum*. The ileocecal valve separates the entrance of the ileum from the cecum of the large intestine.

The inner surface of the small intestine has a velvety appearance because of numerous mucous membrane finger-like projections. These projections are called *intestinal villi*. In addition to the intestinal villi, the small intestine has circular folds of mucosa and submucosa, which increase the surface area for digestion and absorption.

The small intestine has three main *functions*: movement (mixing and peristalsis), digestion, and absorption. Because the intestinal villi increase the surface area of the small intestine, it is the major organ of absorption of the digestive system. The small intestine mixes and transports the chyme to mix with many digestive enzymes. It takes an average of 3 to 10 hours for the contents to be passed by peristalsis through the small intestine. Intestinal enzymes aid in the digestion of proteins, carbohydrates, and lipids.

Large Intestine

The large intestine extends about 5 to 6 feet in length from the ileocecal valve to the anus and is lined with columnar epithelium that has absorptive and mucous cells. It begins with the *cecum*, a dilated, pouchlike structure that is inferior to the ileocecal opening. At the base of the cecum is the vermiform appendix, which has no known digestive function. The large intestine then extends upward from the cecum as the colon. The colon consists of four divisions: ascending colon, transverse colon, descending colon, and sigmoid colon. The sigmoid colon empties into the rectum.

Following the sigmoid colon, the large intestine bends downward to form the rectum. The last 1 to 1½ inches (3 to 4 cm) of the large intestine is called the *anal canal*, which opens to the exterior of the body through the anus. Sphincter muscles surround the anal canal.

The large intestine's *functions* are movement, absorption, and elimination. Movement in the large intestine consists mainly of segmental contractions, like those in the small intestine, to allow enough time for the absorption of water and electrolytes. In addition, peristaltic contractions are triggered by colonic distention to move the contents toward the rectum, where the material is stored until the urge to defecate occurs. Absorption of water and some electrolytes occurs in the large intestine to reduce the fluid volume of the chyme. This process creates a more solid material, the feces, for elimination.

GASTROINTESTINAL CHANGES ASSOCIATED WITH AGING

Physiologic changes occur as people age, especially ages 65 years and older. Changes in digestion and elimination that can affect nutrition are common. For example, decreased gastric hydrochloric acid (HCl) can lead to decreased absorption of essential minerals like iron. [Chart 55-1](#) lists common

CHART 55-1 NURSING FOCUS ON THE OLDER ADULT

Changes in the Gastrointestinal System Related to Aging

PHYSIOLOGIC CHANGE	DISORDERS RELATED TO CHANGE	NURSING INTERVENTIONS	RATIONALES
Stomach Atrophy of the gastric mucosa is characterized by a decrease in the ratio of gastrin-secreting cells to somatostatin-secreting cells. This change leads to decreased hydrochloric acid levels (hypochlorhydria).	Decreased hydrochloric acid levels lead to decreased absorption of iron and vitamin B ₁₂ and to proliferation of bacteria. Atrophic gastritis occurs as a consequence of bacterial overgrowth.	Encourage bland foods high in vitamins and iron. Assess for epigastric pain.	Bland foods help prevent gastritis. Assessment helps detect gastritis.
Large Intestine Peristalsis decreases, and nerve impulses are dulled.	Decreased sensation to defecate can result in postponement of bowel movements, which leads to constipation and impaction.	Encourage a high-fiber diet and 1500 mL of fluid intake daily (if not contraindicated). Encourage as much activity as tolerated.	These interventions increase the sensation of needing to defecate.
Pancreas Distention and dilation of pancreatic ducts change. Calcification of pancreatic vessels occurs with a decrease in lipase production.	Decreased lipase level results in decreased fat absorption and digestion. Steatorrhea, or excess fat in the feces, occurs because of decreased fat digestion.	Encourage small, frequent feedings. Assess for diarrhea.	Small, frequent feedings help prevent steatorrhea. Diarrhea may be steatorrhea. Excessive diarrhea can lead to dehydration.
Liver A decrease in the number and size of hepatic cells leads to decreased liver weight and mass. This change and an increase in fibrous tissue lead to decreased protein synthesis and changes in liver enzymes. Enzyme activity and cholesterol synthesis are diminished.	Decreased enzyme activity depresses drug metabolism, which leads to accumulation of drugs—possibly to toxic levels.	Assess for adverse effects of all drugs.	Assessment can help detect drug toxicity.

GI changes and nursing implications when caring for older adults.

ASSESSMENT METHODS

Patient History

The purpose of the health history is to determine the events related to the current health problem. One tool for assessing GI function is the nutritional-metabolic pattern and the elimination pattern assessment found in [Chart 55-2](#). Focus questions about changes in appetite, weight, and stool. Determine the patient's pain experience.

Collect data about the patient's age, gender, and culture. This information can be helpful in assessing who is likely to have particular GI system disorders. For instance, older adults are more at risk for stomach cancer than are younger adults. Younger adults are more at risk for inflammatory bowel disease (IBD). The exact reasons for these differences continue to be studied.

Question the patient about previous GI disorders or abdominal surgeries. Ask about prescription medications being taken, including how much, when the drugs are taken, and why they have been prescribed. Inquire if the patient takes over-the-counter (OTC) drugs, herbs, and/or supplements. In particular, ask whether aspirin, NSAIDs (e.g., ibuprofen), laxatives, herbal preparations, or enemas are routinely taken. Large amounts of aspirin or NSAIDs can predispose the patient to peptic ulcer disease and GI bleeding.

Long-term use of laxatives or enemas can cause dependence and result in constipation and electrolyte imbalance. Some herbal preparations, especially ayurvedic herbs, can affect appetite, absorption, and elimination. Determine if the patient smokes or has ever smoked cigarettes, cigars, or pipes. Smoking is a major risk factor for most GI cancers. Chewing tobacco is a major cause of oral cancer.

Finally, investigate the patient's travel history. Ask whether he or she has traveled outside of the country recently. This information may provide clues about the cause of symptoms like diarrhea.

Nutrition History

A nutrition history is important when assessing GI system function. Many conditions manifest themselves as a result of alterations in intake and absorption of nutrients. The purpose of a nutritional assessment is to gather information about

CULTURAL AWARENESS

Cultural and religious patterns are important in obtaining a complete nutritional history. Ask if certain foods pose a problem for the patient. For example, the spices or hot pepper used in cooking in many cultures can aggravate or precipitate GI tract symptoms such as indigestion. Note religious patterns such as fasting or abstinence.

About 80% to 90% of black people are lactose intolerant. A much smaller percentage of white people also have this problem. Lactose intolerance causes bloating, cramping, and diarrhea as a result of lack of the enzyme *lactase*. Lactase is needed to convert lactose in milk and other dairy products to glucose and galactose.

CHART 55-2 GASTROINTESTINAL ASSESSMENT

Using Gordon's Functional Health Patterns

Nutritional-Metabolic Pattern

- What is your typical daily food intake? Describe a day's meals, snacks, and vitamins.
- How much salt do you typically add to your food? Do you use salt substitutes?
- How is your appetite? Any recent change?
- Do you have any difficulty chewing or swallowing?
- Do you wear dentures? How well do they fit?
- Do you ever experience indigestion or "heartburn"? How often? What seems to cause it? What helps it?
- Do you have pain, diarrhea, gas, or any other problems? Do any specific foods cause this for you?
- What is your typical daily fluid intake? What types of fluids (water, juices, soft drinks, coffee, tea)? How much?
- Have you had any recent change in your weight? Weight gain? Weight loss? How much?
- Have you noticed a change in the tightness of your rings or shoes? Tighter? Looser?
- Have you noticed any difference in the size of your abdomen?

Elimination Pattern

- What is your usual bowel elimination pattern? Frequency? Character? Discomfort? Laxatives?
- Do you have any pain or bleeding associated with bowel movements?
- Have you experienced any changes in your usual bowel pattern?
- When was your last rectal examination?
- Have you ever had an endoscopy or a colonoscopy?
- What is your usual urinary elimination pattern? Frequency? Amount? Color? Odor? Control?
- Have you noticed a change in the amount of urine?

Based on Gordon, M. (2011). *Manual of nursing diagnosis* (12th ed.). New York: Jones & Bartlett.

how well the patient's nutritional needs are being met. Inquire about any special diet and whether there are any known food allergies. Ask the patient to describe the usual foods that are eaten daily and the times that meals are taken.

Health problems can also affect nutritional intake, so explore any changes that have occurred in eating habits as a result of illness. **Anorexia** (loss of appetite for food) can occur with GI disease. Assess changes in taste and any difficulty or pain with swallowing (dysphagia) that could be associated with esophageal disorders. Also ask if abdominal pain or discomfort occurs with eating and whether the patient has experienced any nausea, vomiting, or **dyspepsia** (indigestion or heartburn). Unknown food allergies often cause these symptoms. Inquire about any unintentional weight loss, because some cancers of the GI tract may present in this manner. Assess for alcohol and caffeine consumption, because both substances are associated with many GI disorders, such as gastritis and peptic ulcer disease.

The patient's socioeconomic status may have a profound impact on his or her nutritional status. For example, people who have limited budgets, such as some older adults or the unemployed, may not be able to purchase foods required for a balanced diet. In addition, they may substitute less expensive and perhaps less effective OTC medications or herbs for prescription drugs. Necessary medical care may be delayed, and patients may not seek health care until conditions are well advanced.

Family History and Genetic Risk

Ask about a family history of GI disorders. Some GI health problems have a genetic predisposition. For example, familial adenomatous polyposis (FAP) is an inherited autosomal dominant disorder that predisposes the patient to colon cancer (McCance et al., 2010). Specific genetic risks are discussed with the GI problems in later chapters.

Current Health Problems

Because GI clinical manifestations are often vague and difficult for the patient to describe, it is important to obtain a chronologic account of the current problem, symptoms, and any treatments taken. Furthermore, ask about the location, quality, quantity, timing (onset, duration), and factors that may aggravate or alleviate each symptom (see [Chart 55-2](#)).

For example, a change in bowel habits is a common assessment finding. Obtain this information from the patient:

- Pattern of bowel movements
- Color and consistency of the feces
- Occurrence of diarrhea or constipation
- Effective action taken to relieve diarrhea or constipation
- Presence of frank blood or tarry stools
- Presence of abdominal distention or gas

An unintentional weight gain or loss is another symptom that needs further investigation. Assess the patient's:

- Normal weight
- Weight gain or loss
- Period of time for weight change
- Changes in appetite or oral intake

Pain is a common concern of patients with GI tract disorders. The mnemonic **PQRST** may be helpful in organizing the current problem assessment ([Jarvis, 2012](#)):

P: Precipitating or palliative. What brings it on? What makes it better? Worse? When did you first notice it?

Q: Quality or quantity. How does it look, feel, or sound? How intense/severe is it?

R: Region or radiation. Where is it? Does it spread anywhere?

S: Severity scale. How bad is it (on a scale of 1 to 10)? Is it getting better, worse, or staying the same?

T: Timing. Onset—Exactly when did it first occur? Duration—How long did it last? Frequency—How often does it occur?

Abdominal pain is often vague and difficult to evaluate. Ask the patient to describe the type of pain, such as burning, gnawing, or stabbing. The location of the pain can be determined by asking him or her to point to the involved site. Ask about the relationship of food intake to the onset or worsening of pain. For example, a high-fat meal may cause gallbladder pain.

Changes in the skin may result from several GI tract disorders, such as liver and biliary system obstruction. Ask about whether these clinical manifestations have occurred, or assess whether they are present:

- Skin discolorations or rashes
- Itching
- **Jaundice** (yellowing of skin caused by bilirubin pigments)
- Increased bruising
- Increased tendency to bleed

FIG. 55-3 A topographic division of the abdomen into quadrants.

Physical Assessment

Physical assessment involves a comprehensive examination of the patient's nutritional status, mouth, and abdomen. Nutritional assessment is discussed in detail in [Chapter 63](#). Oral assessment is described in [Chapter 56](#).

In preparation for examination of the *abdomen*, ask the patient to empty his or her bladder and then to lie in a supine position with knees bent, keeping the arms at the sides to prevent tensing of the abdominal muscles.

The abdominal examination usually begins at the patient's right side and proceeds in a systematic fashion ([Fig. 55-3](#)):

- Right upper quadrant (RUQ)
- Left upper quadrant (LUQ)
- Left lower quadrant (LLQ)
- Right lower quadrant (RLQ)

[Table 55-1](#) lists the organs that lie in each of these areas.

If areas of pain or discomfort are noted from the history, this area is examined last in the examination sequence. This sequence should prevent the patient from tensing abdominal muscles because of the pain, which would make the examination difficult. Examine any area of tenderness cautiously, and instruct the patient to state whether it is too painful. Observe his or her face for signs of distress or pain.

The abdomen is assessed by using the four techniques of examination, but in a sequence different from that used for other body systems: inspection, auscultation, percussion, and then palpation. This sequence is preferred so that palpation and percussion do not increase intestinal activity and bowel sounds. As a nurse generalist, perform inspection, auscultation, and light palpation. Percussion and deep palpation may be done by health care providers, including advanced practice nurses (APNs), or specialty nurses. If appendicitis or an abdominal aneurysm is suspected, palpation is not done.

TABLE 55-1 LOCATION OF BODY STRUCTURES IN EACH ABDOMINAL QUADRANT

Right Upper Quadrant (RUQ)

- Most of the liver
- Gallbladder
- Duodenum
- Head of the pancreas
- Hepatic flexure of the colon
- Part of the ascending and transverse colon

Right Lower Quadrant (RLQ)

- Cecum
- Appendix
- Right ureter
- Right ovary and fallopian tube
- Right spermatic cord

Midline

- Abdominal aorta
- Uterus (if enlarged)
- Bladder (if distended)

Left Upper Quadrant (LUQ)

- Left lobe of the liver
- Stomach
- Spleen
- Body and tail of the pancreas
- Splenic flexure of the colon
- Part of the transverse and descending colon

Left Lower Quadrant (LLQ)

- Part of the descending colon
- Sigmoid colon
- Left ureter
- Left ovary and fallopian tube
- Left spermatic cord

Inspection

Inspect the skin, and note any of these findings:

- Overall symmetry of the abdomen
- Presence of discolorations or scarring
- Abdominal distention
- Bulging flanks
- Taut, glistening skin

Observe the shape of the abdomen by observing its contour and symmetry. The contour of the abdomen can be rounded, flat, concave, or distended. It is best determined when standing at the side of the bed or treatment table and looking down on the abdomen. View the abdomen at eye level from the side. Note whether the contour is symmetric or asymmetric.

! NURSING SAFETY PRIORITY

Action Alert

If a bulging, pulsating mass is present during assessment of the abdomen, do not touch the area because the patient may have an abdominal aortic aneurysm, a life-threatening problem. Notify the health care provider of this finding immediately! Peristaltic movements are rarely seen unless the patient is thin and has increased peristalsis. If these movements are observed, note the quadrant of origin and the direction of peristaltic flow. Report this finding to the health care provider because it may indicate an intestinal obstruction.

Asymmetry of the abdomen can indicate problems affecting the underlying body structures (see Table 55-1). Note the shape and position of the umbilicus for any deviations. The presence of ecchymosis around the umbilicus (**Cullen's sign**) is an indication of intra-abdominal bleeding.

Finally, observe the patient's abdominal movements, including the normal rising and falling with inspiration and expiration, and note any distress during movement. Occasionally, pulsations may be visible, particularly in the area of the abdominal aorta.

Auscultation

Auscultation of the abdomen is performed with the diaphragm of the stethoscope, because bowel sounds are usually high pitched. Place the stethoscope lightly on the abdominal wall while listening for bowel sounds in all four quadrants, beginning in the RLQ at the ileocecal valve area.

Bowel sounds are created as air and fluid move through the GI tract. They are normally heard as relatively high-pitched, irregular gurgles every 5 to 15 seconds, with a normal frequency range of 5 to 30 per minute. Bowel sounds are characterized as normal, hypoactive, or hyperactive. They are diminished or absent after abdominal surgery or in the patient with peritonitis or paralytic ileus.

For many years, nurses have been taught to count the number of bowel sounds in each quadrant as part of routine and postoperative abdominal assessment to assess for peristalsis. However, a classic study showed that the best, most reliable method for assessing the return of peristalsis after abdominal surgery is to ask the patient if he or she has passed flatus within the past 8 hours or a stool within the past 12 to 24 hours (Madsen et al., 2005).

Increased bowel sounds, especially loud, gurgling sounds, result from increased motility of the bowel (**borborygmus**). These sounds are usually heard in the patient with diarrhea or gastroenteritis or above a complete intestinal obstruction.

When auscultating the abdomen, also listen for vascular sounds or **bruits** ("swooshing" sounds) over the abdominal aorta, the renal arteries, and the iliac arteries. A bruit heard over the aorta usually indicates the presence of an aneurysm. *If this sound is heard, do not percuss or palpate the abdomen. Notify the health care provider of your findings!*

Percussion

Percussion may be used by APNs and other health care providers to determine the size of solid organs; to detect the presence of masses, fluid, and air; and to estimate the size of the liver and spleen. The **percussion notes** normally heard in the abdomen are termed **tympanic** (the high-pitched, loud, musical sound of an air-filled intestine) or **dull** (the medium-pitched, softer, thudlike sound over a solid organ, such as the liver).

The liver and spleen can be percussed. An enlarged liver is called **hepatomegaly**. Dullness heard in the left anterior axillary line indicates enlargement of the spleen (**splenomegaly**). Mild to moderate splenomegaly can be detected before the spleen becomes palpable.

Palpation

The purpose of palpation is to determine the size and location of abdominal organs and to assess for the presence of masses or tenderness. Palpation of the abdomen consists of

two types: light palpation and deep palpation. Only physicians and APNs, such as clinical nurse specialists and nurse practitioners, should perform deep palpation. Deep palpation is used to further determine the size and shape of abdominal organs and masses.

The technique of **light palpation** is used to detect large masses and areas of tenderness. Place the first four fingers of the palpating hand close together and then place them lightly on the abdomen and proceed smoothly and systematically from quadrant to quadrant. Depress the abdomen to a depth of $\frac{1}{2}$ to 1 inch (1.25 to 2.5 cm). Proceed with a rotational movement of the palpating hand. Note any areas of tenderness or guarding because these areas will be examined last and cautiously during deep palpation. While performing light palpation, notice signs of rigidity, which, unlike voluntary guarding, is a sign of peritoneal inflammation. Areas of pain should be evaluated for rebound tenderness (**Blumberg's sign**). With fingers placed at a 90-degree angle in relation to the abdomen, the examiner pushes slowly and deeply, releasing quickly. Pain felt on release is a positive sign for rebound tenderness and should be reported to the health care provider.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client is seen in the emergency department with reports of nausea, anorexia, and diarrhea. In what sequence will the nurse assess the client's abdomen? (Select in order of priority.)

- A. Auscultation
- B. Percussion
- C. Inspection
- D. Light palpation

Psychosocial Assessment

Psychosocial assessment focuses on how the GI health problem affects the patient's life and lifestyle. Remember that patients are often reluctant to discuss elimination problems, which may be very personal and embarrassing. The interview focus is on whether usual activities have been interrupted or disturbed, including employment. Question the patient about recent stressful events. Emotional stress has been associated with the development or exacerbation (flare-up) of irritable bowel syndrome (IBS) and other GI disorders. If the patient is diagnosed with cancer, he or she is expected to experience the phases of the grieving process. Patients may be depressed, angry, or in denial. More specific psychosocial assessments are included in later GI chapters as part of each disease discussion.

Diagnostic Assessment

Laboratory Assessment

To make an accurate assessment of the many possible causes of GI system abnormalities, laboratory testing of blood, urine, and stool specimens may be performed.

Serum Tests. A **complete blood count (CBC)** aids in the diagnosis of anemia and infection. It also detects changes in the blood's formed elements. In adults, GI bleeding is the most frequent cause of anemia. It is associated with GI cancer, peptic ulcer disease, and inflammatory bowel disease.

Because the liver is the main site of all proteins involved in coagulation, prothrombin time (PT) is useful in evaluating

the levels of these clotting factors. *PT* measures the rate at which prothrombin is converted to thrombin, a process that depends on vitamin K–associated clotting factors. Severe acute or chronic liver damage leads to a prolonged *PT* secondary to impaired synthesis of clotting proteins.

Many *electrolytes* are altered in GI tract dysfunction. For example, calcium is absorbed in the GI tract and may be measured to detect malabsorption. Excessive vomiting or diarrhea causes sodium or potassium depletion, thus requiring replacement.

Assays of serum enzymes are important in the evaluation of liver damage. **Aspartate aminotransferase (AST)** and **alanine aminotransferase (ALT)** are two enzymes found in the liver and other organs. These enzymes are elevated in most liver disorders, but they are highest in conditions that cause necrosis, such as severe viral hepatitis and cirrhosis.

Elevations in serum *amylase* and *lipase* may indicate acute pancreatitis. In this disease, serum amylase levels begin to elevate within 24 hours of onset and remain elevated for up to 5 days. Serum amylase and lipase are not elevated when *extensive* pancreatic necrosis is present because there are few pancreatic cells manufacturing the enzymes.

Bilirubin is the primary pigment in bile, which is normally conjugated and excreted by the liver and biliary system. It is measured as total serum bilirubin, conjugated (direct) bilirubin, and unconjugated (indirect) bilirubin. These measurements are important in the evaluation of jaundice and in the evaluation of liver and biliary tract functioning. Elevations in direct and indirect bilirubin levels can indicate impaired secretion.

The serum level of *ammonia* may also be measured to evaluate hepatic function. Ammonia is normally used to rebuild amino acids or is converted to urea for excretion. Elevated levels are seen in conditions that cause severe hepatocellular injury, such as cirrhosis of the liver or fulminant hepatitis (Pagana & Pagana, 2010).

Two primary *oncofetal antigens*—*CA19-9* and *CEA*—are evaluated to diagnose cancer, monitor the success of cancer therapy, and assess for the recurrence of cancer in the GI tract. These antigens may also be increased in benign GI conditions. New tests, such as ECCO 15 and ESMO 34, have been developed in Europe and are undergoing clinical trials. **Chart 55-3** lists blood tests commonly used by the health care provider in the diagnosis of GI disorders.

Urine Tests. The presence of **amylase** can be detected in the urine. In acute pancreatitis, renal clearance of amylase is increased. Amylase levels in the urine remain high even after serum levels return to normal. This becomes an important finding in patients who are symptomatic for 3 days or longer (Pagana & Pagana, 2010).

Urine *urobilinogen* is a form of bilirubin that is converted by the intestinal flora and excreted in the urine. Its measurement is useful in the evaluation of hepatic and biliary obstruction, because the presence of bilirubin in the urine often occurs before jaundice is seen.

Stool Tests. The 2010 American Cancer Society Screening Guidelines recommend yearly fecal occult blood test (FOBT), yearly fecal immunochemical test (FIT), or stool DNA (sDNA) at unspecified intervals to detect colorectal cancer early when it can be treated. These tests use a take-home, multi-sample method rather than having the test done during a digital rectal examination.

The traditionally used **FOBT** (e.g., Hemoccult II) requires an active component of guaiac and is therefore more likely than the FIT (e.g., HemeSelect or InSure) to yield false-positive results. In addition, patients having the guaiac-based test must avoid certain foods before the test, such as raw fruits and vegetables and red meat. Vitamin C–rich foods, juices, and tablets must also be avoided. Anticoagulants, such as warfarin (Coumadin), and NSAIDs should be discontinued for 7 days before testing begins. Patient compliance is likely to be higher with the FIT method because drugs and food do not interfere with the test results (Heseltine, 2007).

The newest test for detection of colorectal cancer is stool DNA (ColoSure). This test examines stool DNA to detect changes in the vimentin gene. Most patients with colorectal cancer have genetic changes that can be detected by this simple test.

Stool samples may also be collected to test for *ova* and *parasites* to aid in the diagnosis of parasitic infection. They may also be tested for *fecal fats* when **steatorrhea** (fatty stools) or malabsorption is suspected. Fat is normally absorbed in the small intestine in the presence of biliary and pancreatic secretions. In malabsorption, fat is abnormally excreted in the stool.

Other common stool tests, stool cytotoxic assay and stool culture, detect the presence of infectious agents, especially ***Clostridium difficile***. Patients who are suspected of having *C. difficile* are usually symptomatic. Prolonged antibiotic therapy, especially in older adults, depresses the natural intestinal flora, causing an overgrowth of the pathogen. The bacterium releases a toxin that causes colonic epithelium necrosis resulting in severe diarrhea that is easily transmitted from person to person via the fecal-oral route.

A stool culture takes a longer time to get results and is not the test of choice. Instead, the cytotoxic assay is considered the most reliable because it has a high sensitivity (Keske & Letizia, 2010). However, the results may not be available for up to 3 days. The most common test to detect *C. difficile* is the enzyme-linked immunosorbent assay (ELISA) toxin A+B. It is easy to use, and the results are usually available in 2 to 6 hours (Keske & Letizia, 2010).

Imaging Assessment

Radiographic examinations and similar diagnostic procedures are useful in detecting structural and functional disorders of the GI system. Teach the patient how to prepare for the examination, provide an explanation of the procedure, and teach the required postprocedure care.

A *plain film of the abdomen* may be the first x-ray study that the health care provider requests when diagnosing a GI problem. This film can reveal abnormalities such as masses, tumors, and strictures or obstructions to normal movement. Patterns of bowel gas appear light on the abdominal film and can be useful in detecting an obstruction (ileus). No preparation is required except to wear a hospital gown and remove any jewelry or belts, which may interfere with the film.

When abdominal pain is severe or when bowel perforation is suspected, an *acute abdomen series* may be requested. This procedure consists of a chest x-ray, supine abdomen film, and an upright abdomen film. The chest x-ray may reveal a hiatal hernia, and an upright abdomen film may show air in the peritoneum from a bowel perforation. Today computed tomography (CT) and magnetic resonance imaging (MRI)

CHART 55-3 LABORATORY PROFILE

Gastrointestinal Assessment

TEST (SERUM)	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Calcium (total)	9.0-10.5 mg/dL (values decrease in older adults)	<i>Decreased</i> values indicate possible: Malabsorption Renal failure Acute pancreatitis
Potassium	3.5-5.0 mEq/L or 3.5-5.0 mmol/L	<i>Decreased</i> values indicate possible: Vomiting Gastric suctioning Diarrhea Drainage from intestinal fistulas
Albumin	3.5-5.0 g/dL	<i>Decreased</i> values indicate possible: Hepatic disease
Alanine aminotransferase (ALT)	3-35 international units/L or 8-20 units/L	<i>Increased</i> values indicate possible: Liver disease Hepatitis Cirrhosis
Aspartate aminotransferase (AST)	5-40 units/L	<i>Increased</i> values indicate possible: Liver disease Hepatitis Cirrhosis
Alkaline phosphatase	30-85 international units/L or 42-128 units/L	<i>Increased</i> values indicate possible: Hepatic disease Biliary obstruction
Bilirubin (total)	0.1-1.0 mg/dL	<i>Increased</i> values indicate possible: Hemolysis Biliary obstruction Hepatic damage
Conjugated (direct) bilirubin	0.1-0.3 mg/dL	<i>Increased</i> values indicate possible: Biliary obstruction
Unconjugated (indirect) bilirubin	0.2-0.8 mg/dL	<i>Increased</i> values indicate possible: Hemolysis Hepatic damage
Ammonia	15-110 mg/dL	<i>Increased</i> values indicate possible: Hepatic disease such as cirrhosis
Xylose absorption	<i>5-g dose in 2 hr:</i> >20 mg/dL or >1.3 mmol/L <i>25-g dose in 2 hr:</i> >25 mg/dL or >1.7 mmol/L	<i>Decreased</i> values in blood and urine indicate possible: Malabsorption in the small intestine
Serum amylase	56-90 international units/L or 25-125 units/L	<i>Increased</i> values indicate possible: Acute pancreatitis
Serum lipase	0-110 units/L	<i>Increased</i> values indicate possible: Acute pancreatitis
Cholesterol	<200 mg/dL	<i>Increased</i> values indicate possible: Pancreatitis Biliary obstruction <i>Decreased</i> values indicate possible: Liver cell damage
Carbohydrate antigen 19-9 (CA19-9)	<37 units/mL	<i>Increased</i> values indicate possible: Cancer of the pancreas, stomach, colon Acute pancreatitis Inflammatory bowel disease
Carcinoembryonic antigen (CEA)	<i>Nonsmoker:</i> <2.5 ng/mL <i>Smoker:</i> up to 5 ng/mL	<i>Increased</i> values indicate possible: Colorectal, stomach, pancreatic cancer Ulcerative colitis Crohn's disease Hepatitis Cirrhosis

scans or ultrasound scans are used more often than abdominal x-rays.

An **upper GI radiographic series** is an x-ray visualization from the mouth to the duodenojejunal junction. It is used to detect disorders of structure or function of the esophagus

(barium swallow), stomach, or duodenum. An extension of the upper GI series, the *small bowel follow-through* (SBFT), continues tracing the barium through the small intestine—up to and including the ileocecal junction—to detect disorders of the jejunum or ileum. These tests are not performed

as commonly today because endoscopy procedures allow for direct visualization of the internal GI tract.

Remind the patient to withhold foods and liquids for 8 hours before the test. If possible, opioid analgesics and anticholinergic medications are withheld for 24 hours before the test because they decrease intestinal tract motility. Instruct the patient about the barium preparation and the need to drink about 16 ounces of the barium. The radiology nurse or technician explains that a rotating examination table will be used to assist the patient in assuming the vertical, supine, prone, and lateral positions required for this test.

The initial procedure takes about 30 minutes. Fluoroscopy is used to trace the barium through the esophagus and stomach. The patient stands against the x-ray table for this part of the test. The table then moves to a lying position for more views of the stomach and duodenum. The patient then drinks more barium as quickly as possible while x-rays are taken. To attempt to make him or her as comfortable as possible, a pillow for the head and a sheet to prevent chilling are supplied whenever possible. The position changes help coat the mucosa and identify gastroesophageal reflux and hiatal hernia.

If a small bowel radiographic series is included, the patient drinks additional barium and more x-rays are taken at specific intervals. This series can take several hours, depending on how long it takes the barium to reach the cecum.

After either of these series, teach the patient to drink plenty of fluids to help eliminate the barium. A mild laxative or stool softener may be given to assist in its elimination. The radiology nurse or technician instructs the patient that stools may be chalky white for 24 to 72 hours as barium is excreted. When all barium is passed, brown stools return. If the patient is at home, he or she is instructed to report abdominal fullness, pain, or a delay in return to brown stools.

A **barium enema** examination, also known as a **lower GI series**, is an x-ray of the large intestine. The 2010 American Cancer Society Screening Guidelines include this test as an option to determine the presence of colorectal cancer or polyps for people older than 50 years. The options include:

- Double-contrast barium enema every 5 years
- Flexible sigmoidoscopy every 5 years
- CT colonography (virtual colonoscopy) every 5 years
- Colonoscopy every 10 years

Patient preparation is similar to that for colonoscopy. After the study is completed, the patient expels the barium. The radiology nurse or technician teaches the patient to drink plenty of fluids to assist in eliminating the barium and prevent an intestinal obstruction. A laxative is given to help remove the barium from the intestinal tract. Stools are chalky white for about 24 to 72 hours, until all barium is passed. If the patient has positive results, he or she is scheduled for a colonoscopy.

Percutaneous transhepatic cholangiography (PTC) is an x-ray of the biliary duct system using an iodinated dye instilled via a percutaneous needle inserted through the liver into the intrahepatic ducts. This procedure may be performed when a patient has jaundice or persistent upper abdominal pain, even after cholecystectomy, but is rarely done as a diagnostic procedure today. Better information about dilated biliary ducts can be obtained using ultrasound scans and endoscopic retrograde cholangiopancreatography (ERCP) (discussed on p. 1188).

Computed tomography (CT), also referred to as a **CT scan**, provides a noninvasive cross-sectional x-ray view that can detect tissue densities and abnormalities in the abdomen, including the liver, pancreas, spleen, and biliary tract. It may be performed with or without contrast medium.

For the CT scan, the patient is told that he or she will need to lie still in a rather enclosed space of the machine. He or she must remove all jewelry and metal. If contrast medium is to be used, ask about allergies to seafood and iodine. The patient is NPO for at least 4 hours before the test if a contrast medium is to be used. IV access will be required for injection of the contrast medium. Advise the patient that he or she may feel warm and flushed upon injection. The patient who is mildly claustrophobic may require a mild sedative to tolerate the study. The radiologic technician instructs the patient to lie still and to hold his or her breath when asked, as the technician takes a series of images. The test takes about 30 minutes.

Like other parts of the body, the abdomen and its organs may also be evaluated by **magnetic resonance imaging (MRI)**, such as **magnetic resonance cholangiopancreatography (MRCP)**. For many patients with abdominal symptoms, this may be the first diagnostic test requested by the health care provider.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

An older adult is scheduled for a double-contrast barium enema. What is the priority health teaching the nurse will provide?

- A. "Be sure to take the laxative as prescribed after the test."
- B. "Drink a gallon of GoLYTELY the day before the test."
- C. "Do not take food or fluids for 24 hours before the test."
- D. "Tell the nurse if you have flatus after the test is completed."

Other Diagnostic Assessment

Endoscopy. **Endoscopy** is direct visualization of the GI tract using a flexible fiberoptic endoscope. It is commonly requested to evaluate bleeding, ulceration, inflammation, tumors, and cancer of the esophagus, stomach, biliary system, or bowel. Obtaining specimens for biopsy and cell studies (e.g., *Helicobacter pylori*) is also possible through the endoscope. There are several types of endoscopic examinations. The patient must sign an informed consent form before having these invasive studies.

Esophagogastroduodenoscopy. **Esophagogastroduodenoscopy (EGD)** is a visual examination of the esophagus, stomach, and duodenum. This procedure has significantly reduced the number of upper GI series that are done. If GI bleeding is found during an EGD, the physician can inject a sclerotherapy agent into the affected area to stop the bleeding. If the patient has an esophageal stricture, it can be dilated during an EGD.

Teach the patient preparing for an upper GI endoscopic examination to remain NPO for 6 to 8 hours before the procedure. Usual drug therapy for hypertension or other diseases may be taken the morning of the test. However, diabetic patients should consult their health care provider for special instructions. Patients are also usually asked to avoid anticoagulants, aspirin, or NSAIDs for several days before the test unless it is absolutely necessary. Tell the patient that a flexible tube will be passed down the esophagus while he or she is under moderate sedation. Midazolam hydrochloride (Versed),

FIG. 55-4 Esophagogastroduodenoscopy allows visualization of the esophagus, the stomach, and the duodenum. If the esophagus is the focus of the examination, the procedure is called *esophagoscopy*. If the stomach is the focus, the procedure is called *gastrosocopy*.

fentanyl (Fentanyl, Sublimaze), and/or propofol (Diprivan) are commonly used drugs for sedation. Atropine may be administered to dry secretions. In addition, a local anesthetic is sprayed to inactivate the gag reflex and facilitate passage of the tube. Explain that this anesthetic will depress the gag reflex and that swallowing will be difficult. If the patient has dentures, they are removed.

After the drugs are given, the patient is placed in the left lateral decubitus (Sims', or left side-lying) position with a towel or basin at the mouth for secretions. A bite block is inserted to prevent biting down on the endoscope and to protect the teeth. The physician passes the tube through the mouth and into the esophagus (Fig. 55-4). The procedure takes about 20 to 30 minutes.

After the test, the endoscopy nurse or technician checks vital signs frequently (usually every 30 minutes) until the sedation wears off. The siderails of the bed are raised during this time. The patient remains NPO until the gag reflex returns (usually in 1 to 2 hours).

! NURSING SAFETY PRIORITY

Action Alert

The priority for care after esophagogastroduodenoscopy is to prevent aspiration. Do not offer fluids or food by mouth until you are sure that the gag reflex is intact! Monitor for signs of perforation, such as pain, bleeding, or fever.

Remind the patient to not drive for at least 12 hours after the procedure because of sedation. Teach him or her that a hoarse voice or sore throat may persist for several days after the test. Throat lozenges can be used to relieve throat discomfort.

Endoscopic Retrograde Cholangiopancreatography. **Endoscopic retrograde cholangiopancreatography (ERCP)** includes visual and radiographic examination of the liver, gallbladder, bile ducts, and pancreas to identify the cause and location of obstruction. It is commonly used today for therapeutic purposes rather than for diagnosis. After a cannula is inserted into the common bile duct, a radiopaque dye is instilled and then several x-ray images are obtained. The

physician may perform a **papillotomy** (a small incision in the sphincter around the ampulla of Vater) to remove gallstones. If a biliary duct stricture is found, plastic or metal stents may be inserted to keep the ducts open. Biopsies of tissue are also frequently taken during this test.

The patient prepares for this test in the same manner as for an EGD, including being NPO for 6 to 8 hours before the test. The patient requires IV access for moderate sedation drugs. Ask about prior exposure to x-ray contrast media and any sensitivities or allergies. If the patient has dentures, they are removed.

Ask the patient if he or she has an implantable medical device, such as a cardiac pacemaker. Electrocautery cannot be used with this type of device (Brueschoff, 2010). Perform medication reconciliation to determine if the patient is taking anticoagulants, NSAIDs, antiplatelet drugs, or antihyperglycemic agents. The physician decides which of these drugs are safe to take and whether any will need to be stopped before the test.

The endoscopic portion of an ERCP is similar to that of an EGD, except that the endoscope is advanced farther to the duodenum and into the biliary tract. Once the cannula is in the common duct, contrast medium is injected and x-rays are taken to view the biliary tract. A tilt table assists in distributing the contrast medium to all areas to be assessed. The patient is placed in a left lateral position for viewing the common bile duct. Once the cannula is placed, he or she is put in a prone position. After examination of the biliary tree, the cannula is directed into the pancreatic duct for examination. The ERCP lasts from 30 minutes to 2 hours, depending on the treatment that may be done.

After the test, assess vital signs frequently, usually every 15 minutes, until the patient is stable. To prevent aspiration, check to ensure that the gag reflex has returned before offering fluids or food. *Teach the patient and family to monitor for severe postprocedure complications at home, including cholangitis (gallbladder inflammation), bleeding, perforation, sepsis, and pancreatitis. The patient has severe pain if any of these complications occur. Fever is present in sepsis. These problems do not occur immediately after the procedure; they may take several hours to 2 days to develop.*

Colicky abdominal pain can result from air instilled during the procedure. Instruct the patient to report abdominal pain, fever, nausea, or vomiting that fails to resolve after returning home. Be sure that the patient has someone to drive him or her home if the test was done on an ambulatory basis.

Small Bowel Capsule Endoscopy. Small bowel endoscopy, or **enteroscopy**, provides a view of the small intestine. Capsule video endoscopy (M2A) is a small bowel enteroscopy that visualizes the entire small bowel, including the distal ileum. It is used to evaluate and locate the source of GI bleeding. Before the development of the M2A Capsule Endoscope, viewing the small intestine was inadequate. The capsule battery lasts around 8 hours so it is not used to view the colon.

Prepare the patient by explaining the procedure, the purpose, and what to expect during the testing. The patient must fast (water only) for 8 to 10 hours before the test and be NPO for the first 2 hours of the testing.

At the time of the procedure, the patient's abdomen is marked for the location of the sensors, and the eight-lead sensors (Sensor Array) are applied. The patient wears an

abdominal belt that houses a data recorder to capture the transmitted images. After the capsule is taken with a glass of water, the patient may return to normal activity for the remainder of the study. He or she can resume a normal diet 4 hours after swallowing the capsule. At the end of the procedure, the patient returns to the facility with the capsule equipment for downloading to a central computer. The procedure lasts about 8 hours.

Because the M2A Capsule Endoscope is a single-use device that moves through the GI tract by peristalsis and is excreted naturally, explain to the patient that the capsule will be seen in the stool. No other follow-up is necessary.

Colonoscopy. Colonoscopy is an endoscopic examination of the entire large bowel. The American Cancer Society recommends that, beginning at age 50 years, all men and women should have a colonoscopy every 10 years or choose another equally effective recommended screening option (ACS, 2010). Those at high risk for cancer (e.g., family history) or those who had polyps removed should have the test more often. The physician may also obtain tissue biopsy specimens or remove polyps through the colonoscope. A colonoscopy can also evaluate the cause of chronic diarrhea or locate the source of GI bleeding. A sclerotherapy drug may be injected at the site of any bleeding. An alternative to this invasive procedure is the *CT colonography (virtual colonoscopy)*, which is not invasive and uses a CT scanner to view the colon. Patient preparation for this alternative is the same as that for the traditional colonoscopy.

Patient Preparation. Teach the patient to stay on a clear liquid diet the day before the scheduled colonoscopy. Instruct him or her to avoid red, orange, or purple (grape) beverages, and drink an abundant amount of Gatorade or other sports drink to replace electrolytes that are lost during bowel preparation. The patient should be NPO (except water) 4 to 6 hours before the procedure.

Remind patients to avoid aspirin, anticoagulants, and antiplatelet drugs for several days before the procedure. Diabetic patients should check with their health care provider about drug therapy requirements on the day of the test because they are NPO.

The patient drinks an oral liquid preparation for cleaning the bowel (e.g., sodium phosphate [Phospho-Soda]) the evening before the examination and may repeat that procedure the morning of the study. Some physicians prescribe a gallon of GoLYTELY to cleanse the bowel the day before. This regimen should not be used for older adults to prevent excessive fluid and electrolyte loss. All solutions should be chilled to improve their taste. Remind the patient to drink them quickly to prevent nausea. Watery diarrhea usually begins in about an hour after starting the bowel preparation process. In some cases, the patient may require laxatives, suppositories (e.g., bisacodyl [Dulcolax]), or one or more small-volume cleansing enemas (e.g., Fleet's).

Procedure. IV access is necessary for the administration of moderate sedation. The physician prescribes drugs to aid in relaxation, usually IV midazolam hydrochloride (Versed), propofol (Diprivan), and/or an opiate, such as Fentanyl. Complementary and alternative therapies, such as reiki, are being studied to determine if they reduce the amount of sedation needed (see the Evidence-Based Practice box above).

EVIDENCE-BASED PRACTICE

Does Modified Reiki Decrease Pain and Anxiety in Patients Undergoing a Colonoscopy?

Hulse, R.S., Stuart-Shor, E.M., & Russo, J. (2010). Endoscopic procedure with a modified Reiki intervention: A pilot study. *Gastroenterology Nursing, 33*(1), 20-26.

This pilot study examined the use of Reiki before colonoscopy to reduce anxiety and intra-procedure medications compared with usual care. A prospective, nonblinded, partially randomized patient preference design was used for 21 first-time colonoscopy patients. There were no differences in the makeup of the control ($n = 10$) and experimental groups ($n = 11$): about half were woman, and the mean age was 58 years.

The Reiki intervention reduced the patients' blood pressure, pulse, and respirations, but the drug regimen used during the procedure was the same in both groups. The experimental group did not require additional medication during the procedure. The researchers concluded that adjunctive therapy may help reduce anxiety and pain in patients having a colonoscopy.

Level of Evidence: 5

This pilot study is very small and needs to be replicated using a more rigorous, randomized, controlled trial.

Commentary: Implications for Practice and Research

The use and study of complementary and alternative medicine (CAM) have increased in the past decade. A number of therapies have been shown to decrease pain and anxiety. Nurses need to consider using these modalities as part of holistic patient care. Many patients employ CAM and would prefer it be a part of their care. Assess the patient's use of adjunctive therapies, and ask the patient what he or she prefers.

Initially, the patient is placed on the left side with the knees drawn up while the endoscope is placed into the rectum and moved to the cecum. Air may be instilled for better visualization. The entire procedure lasts about 30 to 60 minutes. Atropine sulfate is kept available in case of bradycardia resulting from vasovagal response.

Follow-up Care. Check vital signs every 15 minutes until the patient is stable. Keep the siderails up until the patient is fully alert, and maintain NPO status. Observe for signs of perforation (causes severe pain) and hemorrhage, such as a rapid drop in blood pressure. Reassure the patient that a feeling of fullness, cramping, and passage of flatus are expected for several hours after the test. Fluids are permitted after the patient passes flatus to indicate that peristalsis has returned.

If a polypectomy or tissue biopsy was performed, there may be a small amount of blood in the first stool after the colonoscopy. However, report excessive bleeding or severe pain to the health care provider immediately (Chart 55-4).

As with other endoscopic procedures, the patient will need someone to provide transportation home. Remind the patient to avoid driving for 12 hours after the procedure because of the effects of sedation.

Virtual Colonoscopy. A noninvasive imaging procedure to obtain multi-dimensional views of the entire colon is the *CT colonography*, most popularly known as the **virtual colonoscopy**. The bowel preparation and dietary restrictions are

CHART 55-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient after a Colonoscopy

- Do not allow the patient to take anything by mouth until sedation wears off and he or she is alert and passes flatus.
- Take vital signs every 15 to 30 minutes until the patient is alert.
- Keep the top siderails up until the patient is alert.
- Assess for rectal bleeding or severe pain.
- Remind the patient that fullness and mild abdominal cramping are expected for several hours.
- Assess for manifestations of bowel perforation, including severe abdominal pain and guarding. Fever may occur later.
- Assess for manifestations of hypovolemic shock, including dizziness, light-headedness, decreased blood pressure, tachycardia, pallor, and altered mental status (may be the first sign).
- If the procedure is performed in an ambulatory care setting, arrange for another person to drive the patient home.

DECISION-MAKING CHALLENGE

Safety; Evidence-Based Practice

A 55-year-old woman has her first screening colonoscopy today, and you are assigned as her preprocedure and postprocedure nurse. When you take her vital signs before the procedure, her blood pressure is 156/88 mm Hg. She does not have a history of hypertension or diabetes mellitus. Upon further observation, you notice that the patient seems very anxious. She states that her sister had a colonoscopy last year and was diagnosed with stage 3 colorectal cancer for which she is being treated.

1. How will you respond to the patient at this time?
2. What other preprocedure care will you provide before she has her colonoscopy?
3. After the procedure, the patient seems very drowsy and asks for something to drink. How will you respond to her and why? What evidence supports this decision?
4. The patient tells you that she had two polyps removed but there is no sign of cancer. In view of her polyps and her family history of colorectal cancer, what health teaching about colorectal cancer screening will you provide?

similar to those for traditional colonoscopy. However, if a polyp is detected during a virtual colonoscopy or bleeding is found, the patient must have a follow-up invasive colonoscopy for treatment. Therefore the advantage of the traditional colonoscopy is that both diagnostic testing and minor surgical procedures can be done at the same time.

Sigmoidoscopy. Proctosigmoidoscopy, often referred to as a *sigmoidoscopy*, is an endoscopic examination of the rectum and sigmoid colon using a flexible scope. The purpose of this test is to screen for colon cancer, investigate the source of GI bleeding, or diagnose or monitor inflammatory bowel disease. If sigmoidoscopy is used as an alternative to colonoscopy for colorectal cancer screening, it is recommended that screening begin at 50 years of age and should be done every 5 years thereafter ([American Cancer Society, 2010](#)). Patients at high risk for cancer may require more frequent screening.

The patient should have a clear liquid diet for at least 24 hours before the test. A cleansing enema or sodium biphosphate (Fleet's) enema is usually required the morning of the procedure. A laxative may also be prescribed the evening before the test.

The patient is placed on the left side in the knee-chest position. No moderate sedation is required. The endoscope is lubricated and inserted into the anus to the required depth for viewing. Tissue biopsy may be performed during this procedure, but the patient cannot feel it. The examination usually lasts about 30 minutes.

Inform the patient that mild gas pain and flatulence may be experienced from air instilled into the rectum during the examination. If a biopsy was obtained, a small amount of bleeding may be observed. Instruct the patient that excessive bleeding should be reported immediately to the health care provider.

Gastric Analysis. Gastric analysis measures the hydrochloric acid and pepsin content for evaluation of aggressive gastric and duodenal disorders (e.g., Zollinger-Ellison syndrome). There are two tests in gastric analysis: basal gastric secretion and gastric acid stimulation. Basal gastric secretion measures the secretion of hydrochloric acid between meals. If only small amounts of secretion are collected, a follow-up gastric stimulation test is given.

The patient is NPO for at least 12 hours before the test. Teach patients to avoid alcohol, tobacco, and drugs that may affect gastric secretion for 24 hours before the study. A nasogastric (NG) tube is inserted, and gastric residual contents are aspirated and discarded.

The NG tube is attached to suctioning equipment for collecting the contents at 15-minute intervals for 1 hour. Samples are collected and labeled with basal acid output (BAO), time, and volume of each specimen.

For the gastric acid stimulation test, the NG tube is left in place and a drug that stimulates gastric acid secretion (e.g., pentagastrin or betazole dihydrochloride [Histalog]) is given. Fifteen minutes after injection of the drug, specimens are again collected at 15-minute intervals for 1 hour. Samples are collected and labeled with maximal acid output (MAO), time, and volume of each specimen. Depressed levels of gastric secretion suggest the presence of gastric cancer. Increased levels of gastric secretion indicate Zollinger-Ellison syndrome and duodenal ulcers (see [Chapter 58](#)).

After the test is completed, the NG tube is removed and the patient can resume normal eating patterns. No other follow-up is necessary.

Ultrasonography. Ultrasonography (US) is a technique in which high-frequency, inaudible vibratory sound waves are passed through the body via a transducer. The echoes of the sound waves created are then recorded and converted into images for analysis. US is commonly used to view soft tissues, such as the liver, the spleen, the pancreas, and the biliary system. The advantages of this test are that it is painless and noninvasive and requires no radiation.

The patient may be fasting, depending on the abdominal organs to be examined. Inform the patient that it will be necessary to lie still during the study. He or she is instructed to drink 1 to 2 L of fluid just before the test, because a full bladder is necessary for accurate visualization.

The patient is usually placed in a supine position. The technician applies insulating gel to the end of the transducer and on the area of the abdomen under study. This gel allows airtight contact of the transducer with the skin. The technician moves the transducer back and forth over the skin until the desired images are obtained. The study takes about 15 to 30 minutes. No follow-up care is necessary.

Endoscopic Ultrasonography. Endoscopic ultrasonography (EUS) provides images of the GI wall and high-resolution images of the digestive organs. The ultrasonography is performed through the endoscope. This procedure is useful in diagnosing the presence of lymph node tumors, mucosal tumors, and tumors of the pancreas, stomach, and rectum. The patient preparation and follow-up care are similar to the preparation and follow-up care for both endoscopy and ultrasonography.

Liver-Spleen Scan. A liver-spleen scan uses IV injection of a radioactive material that is taken up primarily by the liver and secondarily by the spleen. The scan evaluates the liver and the spleen for tumors or abscesses, organ size and location, and blood flow.

Teach the patient about the need to lie still during the scanning. Assure the patient that the injection has only small amounts of radioactivity and is not dangerous. Ask female patients of childbearing age if they may be pregnant or are currently breast-feeding. The radionuclide can be found in breast milk, and radiation from x-rays or scans should be avoided in pregnancy.

The technician or the physician gives the radioactive injection through an IV line, and a wait of about 15 minutes is necessary for uptake. The patient is placed in many different positions while the scanning takes place. Tell the patient that the radionuclide is eliminated from the body through the urine in 24 hours. Careful handwashing after toileting decreases the exposure to any radiation present in the urine.

NURSING CONCEPT REVIEW

What should you NOTICE in a patient with adequate digestion and elimination related to the GI system?

Physical Assessment

- No nausea or vomiting
- Sufficient appetite
- No intentional weight loss
- No dyspepsia (indigestion)
- No jaundice
- Abdomen soft and not tender
- Normoactive bowel sounds present in all quadrants
- No change in bowel habits

- No abdominal pain
- Normal brown, formed stool
- No frequent diarrhea or constipation

Diagnostic Assessment

- No occult blood in stool
- Normal liver enzymes, such as ALT
- Normal bilirubin levels
- Serum and urine amylase within normal limits
- Serum ammonia level within normal limit
- Serum albumin within normal limit
- Electrolytes within normal limits

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Remember that the priority for care is to check for the return of the gag reflex after an upper endoscopic procedure before offering fluids or food; aspiration may occur if the gag reflex is not intact.

Health Promotion and Maintenance

- If an endoscopic procedure on an ambulatory basis is scheduled, remind the patient to have someone available to drive him or her home because of the effects of moderate sedation.
- Teach patients having invasive colon diagnostic procedures to follow instructions carefully for the bowel preparation before testing; the bowel must be clear to allow visualization of the colon.
- Instruct the patient to drink plenty of fluids and take a laxative as prescribed to eliminate barium if used during diagnostic testing.

Psychosocial Integrity

- Remember that problems of digestion, nutrition, and elimination can markedly affect lifestyle.

Physiological Integrity

- Perform a focused abdominal assessment using inspection, auscultation, and light palpation.
- Do not palpate or auscultate any abdominal pulsating mass because it could be a life-threatening aortic aneurysm.
- Assess and report any major complications of GI testing to the health care provider.
- Review and interpret laboratory results, and report abnormal findings to the health care provider (see [Chart 55-3](#)).
- Monitor vital signs carefully for the patient having any endoscopic procedure and moderate sedation.
- Assess patients who have endoscopies for bleeding, fever, and severe pain.
- For patients having a colonoscopy, check for passage of flatus before allowing fluids or food.

Care of Patients with Oral Cavity Problems

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Plan continuity of care between the hospital and community-based agencies for patients having oral surgery.
2. Identify appropriate community resources for patients with oral cavity health problems.

Health Promotion and Maintenance

3. Teach patients ways to prevent oral cancer and maintain good oral health.
4. Develop a teaching plan for patients who have stomatitis to promote digestion and nutrition.
5. Develop a teaching plan for community-based care of patients with oral cancer.

Psychosocial Integrity

6. Identify the patient's response to an oral cancer diagnosis.

7. Refer patients with oral cancer to appropriate support groups.

Physiological Integrity

8. Prioritize postoperative care for patients undergoing surgery for oral cancer to maintain a patent airway and prevent aspiration.
9. Describe collaborative interventions to promote nutrition for postoperative patients having extensive oral surgery.
10. Identify methods to help patients communicate effectively after oral surgery.
11. Plan care for patients who have disorders of the salivary glands.
12. State best practices for teaching or providing oral care for patients.

The oral cavity, or mouth, is where *digestion* of food begins. The teeth tear, grind, and crush food into small particles to promote swallowing. The enzymes in saliva begin the breakdown of carbohydrates. If a person cannot take food or fluid into the mouth, cannot chew food, or cannot swallow, the basic *human need for nutrition* may not be met by use of the GI tract. Adequate intake of fluids and nutrients into the body is vital to promote function of every body organ and system.

The pharynx (throat) is located just behind the mouth and has a role in both *digestion* and oxygenation. The pharynx is the portal between the mouth and the GI tract, where

nutrients are broken down for utilization within the body. The pharynx also is a portal for oxygenation, as inhaled air passes through the nose, into the pharynx, and down into the trachea. A blockage of the posterior oral cavity, for example, by a tumor, can interfere with oxygenation and digestion.

Oral cavity disorders, then, can severely affect *nutrition* and oxygenation, as well as speech, body image, and self-esteem. Although there are many oral health problems, this chapter discusses the most common disorders. Nurses play an important role in maintaining and restoring oral health through nursing interventions, including patient and family

CHART 56-1 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Maintaining a Healthy Oral Cavity

- Perform self-examination of your mouth every week; report any unusual finding or any noted change.
- Be sure to eat a well-balanced diet.
- Brush and floss your teeth every day. Set a routine, and keep to it. Keeping floss where you can see it (such as on the countertop by the sink) will encourage you to stick to your routine.
- Manage your stress as much as possible; learn how to maintain your emotional health by using healthy coping mechanisms.
- Avoid contact with agents that may cause inflammation of the mouth, such as mouthwashes that contain alcohol.
- If possible, avoid drugs that may cause inflammation of the mouth or reduce the flow of saliva.
- Be aware of any changes in the occlusion of your teeth, mouth pain, or swelling; seek medical attention promptly.
- See your dentist regularly; have problems attended to promptly.
- If you wear dentures, make sure they are in good repair and fit properly.

education. [Chart 56-1](#) lists ways to help maintain a healthy oral cavity.

STOMATITIS

Pathophysiology

Stomatitis is a broad term that refers to inflammation within the oral cavity and may present in many different ways. Painful single or multiple ulcerations (called *aphthous ulcers* or “canker sores”) that appear as inflammation and erosion of the protective lining of the mouth are one of the most common forms of stomatitis. The sores cause pain, and open areas place the person at risk for bleeding and infection. Mild erythema (redness) may respond to topical treatments. Extensive stomatitis may require treatment with opioid analgesics. Stomatitis is classified according to the cause of the inflammation. *Primary stomatitis*, the most common type, includes **aphthous** (noninfectious) **stomatitis**, herpes simplex stomatitis, and traumatic ulcers. *Secondary stomatitis* generally results from infection by opportunistic viruses, fungi, or bacteria in patients who are immunocompromised. It can also result from drugs, such as chemotherapy. (See [Chapter 24](#) for discussion of chemotherapy-induced stomatitis.)

A common type of secondary stomatitis is caused by *Candida albicans*. *Candida* is sometimes present in small amounts in the mouth, especially in older adults. Long-term antibiotic therapy destroys other normal flora and allows the *Candida* to overgrow. The result can be **candidiasis**, also called *moniliasis*, a fungal infection that is very painful. Candidiasis is also common in those undergoing immunosuppressive therapy, such as chemotherapy, radiation, and steroids.

In addition, the mouth is susceptible to the effects of human immune deficiency virus (HIV) infection. Other systemic diseases that can cause stomatitis include chronic kidney disease and inflammatory bowel disease. Poor oral

EVIDENCE-BASED PRACTICE

What Are Best Practices When Providing Oral Hygiene to Critically Ill Older Adults Who Are Orally Intubated?

Feider, L., Mitchell, P., & Bridges, E. (2010). Oral care practices for orally intubated critically ill adults. *American Journal of Critical Care*, 19(2), 175-183.

Evidence shows that when proper oral care is provided as a nursing intervention for older adults, infections such as aspiration pneumonia and ventilator-associated pneumonia (VAP) decrease. In this study, a survey of 347 respondents was conducted to determine the type of oral care provided by critical care nurses for older adults who were orally intubated. These data were compared with the recommendations for oral care found in the *AACN Procedure Manual for Critical Care Nurses* and the Centers for Disease Prevention and Control (CDC) oral care guidelines.

Survey results demonstrated that there was a variety of facility policies for oral care and therefore various interpretations of how oral care should be given. Methods included a mix of brushing, swabbing, suctioning, and rinsing with chlorhexidine gluconate. Nurses were not aware that facility policies were often not consistent with national oral care standards based on current evidence.

Level of Evidence: 2

The study was a large descriptive, cross-sectional survey, with results compared against national recommendations for best practice.

Commentary: Implications for Practice and Research

The findings of this research clearly indicate that nurses recognize and practice facility-based policies but are not aware of published best practices, such as those from the CDC. Because proper oral care has been associated with a decrease in complications associated with VAP, nurses must become aware of these evidence-based standards of care and bridge the gap that exists between those standards and facility policy.

CONSIDERATIONS FOR OLDER ADULTS

Older adults are especially at high risk for candidiasis because aging causes a decrease in immune function. The risk increases for patients who are diabetic, malnourished, or under emotional stress. Those who wear dentures may use soft denture liners that provide comfort but can also be colonized by *C. albicans*, contributing to denture stomatitis. In addition, it is now known that older adults who have poor oral hygiene are at high risk for mouth infections and aspiration pneumonia. All health care professionals in any health care setting should be trained in and aware of best practices for oral care for geriatric populations; this could greatly improve patient outcomes, especially for older intubated adults in critical care settings. (See the Evidence-Based Practice box above.)

health is a risk factor for certain infections, such as ventilator-associated pneumonia.

Stomatitis can result from infection, allergy, vitamin deficiency, systemic disease, and irritants such as tobacco and alcohol. Infectious agents, such as bacteria and viruses, may have a role in the development of recurrent stomatitis.

Certain foods may trigger allergic responses that cause aphthous ulcers. Foods such as coffee, potatoes, cheese, nuts, citrus fruits, and gluten may be causative factors. In some cases, strict diets have resulted in the improvement of ulcers. Deficiencies in complex B vitamins, folate, zinc, and iron associated with malnutrition can contribute to the formation of recurrent stomatitis.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

When performing an oral assessment, ask about a history of recent infections, nutritional changes, oral hygiene habits, oral trauma, or stress. A drug history should also be collected, including over-the-counter (OTC) drugs and nutritional and herbal supplements. Document the course of the current outbreak, and determine if stomatitis has occurred frequently. Ask the patient if the lesions interfere with swallowing, eating, or communicating.

The symptoms of stomatitis range in severity from a dry, painful mouth to open ulcerations, predisposing the patient to infection. These ulcerations can alter *nutritional* status because of difficulty with eating or swallowing. When they are severe, stomatitis and edema have the potential to obstruct the airway.

In oral candidiasis, a type of yeast infection, white plaque-like lesions appear on the tongue, palate, pharynx (throat), and buccal mucosa (inside the cheeks) (Fig. 56-1). When these patches are wiped away, the underlying surface is red and sore. Patients may report pain, but others describe the lesions as dry or hot. The older adult patient who has systemic illness or is taking antibiotics or chemotherapy is particularly susceptible to oral candidiasis.

While examining the mouth, wear nonsterile gloves. Use adequate lighting, using a penlight and tongue blade. Assess the mouth for lesions, coating, and cracking. Document characteristics of the lesions including their location, size, shape, odor, color, and drainage.

If lesions are seen along the pharynx and the patient reports **dysphagia** (pain on swallowing), suspect that the lesions might extend down the esophagus. Additional swallowing studies may be prescribed by the health care provider to establish a firm diagnosis.

The physical assessment should also include palpating the cervical and submandibular lymph nodes for swelling.

FIG. 56-1 Oral candidiasis.

Advanced practice nurses and other health care providers usually perform this part of the examination.

! NURSING SAFETY PRIORITY

Action Alert

When assessing the patient with stomatitis, be alert for signs and symptoms of dysphagia, such as coughing or choking when swallowing, a sensation of food “sticking” in the pharynx, or difficulty initiating the swallowing process. If dysphagia is suspected based on the patient’s subjective description or the objective assessment, document all findings and report these to the health care provider. Dysphagia can cause numerous problems, including airway obstruction, aspiration pneumonia, and malnutrition.

INTERVENTIONS

Interventions for stomatitis are targeted toward health promotion through careful *oral hygiene* and food selection. When providing mouth care for the patient, the nurse may delegate oral care to unlicensed assistive personnel (UAP). Because the accountability for the delegated task is the nurse’s, remind UAP to use a soft-bristled toothbrush or disposable foam swabs to stimulate gums and clean the oral cavity. Toothpaste should be free of sodium lauryl sulfate (SLS), if possible, because this ingredient has been associated with various types of stomatitis. Teach the patient to rinse the mouth every 2 to 3 hours with a sodium bicarbonate solution or warm saline solution (may be mixed with hydrogen peroxide). He or she should avoid most commercial mouthwashes because they have high alcohol content, causing a burning sensation in irritated or ulcerated areas. Health food stores sell more natural mouthwashes that are not alcohol-based. Teach the patient to check the labels for alcohol content. Frequent, gentle mouth care promotes débridement of ulcerated lesions and can prevent superinfections. Chart 56-2 lists measures for special oral care.

Drug therapy used for stomatitis includes antimicrobials, immune modulators, and symptomatic topical agents. Complementary and alternative therapies may also be tried.

Antimicrobials, including antibiotics, antivirals, and antifungals, may be necessary for control of infection. Tetracycline syrup (swish/swallow) 250 mg/10 mL four times daily for 10 days may be prescribed, especially for recurrent

CHART 56-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient with Problems of the Oral Cavity

- Remove dentures if the patient has severe stomatitis or oral pain.
- Encourage the patient to perform oral hygiene or provide it after each meal and as often as needed.
- Increase mouth care to every 2 hours or more frequently if stomatitis is not controlled.
- Use a soft toothbrush or gauze for oral care.
- Encourage frequent rinsing of the mouth with warm saline or sodium bicarbonate (baking soda) solution, or a combination of these solutions.
- Teach the patient to avoid commercial mouthwashes, particularly those with high alcohol content, and lemon-glycerin swabs.
- Assist the patient in selecting soft, bland, and nonacidic foods.
- Apply topical analgesics or anesthetics as prescribed by the health care provider, and monitor their effectiveness.

aphthous ulcers (RAUs). The patient rinses for 2 minutes and swallows the syrup, thus obtaining both topical and systemic therapy. Minocycline swish/swallow and chlorhexidine mouthwashes may also be used.

A regimen of IV acyclovir (Zovirax) is prescribed for immunocompromised patients who contract herpes simplex stomatitis. Acyclovir is typically administered to those with normal kidney function at a dose of 5 mg/kg, infused at a constant rate over a 1-hour period every 8 hours for 7 days. Patients with healthy immune systems may be given acyclovir in oral or topical form.

For fungal infections like yeast, nystatin (Mycostatin) oral suspension 600,000 units four times daily for 7 to 10 days is the drug most often used. The patient swishes and swallows the topical preparation. Ice pop troches (lozenges) of the antifungal preparation allow the drug to slowly dissolve, and the cold provides an analgesic effect. Topical triamcinolone in benzocaine (Kenalog in Orabase) and oral dexamethasone elixir used as a swish/expectorate preparation are commonly used for stomatitis, especially RAU.

Immune modulating agents that may be prescribed include:

- Oral levamisole
- Topical amlexanox (Aphthasol)
- Topical granulocyte-macrophage colony-stimulating factor (GM-CSF)
- Thalidomide

The exact mechanism for how these drugs work is not clear. However, they may inhibit release of mediators that contribute to the inflammation seen in patients with RAU.

Other drugs can be used to control pain, such as OTC benzocaine anesthetics (e.g., Orabase, Anbesol) and camphor phenol (Campho-Phenique). Fifteen mL of 2% viscous lidocaine every 3 hours (maximum of 8 doses per day) can be used as a gargle or mouthwash. Teach patients to use this drug with extreme caution because its anesthetizing effect may cause burns from hot liquids in the mouth. Patients may also become more susceptible to choking when using viscous lidocaine.

Dietary changes may also help decrease pain. Cool or cold liquids can be very soothing. Teach patients to avoid hard, spicy, salty, and acidic foods or fluids that can further irritate the ulcers. Include foods high in protein and vitamin C to promote healing, including scrambled eggs, bananas, custards, puddings, and ice cream, unless the patient has lactose intolerance.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Nystatin (Mycostatin) suspension is prescribed for a client who is diagnosed with oral candidiasis. What instructions does the nurse provide to the client when using this drug?

- A. "Take the drug when your mouth hurts or seems dry."
- B. "Swish the drug around in your mouth before swallowing it."
- C. "Spit the drug out after you rinse your mouth with it."
- D. "Use the drug once a day for 7 to 10 days."

ORAL TUMORS

Oral cavity tumors can be benign, precancerous, or cancerous. Whether benign or malignant, tumors of the mouth affect many daily functions, including swallowing, chewing, and speaking. Pain accompanying the tumor can also limit

daily activities and self-care. Oral tumors affect body image, especially if treatment involves removal of the tongue or part of the mandible (jaw) or requires a tracheostomy.

PREMALIGNANT LESIONS

Leukoplakia

Leukoplakia presents as slowly developing changes in the oral mucous membranes causing thickened, white, firmly attached patches that cannot easily be scraped off. These patches appear slightly raised and sharply rounded. Most of these lesions are benign. However, a small percentage of them become cancerous. Although leukoplakia can be found anywhere on the oral mucosa, lesions on the lips or tongue are more likely to progress to cancer.

Leukoplakia results from mechanical factors that cause long-term oral mucous membrane irritation, such as poorly fitting dentures, chronic cheek nibbling, or broken or poorly repaired teeth. In addition, oral hairy leukoplakia (OHL) can be found in patients with HIV infection. Tobacco products (smoked, dipped, or chewed) have also been implicated in the development of leukoplakia, sometimes referred to as "smoker's patch." Oral leukoplakia can be confused with oral candidal infection. However, unlike candidal infection, leukoplakia cannot be removed by scraping.

Leukoplakia is the most common oral lesion among adults. OHL is associated with Epstein-Barr virus (EBV) and can be an early manifestation of HIV infection. When associated with HIV infection, the appearance of OHL is highly correlated with progression from HIV infection to acquired immune deficiency syndrome (AIDS). Leukoplakia not associated with HIV infection is more often seen in people older than 40 years. Men have twice the incidence of leukoplakia that women have, but this ratio is changing because increasing numbers of women are smoking.

Erythroplakia

Erythroplakia presents as a red, velvety mucosal lesion on the surface of the oral mucosa. There are more malignant changes in erythroplakia than in leukoplakia; therefore erythroplakia is often considered "precancerous" in presentation. As such, these lesions should be regarded with suspicion and analyzed by biopsy. Erythroplakia is most commonly found on the floor of the mouth, tongue, palate, and mandibular mucosa. It can be difficult to distinguish from inflammatory or immune reactions.

ORAL CANCER

In the past decade, dentists and physicians have begun systematically screening their patients for oral cancer. Oral assessment has become a part of the routine dental examination. People should visit a dentist at least twice a year for professional dental hygiene and oral cancer screening, which includes inspecting and palpating the mouth for lesions.

Prevention strategies for oral cancer include minimizing sun and tanning bed exposure, tobacco cessation, and decreasing alcohol intake. Most dentists now use digital technology instead of x-rays when performing the annual or biannual dental examination. Excessive, prolonged radiation from x-rays has been associated with head and neck cancer ([Oral Cancer Foundation, 2010](#)). Teach patients to follow the guidelines in [Chart 56-1](#) to maintain oral health.

Pathophysiology

Squamous Cell Carcinoma

More than 90% of oral cancers are squamous cell carcinomas that begin on the surface of the epithelium. Over a period of many years, premalignant (or dysplastic) changes begin. Cells begin to vary in size and shape. Alterations in the thickness of the lining of the epithelium develop, resulting in atrophy. These tumors usually grow slowly, and the lesions may be large before the onset of symptoms unless ulceration is present. *Mucosal erythroplasia is the earliest sign of oral carcinoma. Oral lesions that appear as red, raised, eroded areas are suspicious for cancer. A lesion that does not heal within 2 weeks or a lump or thickening in the cheek is a symptom that warrants further assessment (Oral Cancer Foundation, 2010).*

Squamous cell cancer can be found on the lips, tongue, buccal mucosa, and oropharynx. The major risk factors in its development are increasing age, tobacco use, and alcohol use. Most oral cancers occur in people older than 40 years. Tobacco use in any form (e.g., smoking or chewing tobacco) can increase the risk for cancer. A person who frequently consumes alcohol and uses tobacco in any form is at the highest risk. Genetic changes in patients with oral cancer have been found, especially the mutation of the *TP53* gene (McCance et al., 2010).

An increased rate of oral cancer is found in people with occupations such as textile workers, plumbers, and coal and metal workers. Additional factors, such as sun exposure, poor nutritional habits, poor oral hygiene, and infection with the human papilloma virus (HPV16) may also contribute to oral cancer (Oral Cancer Foundation, 2010). People with **periodontal** (gum) **disease** in which mandibular (jaw) bone loss has occurred are especially at risk for cancer of the mouth.

Mouth cancers account for about 3% of all cancers in men and 2% of all cancers in women in the United States. Over 37,000 new cases are diagnosed each year, with almost 8000 deaths (Oral Cancer Foundation, 2010). Most cancers occur in middle-aged and older people, although in recent years, younger adults have been affected, probably as a result of sun exposure.

Basal Cell Carcinoma

Basal cell carcinoma of the mouth occurs primarily on the lips. The lesion is asymptomatic and resembles a raised scab. With time, it evolves into a characteristic ulcer with a raised, pearly border. Basal cell carcinomas do not metastasize (spread) but can aggressively involve the skin of the face. The major risk factor for this type of cancer is excessive sunlight exposure.

Basal cell carcinoma occurs as a result of the failure of basal cells to mature into keratinocytes. It is the second most common type of oral cancer, but it is much less common than squamous cell carcinoma.

Kaposi's Sarcoma

Kaposi's sarcoma is a malignant lesion in blood vessels. It is usually painless and appears as a raised, purple nodule or plaque. In the mouth, the hard palate is the most common site of Kaposi's sarcoma, but it can be found also on the gums, tongue, or tonsils. It is most often associated with AIDS. (See Chapter 21 for a complete discussion of Kaposi's sarcoma.)

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Begin by assessing the patient's routine oral hygiene regimen and use of dentures or oral appliances, which might add to discomfort or mechanically irritate the mucosa. Ask about oral bleeding, which might indicate an ulcerative lesion or periodontal (gum) disease. Determine the patient's past and current appetite and nutritional state, including difficulty with chewing or swallowing. A continuing trend of weight loss may be related to metastasis, heavy alcohol intake, difficulty in eating or chewing, or an underlying health problem (Chart 56-3).

An examination of the oral cavity requires adequate lighting. Thoroughly inspect the oral cavity for any lesions, evidence of pain, or restriction of movement. Gently using a tongue blade and penlight, examine all areas of the mouth. Carefully note any change in speech caused by tongue movement. Notice any change in voice or swallowing, and assess for thick or absent saliva. After inspection, the advanced practice nurse, specialty nurse, or other health care provider uses bimanual palpation of any visible nodules to determine size and fixation. The cervical lymph nodes should also be palpated (Fig. 56-2).

The functioning and appearance of the mouth are strongly linked with body image and quality of life. Therefore it is

CHART 56-3 KEY FEATURES

Oral Cancer

- Bleeding from the mouth
- Poor appetite
- Difficulty chewing
- Difficulty swallowing
- Poor nutritional status and weight loss
- Thick or absent saliva
- Painless oral lesion that is red, raised, or eroded
- Thickening or lump in cheek

FIG. 56-2 The lymph nodes of the cervical region.

important to assess the impact of oral lesions on the patient's self-concept. In addition, assess for any educational or cultural needs that might affect health teaching or treatment. Evaluate the patient's support system and past coping mechanisms.

Oral CDx brushing of a lesion is helpful in determining whether it is precancerous. This procedure is usually performed by a dentist during a routine dental examination (Oral CDx, 2008). However, biopsy is the definitive method for diagnosis of oral cancer. The physician obtains a needle biopsy specimen of the abnormal tissue to assess for malignant or premalignant changes. Incisional biopsies may also be performed. An intraoral biopsy can be done under local anesthesia. In very small lesions, an excisional biopsy can permit complete tumor removal. Magnetic resonance imaging (MRI) is useful in detecting perineural involvement and in evaluating thickness in cancers of the tongue. Both computed tomography (CT) and MRI can be used to determine spread to the liver or lungs if further staging of the disease is warranted.

An aqueous solution of toluidine blue 1% can be applied to oral lesions to determine if they are malignant. This preparation stains malignant lesions, leaving normal tissue unaffected. However, a lesion that is the result of an inflammatory process may also absorb the stain, leading to a false-positive result. Although a biopsy is still needed to confirm a cancer diagnosis, toluidine blue may be useful for screening high-risk patients (National Institute of Dental and Craniofacial Research, 2008).

INTERVENTIONS

Both the presence of tumors of the oral cavity and the effects of their treatment threaten the integrity of the oral mucosa and the patient's airway. Oral cavity lesions can be treated by surgical excision, by nonsurgical treatments such as radiation or chemotherapy, or by a combination of treatments (referred to as *multimodal therapy*). Chemotherapy is currently not used independently in the treatment of oral cancers but is used in addition to other modes of treatment to sensitize malignant cells to radiation, to shrink a malignancy before surgery, or to decrease the potential for malignancy (Oral Cancer Foundation, 2010). Multimodal therapy is the most costly treatment option, yet more frequently used (Oral Cancer Foundation, 2010). *If the patient has extensive tumor involvement and copious, tenacious (thick and "stringy") secretions, maintaining an open airway is the nurse's priority for care.* Other nursing interventions focus on restoring and maintaining oral health

Nonsurgical Management

Implement interventions to *manage the patient's airway* by increasing air exchange, removing secretions, and preventing aspiration as needed. Assess for dyspnea resulting from the tumor obstruction or from excessive secretions. Assess the quality, rate, and depth of respirations. Auscultate the lungs for adventitious sounds, such as wheezes caused by aspiration. Listen for stridor caused by partial airway obstruction. Promote deep breathing to help produce an effective cough to mobilize the patient's secretions.

To increase air exchange, place the patient in a semi-Fowler's or high-Fowler's position. Encourage fluids to help liquefy secretions. Chest physiotherapy also increases air exchange as well as promotes effective coughing. If available,

collaborate with the respiratory therapist about performing this procedure. If needed, use oral suction equipment with a dental tip or a tonsil tip (Yankauer catheter) to remove secretions that obstruct the airway. Teach the patient and family to use the catheters as needed.

If edema occurs with oral cavity lesions, the patient may receive steroids to reduce inflammation. Antibiotics may be prescribed if infection is present because it can increase inflammation and edema. A cool mist supplied by a face tent may assist with oxygen transport and control of edema.

! NURSING SAFETY PRIORITY

Action Alert

Aspiration precautions prevent or reduce the risk factors for aspiration. Assess the patient's level of consciousness (LOC), gag reflex, and ability to swallow. To prevent aspiration, place the patient sitting upright at 90 degrees (high-Fowler's position). As a precaution, keep suction equipment nearby. For patients at high risk, assess the gag reflex before giving any fluids. Remind UAP to feed patients at risk for aspiration in small amounts. Teach visitors to speak with the nurse before offering any type of food or drink to the patient. Provide thickened liquids as an aid to prevent aspiration.

It is important to work with the patient to *establish an oral hygiene routine*. Perform oral hygiene every 2 hours for ulcerated lesions, infection, or in the immediate postoperative period. Modifications might be needed because of oral discomfort, bleeding, or edema. Oral care with a soft-bristled toothbrush is preferred. If the platelet count falls below 40,000/mm³, switch the patient to an ultrasoft "chemobrush." The use of "toothettes" or a disposable foam brush is discouraged because these products may not adequately control bacteremia-promoting plaque and may further dry the oral mucosa. Lubricant can be applied to moisten the lips and oral mucosa as needed.

Teach patients and their families that the patient should avoid using commercial mouthwashes and lemon-glycerin swabs. Commercial mouthwashes contain alcohol, and lemon-glycerin swabs are acidic. These substances can cause a burning sensation and contribute to dry oral mucous membranes. Encourage frequent rinsing of the mouth with sodium bicarbonate solution or warm saline (see also Chart 56-2). Follow hospital or health care provider protocol if available.

Radiation therapy for oral cancers can be given by external beam or interstitial implantation to reduce the size of the tumor before surgery. *External-beam* radiation passes through the skin or mucous membrane to the tumor site. Typically, treatments are given as five daily treatments per week, with a 2-day break each week, over a 6- to 9-week period. Each treatment lasts only about 10 to 15 minutes, with more time being dedicated to undertaking special precautions to minimize the dose of radiation to the brain or spinal cord (Oral Cancer Foundation, 2010).

Another option is the implantation of radioactive substances (*interstitial radiation* therapy or brachytherapy) either to boost the dosage or to deliver a radiation dose close to the tumor bed. This form of implant therapy can be curative in early-stage lesions in the floor of the mouth or anterior tongue. It may also add a boost of radiation to a tumor that received external-beam radiation.

With the exception of radioactive seeds, which have a low level of emission, patients receiving interstitial radiation are

usually hospitalized for the duration of treatment. *Place patients on radiation transmission precautions while the materials are active or in place.* A tracheostomy may be required with interstitial implants because of edema and increased oral secretions. (See [Chapter 24](#) for general nursing care of patients undergoing radiation therapy.)

Teach the patient undergoing *chemotherapy* and family members about the side effects of these agents, which vary with each drug. Give antiemetics as prescribed, and provide other comfort measures as needed. (See [Chapter 24](#) for general care of patients receiving chemotherapy.)

! NURSING SAFETY PRIORITY

Drug Alert

Patients who are undergoing radiation and/or chemotherapy treatment may experience a decreased ability to tolerate prescribed and over-the-counter medications. Teach patients about expected side effects, and remind them to not take any medication (including over-the-counter medications, herbs, or vitamin supplements) without first discussing them with their health care provider.

One of the most recent advances in the use of drugs for oral cancer is targeted therapy. Hormone-like substances known as *growth factors* (GFs) occur in the body's cells. Oral tumor cells, along with other types of cancers, grow quickly because they have more GF receptors than normal healthy tissue. One of these GFs is called *epidermal growth factor* (EGF), which has been associated with oral cancers. Newer drugs that can target and block EGF receptors (EGF-R) are being tested, and more than a dozen have been approved, including cetuximab (Erbix), erlotinib (Tarceva), and panitumumab (Vectibix). [Chapter 24](#) describes targeted molecular therapy.

Surgical Management

The physician can often remove small, noninvasive lesions of the oral cavity in an ambulatory setting with local anesthesia. The surgical defect is usually small enough to be closed by sutures. These smaller lesions may also be responsive to carbon dioxide laser therapy or *cryotherapy* (extreme cold application), as well as photodynamic therapy. These procedures can be performed as an ambulatory care procedure in a surgical center but may require general anesthesia.

Small oral cancers are equally responsive to radiation or photodynamic therapy and to surgery. More invasive lesions (stages III and IV) require more extensive surgical excision and result in a greater loss of function and disfigurement. Not all lesions can be excised by the peroral approach (through the mouth). The goal of surgical resection is removal of the tumor with a surgical margin that is free of cancer cells.

Preoperative Care. Before excision of a lesion in the oral cavity, assess and document the patient's level of understanding of the disease process, the rationale for the surgery, and the planned intervention. Problems associated with cancer therapy can be reduced or optimally managed by collaborating with the patient and family regarding preparation and instruction. Reinforce information as needed. Include family members or other caregivers in the health teaching unless culturally inappropriate.

For small, local excisions, postoperative restrictions include a liquid diet for a day and then advancing as tolerated.

There are no activity limitations, and postoperative analgesics are prescribed.

Instructions for the patient undergoing large surgical resections may include but are not limited to these expectations after surgery:

- Placement of a temporary tracheostomy, oxygen therapy, and suctioning
- Temporary loss of speech because of the tracheostomy
- Frequent monitoring of postoperative vital signs
- NPO status until intraoral suture lines are healed
- Need to have IV lines in place for drug delivery and hydration
- Postoperative drug therapy and activity (out of bed on the first postoperative day)
- Possibility of surgical drains

Because communication is interrupted, assess the patient's ability to read, write, and draw pictures to communicate. In coordination with the patient, select the method of communication to use after surgery with staff and family members (e.g., Magic Slate, computer, picture board, or pad and pencil). Preprinted flashcards may be used to communicate the patient's needs, such as "I am tired," "I am in pain," or "I am hungry." Urge the patient to practice the chosen method before surgery to reduce frustration after surgery.

Operative Procedures. Three factors influence the extent of surgery performed for oral cancers: the size and location of the tumor, tumor invasion into the bone, and whether there has been metastasis (cancer spread) to neck lymph nodes. Small, noninvasive tumors can be removed perorally (through the mouth). Otherwise, an external approach may be used. The most extensive oral operations are composite resections, which combine partial or total *glossectomy* (tongue removal) and partial *mandibulectomy* (jaw removal). In the **com-mando** (co-mandible) **procedure** (**COM**bined neck dissection, **MAND**ibulectomy, and **O**ropharyngeal resection), the surgeon removes a segment of the mandible with the oral lesion and performs a radical neck dissection (see [Chapter 31](#)).

Metastasis to cervical lymph nodes usually indicates a poor prognosis for patients with cancer of the oral cavity. In those with cervical node metastasis, a neck dissection may also be performed. A radical neck dissection usually involves the removal of all cervical lymph nodes on the affected side, along with cranial nerve XI (the accessory nerve), the internal jugular vein, and the sternocleidomastoid (front neck) muscle. Modified and selective neck dissections may be performed in patients with minimal lymph node involvement.

Postoperative Care. The patient may have a temporary or permanent tracheostomy, requiring intensive nursing care to promote airway clearance. In addition, care must be taken to protect the surgical incision site from mechanical damage and infection (see [Chapter 31](#)). Nursing interventions to relieve pain or discomfort and promote nutrition are also important. Older adults are a special risk for surgery and need to be monitored very carefully ([Chart 56-4](#)).

Ensure that the predetermined method of communication is available for the patient, family members, and staff. When the patient has an adequate airway and can effectively clear secretions by coughing, the tracheostomy tube may be removed. When the tube is removed, an airtight dressing is placed over the site and the tracheostomy incision heals without the need for sutures.

CHART 56-4 FOCUSED ASSESSMENT

The Postoperative Older Adult with Oral Cancer

- Assess the mouth and surrounding tissues for candidiasis, mucositis, and pain; assess for loss of appetite and taste.
- Monitor the patient's weight.
- Monitor nutritional and fluid intake.
- Assess for difficulty in eating or speech.
- Assess pain status and measures used to control pain.
- Monitor the patient's response to medications.
- Identify psychosocial problems, such as depression, anxiety, and fear.
- Assess the patient's overall physiological condition and how this may affect pharmacologic therapy.

NURSING SAFETY PRIORITY**Action Alert**

After extensive excision or resection for oral cancer, the most important nursing intervention is maintaining the patient's airway! Upon awakening from anesthesia, the patient may not recall, or realize, that a tracheostomy tube is in place and may initially panic because of the inability to speak. Remind the patient why he or she cannot speak, and provide reassurance that the vocal cords are intact (unless a total laryngectomy has been performed, in which case the loss of voice is permanent).

Patients who have undergone extensive resection may have slurred speech or difficulty in speaking as a result of nerve damage or tongue removal. Collaborate with the speech-language pathologist if speech is altered.

Protect the incision site to avoid infection. Provide gentle mouth care for cleaning away thick secretions and stimulating the flow of saliva. The delivery of oral care depends on the nature and extent of the surgical procedure. Give oral care at least every 4 hours in the early postoperative phase. The presence of unusual odors from the mouth can indicate infection; therefore continual assessment of the oral cavity is very important. In the early postoperative phase, take care to avoid disruption of the suture line during oral hygiene.

Elevate the head of the bed to assist in decreasing edema by gravity. If skin grafting was done, inspect the donor site (generally on the anterior thigh) every 8 hours for bleeding or signs of infection. (See [Chapter 31](#) for specific nursing care of the patient with a radical neck dissection.)

To provide optimal *pain relief* in the postoperative period, rely on subjective and objective data to assess the need for analgesics and their effectiveness. The desired outcome of drug therapy during this period is relief of pain while allowing the patient to function at an optimal level. Those who have undergone surgery for oral cancer describe their pain as throbbing or pounding. IV morphine is usually the initial pain medication given. Tylox or Percocet (oxycodone plus acetaminophen) may be used for systemic relief of moderate pain after the IV morphine is discontinued.

Patients who have undergone extensive resections of the oral cavity remain on NPO status for several days. This time allows healing in the oral cavity before food comes in contact with the incision. Nasogastric feeding or total parenteral nutrition may be needed until oral nutrition can begin (see [Chapter 63](#)).

When oral fluid intake is started, assess for and document signs of difficulty swallowing, aspiration, or leakage of saliva or

fluids from the suture line. Monitor daily weights and hydration. Nutritional supplementation may be used to improve the patient's quality of life. Patients who have weight loss or who are having difficulty maintaining hydration may be candidates for the placement of a gastrostomy tube. Coordinate nutritional care with the dietitian.

Encourage the patient to perform swallowing exercises. Collaborate with the speech-language pathologist to assist with swallowing techniques. Thickened fluids may be needed to prevent aspiration. A swallowing impairment may be temporary or permanent.

**DECISION-MAKING CHALLENGE****Teamwork and Collaboration; Patient-Centered Care**

A 40-year-old homeless woman is admitted to the emergency department with difficulty breathing and swallowing. On assessment, the triage nurse finds that she has very poor dental hygiene and a large oral tumor. After a thorough evaluation, the patient is scheduled for oral surgery to remove as much of the tumor as possible.

1. As the patient's nurse, what is your priority for her care immediately after surgery?
2. As you develop her plan of care, for what complications is this patient most at risk?
3. With what members of the health care team will you collaborate?
4. In view of her homelessness, what support systems might you seek?
5. What follow-up care is realistic for this patient?

Community-Based Care

Continuing care for the patient with an oral tumor depends on the severity of the tumor, its collaborative care, and available support systems. Most patients are maintained at home during follow-up care. Ongoing nutritional management remains a vital part of the treatment plan. In addition, the patient and family may benefit from a community-based support group for cancer victims.

Home Care Management

If radiation therapy is part of the patient's treatment plan, home care considerations include health teaching and management strategies. Complications due to radiation to the head or neck can be acute or delayed. Acute effects include treatment-related mucositis, stomatitis, and alterations in taste. Long-term effects such as **xerostomia** (excessive mouth dryness) and dental decay require ongoing oral care, the use of saliva substitutes, and follow-up dental visits. Although ongoing dental care is important, the possible adverse effects that radiation has on bone make elective oral surgical procedures, such as tooth extraction, impossible in the area of the radiation. Fatigue is a common side effect of radiation and chemotherapy.

The patient whose tracheostomy tube has been removed is often placed on a soft diet by mouth before discharge. Occasionally, however, patients are discharged from the hospital while still requiring tracheostomy suction, oral suction, and nasogastric feedings. Suction equipment, nutritional supplies, and nursing care can be provided by home care companies. (See [Chapter 63](#) for home care preparation for the patient receiving home parenteral nutrition and [Chapter 31](#) for home care preparation for the patient with a tracheostomy.)

CHART 56-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Care of the Patient with Oral Cancer at Home

- Follow the treatment plan for cancer therapies.
- Remember that taste sensation may be decreased; add seasonings to food to better enjoy it.
- Use a thickening agent for liquids if dysphagia is present.
- Eat soft foods if stomatitis occurs.
- Inspect the mouth every day for changes, such as redness.
- Continue meticulous oral hygiene at home using a chemobrush and frequent rinsing; clean after every use.
- Use saliva substitute as prescribed.
- Avoid sun or tanning bed exposure if radiation is part of therapy.
- Clean with a gentle, nondeodorant soap, such as Ivory.

Teaching for Self-Management

Teach the patient and family about drug therapy, nutritional therapies, any treatments (e.g., tracheostomy care, suture line care, dressing changes), and early symptoms of infection before hospital discharge (Chart 56-5). Alterations in taste and dysphagia make maintaining adequate nutrition a challenge for the oral cancer patient. Alterations in taste occur when the taste buds are included in the radiation treatment field. Taste sensation may begin to return several weeks after the completion of treatment. Some types of chemotherapy can also affect the patient's taste. Sometimes the loss of taste is permanent.

Changes in taste include dislike of meat, such as beef or pork, and metallic tastes in the mouth. Teach patients to add seasonings to foods, to use gravies or sauces to make foods more palatable, and to use high-protein foods such as cheeses, milk, eggs, puddings, and legumes in place of meat. Instruct patients with dysphagia in swallowing exercises. Recommend thickened liquids because thin liquids, such as water, are difficult to control during swallowing. Collaborate with the dietitian to teach the family how to assess the nutritional intake of the patient who is just beginning to eat. Liquid dietary supplements are usually recommended at this time. If bleeding or stomatitis is present, recommend soft foods to prevent further injury to the mucous membranes.

Teach the patient or family members to inspect the oral cavity daily for areas of redness, which can indicate the onset of stomatitis. Meticulous oral hygiene should be continued at home, especially with adjuvant chemotherapy or radiation. Reinforce the oral hygiene routine, emphasizing the need for frequent mouth rinsing to reduce the number of microorganisms and to maintain adequate hydration. The patient should use a chemobrush (an extra-soft type of toothbrush), rinse the chemobrush with hydrogen peroxide and water or with a diluted bleach solution after each use, and change chemobrushes weekly. The brush may also be cleaned in a dishwasher.

Saliva production is greatly reduced as a consequence of radiation. The resulting xerostomia (dry mouth) causes the inability to eat dry foods and may be permanent. Teach the patient regarding the use of saliva substitutes.

Skin reactions are also a common side effect of radiation. Instruct the patient to avoid sun exposure, to avoid perfumed lotions and powders, and to cleanse the face and neck area with a gentle nondeodorant soap. Teach male patients to use an electric razor for shaving and to avoid alcohol-based after-shave lotions to prevent further skin irritation.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A client who has completed radiation therapy for an oral tumor is being discharged to home. What health teaching should the nurse provide? **Select all that apply.**

- A. "Eat any foods that appeal to you."
- B. "Rinse your mouth several times daily with Listerine."
- C. "Use saliva substitutes as prescribed."
- D. "Avoid exposure to the sun and tanning beds."
- E. "Use a nondeodorant soap like Ivory."
- F. "Use a firm-bristled toothbrush to remove plaque."

Health Care Resources

Patients who have undergone composite resection often require community services because they have both physical and psychosocial needs. Depression related to a change in body image is common. Excision of a portion of the jaw can leave a facial defect that may be difficult to hide. Assess for depression and other behavioral responses. A social worker or other health care professional may be needed for patient and family counseling. Those who have undergone a total glossectomy may be able to speak with special training and the use of an intraoral prosthesis created by a maxillofacial prosthodontist. The prosthesis is similar to dentures.

Collaborate with the case manager to provide assistance in obtaining special equipment or nutritional resources needed by the patient at home. The case manager assesses the patient's financial needs and makes referrals to government, community, and religious organizations as needed. Refer the patient to the American Cancer Society (ACS) (www.cancer.org) or the Oral Cancer Foundation (www.oralcancerfoundation.org) for local support groups and resources, including additional information. The ACS often provides dressing supplies and transportation to and from follow-up visits or medical treatments.

DISORDERS OF THE SALIVARY GLANDS

ACUTE SIALADENITIS

Pathophysiology

Acute sialadenitis, the inflammation of a salivary gland, can be caused by infectious agents, irradiation, or immunologic disorders. Salivary gland inflammation can have a bacterial or viral cause, such as infection with cytomegalovirus (CMV). The most common bacterial organisms are *Staphylococcus aureus*, *Staphylococcus pyogenes*, *Streptococcus pneumoniae*, and *Escherichia coli*. This disorder most commonly affects the parotid or submandibular gland in adults.

A decrease in the production of saliva (as in dehydrated or debilitated patients or in those who are on NPO status postoperatively for an extended time) can lead to acute sialadenitis. The bacteria or viruses enter the gland through the ductal opening in the mouth. Systemic drugs, such as phenothiazines and the tetracyclines, can also trigger an episode of acute sialadenitis. Untreated infections of the salivary glands can evolve into abscesses, which can rupture and spread infection into the tissues of the neck and the mediastinum.

Patients who receive radiation for the treatment of cancers of the head and neck or thyroid may develop decreased salivary flow, predisposing them to acute or persistent sialadenitis. The effect of radiation on the salivary glands is rapid and

dose related. Immunologic disorders such as HIV infection can cause enlargement of the parotid gland that result from secondary infection. Sjögren's syndrome, an autoimmune disorder, is characterized by chronic salivary gland enlargement and inflammation (see Chapter 20).

PATIENT-CENTERED COLLABORATIVE CARE

During the initial interview, assess for any predisposing factors for sialadenitis, such as ionizing radiation to the head or neck area. Collect a thorough drug history, and ask about systemic illnesses, such as HIV infection.

Dehydration can be assessed by examining the oral membrane for dryness and the skin for turgor. Other assessment findings include pain and swelling of the face over the affected gland. Assess facial function because the branches of cranial nerve VII (the facial nerve) lie close to the salivary glands. Fever and general malaise also occur, and purulent drainage can often be massaged from the affected duct in the oral cavity.

Collaborative care includes the administration of IV fluids and measures such as these to treat the underlying cause and increase the flow of saliva:

- Hydration
- Application of warm compresses
- Massage of the gland
- Use of a saliva substitute
- Use of **sialagogues** (substances that stimulate the flow of saliva)

Sialagogues include lemon slices and citrus-flavored and other fruit-flavored candy. Massage is accomplished by milking the edematous gland with the fingertips toward the ductal opening. Elevation of the head of the bed promotes gravity drainage of the edematous gland.

Acute sialadenitis is best prevented by adherence to routine oral hygiene. This practice prevents infections from ascending to the salivary glands from the mouth.

POST-IRRADIATION SIALADENITIS

The salivary glands are sensitive to ionizing radiation, such as from radiation therapy or radioactive iodine treatment of thyroid cancers. Exposure of the glands to radiation produces a type of sialadenitis known as **xerostomia** (very dry mouth caused by a severe reduction in the flow of saliva) within 24 hours. Radiation to the salivary glands can also produce pain and edema, which generally abate after several days.

Xerostomia may be temporary or permanent, depending on the dose of radiation and the percentage of total salivary

gland tissue irradiated. Little can be done to relieve the patient's dry mouth during the course of radiation therapy. Frequent sips of water and frequent mouth care, especially before meals, are the most effective interventions. After the course of radiation therapy has been completed, saliva substitutes may provide moisture for 2 to 4 hours at a time. Over-the-counter solutions are available, or methylcellulose (Cologel), glycerin, and saline may be mixed to form a solution.

SALIVARY GLAND TUMORS

Of all oral tumors, those of the salivary glands are relatively rare. Initially, malignant tumors present as slow-growing, painless masses. Involvement of the facial nerve results in facial weakness or paralysis (partial or total) on the affected side.

Collect information about any prior radiation exposure, because radiation to the head and neck areas is associated with the occurrence of salivary gland tumors. Salivary gland tumors present as localized, firm masses. Large tumors may cause facial nerve paralysis. Submandibular and minor salivary gland tumors may be tender or painful. Tumor invasion of the hypoglossal nerve causes impaired movement of the tongue, and a loss of sensation can follow. *Pay particular attention to assessment of the facial nerve because of its proximity to the salivary glands.* Assess the patient's ability to:

- Wrinkle the brow
- Raise the eyebrows
- Squeeze and hold the eyes shut, while the nurse gently pulls upwards on the eyebrows and cheeks beneath the orbit to check for symmetry
- Wrinkle the nose
- Pucker the lips
- Puff out the cheeks
- Grimace or smile

Be aware of any asymmetry when the patient performs these motions. The treatment of choice for both benign and malignant tumors of the salivary glands is surgical excision. However, radiation therapy is often used for salivary gland cancers that are large, have recurred, show evidence of residual disease after excision, or are highly malignant.

Patients who have undergone **parotidectomy** (surgical removal of the parotid glands) or submandibular gland surgery are at risk for weakness or loss of function of the facial nerve because the nerve courses directly through the gland. Facial nerve repair with grafting can be done at the time of surgery. A combination of surgery followed by radiation is common for advanced disease. Care for patients after parotidectomy is similar to that required for those having oral cancer surgery, described on p. 1197.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient has inadequate digestion and oxygenation as a result of oral cavity problems?

- Dysphagia (difficulty swallowing)
- Dyspnea
- Stridor or wheezes
- Changes in speech or voice
- Copious, thickened oral secretions
- Excessive coughing during meals

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate digestion and oxygenation as a result of oral cavity problems?

Perform and interpret focused physical assessment findings, including:

- Breath sounds
- Oxygen saturation by pulse oximetry
- Ability to cough and clear the airway

NURSING CONCEPT REVIEW—cont'd

- Ability to manage excessive oral secretions
- Ability to chew food and swallow

Respond:

- Place the patient with the head elevated to at least 30 degrees.
- Apply oxygen as needed.
- Suction the oral cavity as needed.
- Encourage deep breathing and coughing every 2 hours.
- Increase fluids to liquefy secretions, depending on swallowing ability.
- Notify the respiratory therapist or Rapid Response Team if interventions are not successful in restoring oxygenation.

On what should you REFLECT?

- Observe patient for evidence of increased oxygenation, including increased ease of breathing.
- Observe patient for evidence of increased ability to swallow.
- Observe patient for evidence of increased ability to manage oral secretions.
- Consider follow-up interventions to manage patient, including coordinating care with dietitian and speech-language pathologist.
- Think about what else you might do to promote digestion and nutrition.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Be aware that airway management is the priority for care for patients having surgery for oral cancer.
- Place patients having oral cancer surgery in a high-Fowler's position to facilitate breathing and prevent aspiration.
- Be sure to assess for swallowing ability to prevent aspiration by checking the gag reflex before offering liquids or food to the patient who has had oral cancer surgery.
- Plan continuity of care to meet patients' needs when they are transferred from the hospital to community-based agencies.

Health Promotion and Maintenance

- Teach patients to seek medical or dental attention for oral lesions that do not heal; these lesions could be oral carcinomas.
- Remind patients to visit their dentist regularly for dental hygiene and oral examination.
- Follow the best practice recommendations for maintaining oral health as listed in [Chart 56-1](#).
- Instruct patients to avoid harsh commercial mouthwashes if they have oral lesions.
- Teach patients to avoid tobacco, alcohol, and sun exposure to decrease their chance of having oral cancer.
- Instruct patients with acute sialadenitis to use sialogogues to stimulate saliva, such as citrus foods or candies.

Psychosocial Integrity

- Assist the patient and family in identifying and using coping mechanisms to deal with possible changes in body image and altered self-esteem.

- Recognize that patients with stomatitis are often unable to eat or swallow without discomfort.
- Refer patients with oral cancer to support groups, such as those available through the American Cancer Society.

Physiological Integrity

- Remember that stomatitis usually manifests as painful single or multiple ulcerations within the mouth.
- Recognize that stomatitis can be caused by a variety of organisms; *Candida* infections are very common in patients who receive antibiotic therapy and in those who are immunocompromised.
- Provide gentle oral care for patients with oral lesions, including chemobrushes and warm saline or sodium bicarbonate solution.
- Be aware that patients with stomatitis receive antimicrobials, anti-inflammatory agents, immune modulators, and topical agents for relief of symptoms, including pain.
- Differentiate leukoplakia and erythroplakia: leukoplakia presents as thin, white patches, and erythroplakia presents as red, velvety lesions.
- Be aware that patients with oral cancer may have chemotherapy, radiation, surgery, or a combination of these treatment methods.
- Be aware that sialadenitis can occur as result of radiation therapy.
- For patients with salivary gland tumors, assess for facial nerve involvement.
- Remember that a parotidectomy involves the removal of the salivary glands; postoperative care is similar to that for patients who have oral cancer surgery.

Care of Patients with Esophageal Problems

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Explain the importance of collaborating with the health care team when providing care to patients with esophageal health problems that impair swallowing or limit nutrition.

Health Promotion and Maintenance

2. Teach the patient and family about lifestyle changes to decrease gastroesophageal reflux disease (GERD) and the discomfort of hiatal hernias.
3. Describe special considerations for the older adult with GERD.

Psychosocial Integrity

4. Identify the need for psychosocial support to patients and their families through diagnosis and treatment of esophageal cancer.

Physiological Integrity

5. Evaluate the impact of esophageal cancer on the patient's nutritional status, including the risk for aspiration.
6. Perform focused assessments for patients with esophageal health problems.
7. Apply knowledge of pathophysiology to anticipate complications of GERD.
8. Plan how to teach patients with GERD about drug therapy.
9. Develop a teaching plan for the patient and family about postoperative care after esophageal surgery.
10. Apply knowledge of pathophysiology to recognize complications of esophageal surgical procedures.
11. Plan community-based care for patients diagnosed with esophageal cancer.

The esophagus moves partially digested food from the mouth to the stomach. If food cannot reach the stomach, the patient cannot meet the *human need for nutrition*. Nutrients in food are necessary for normal body cell function. Common problems of the esophagus that can interfere with *digestion* and *nutrition* are caused by inflammation, structural defects or obstruction, and cancer. Patient-centered collaborative care requires dietary and lifestyle changes, as well as medical and surgical therapies.

GASTROESOPHAGEAL REFLUX DISEASE

Pathophysiology

Gastroesophageal reflux disease (GERD) is the most common upper GI disorder in the United States. It occurs most often in middle-aged and older adults but can affect people of any age. **GERD** occurs as a result of **reflux** (backward flow) of GI contents into the esophagus. The incidence of GERD is increasing throughout the world (Chait, 2010).

Reflux produces symptoms by exposing the esophageal mucosa to the irritating effects of gastric or duodenal contents, resulting in inflammation. A person with acute symptoms of inflammation is often described as having **reflux esophagitis**, which may be mild or severe (McCance et al., 2010).

The reflux of gastric contents into the esophagus is normally prevented by the presence of two high-pressure areas that remain contracted at rest. A 1.2-inch (3-cm) segment at the proximal end of the esophagus is called the *upper esophageal sphincter (UES)*. Another small portion at the gastroesophageal junction (near the cardiac sphincter) is called the **lower esophageal sphincter (LES)**. The function of the LES is supported by its anatomic placement in the abdomen, where the surrounding pressure is significantly higher than in the low-pressure thorax. Sphincter function is also supported by the acute angle (angle of His) that is formed as the esophagus enters the stomach.

The most common cause of GERD is excessive relaxation of the LES, which allows the reflux of gastric contents into the esophagus and exposure of the esophageal mucosa to acidic gastric contents. Nighttime reflux tends to cause prolonged exposure of the esophagus to acid because the supine position decreases peristalsis and the benefit of gravity. Although controversial, *Helicobacter pylori* may contribute to reflux as well (McCance et al., 2010).

A person having reflux may be asymptomatic and not aware that reflux is occurring. However, the esophagus has only limited resistance to the damaging effects of the acidic GI contents. The pH of acid secreted by the stomach ranges from 1.5 to 2.0, whereas the pH of the distal esophagus is normally neutral (6.0 to 7.0).

Refluxed material is returned to the stomach by a combination of gravity, saliva, and peristalsis. The inflamed esophagus cannot eliminate the refluxed material as quickly as a healthy one, and therefore the length of exposure increases with each reflux episode. Hyperemia (increased blood flow) and **erosion** (ulceration) occur in the esophagus in response to the chronic inflammation. Gastric acid and pepsin injure tissue. Minor capillary bleeding often occurs with the erosion, but hemorrhage is rare.

During the process of healing, the body may substitute **Barrett's epithelium** (columnar epithelium) for the normal squamous cell epithelium of the lower esophagus. Although this new tissue is more resistant to acid and therefore supports esophageal healing, it is considered premalignant. It is associated with an increased risk for cancer in patients with prolonged GERD. The fibrosis and scarring that accompany the healing process can produce **esophageal stricture** (narrowing of the esophageal opening). The stricture leads to progressive difficulty in swallowing. Uncontrolled esophageal reflux also creates a risk for other serious complications, such as hemorrhage and aspiration pneumonia. GERD may be one of the causes of adult-onset asthma, laryngitis, and dental decay. It has also been associated with cardiac disease.

Gastric distention caused by eating very large meals or delayed gastric emptying predisposes the patient to reflux. A number of individual factors, including certain foods and drugs, influence the function of the LES (Table 57-1). Smoking and alcohol also weaken the tone of the LES.

Patients who have a nasogastric tube also have decreased esophageal sphincter function. The tube keeps the cardiac

TABLE 57-1 FACTORS CONTRIBUTING TO DECREASED LOWER ESOPHAGEAL SPHINCTER PRESSURE

sphincter open and allows acidic contents from the stomach to enter the esophagus. Other factors that increase intra-abdominal and intragastric pressure (e.g., pregnancy, wearing tight belts or girdles, bending over, ascites) overcome the gastroesophageal pressure gradient maintained by the LES and allow reflux to occur. Many patients with obstructive sleep apnea report frequent episodes of GERD. People with hiatal hernias often have reflux because the upper portion of the stomach protrudes through the diaphragm into the thorax to allow acid to reach the esophagus (see later discussion of hiatal hernia).

Overweight and obese patients are at an increased risk for the disease. Increased weight increases intra-abdominal pressure, which contributes to reflux of stomach contents into the esophagus.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Ask the patient about a history of heartburn or atypical chest pain associated with the reflux of GI contents. Ask whether he or she has been newly diagnosed with asthma or has experienced morning hoarseness or pneumonia. These symptoms are suggestive of severe reflux reaching the pharynx or mouth or pulmonary aspiration.

Physical Assessment/Clinical Manifestations

The clinical manifestations of reflux vary in severity, depending on the patient (Chart 57-1). **Dyspepsia**, also known as “heartburn,” and *regurgitation* are the main symptoms of GERD. The pain is described as a substernal burning sensation that tends to move up and down the chest in a wavelike fashion. Because heartburn might not be viewed as a serious concern, patients may delay seeking treatment. If the

heartburn is severe, the pain may radiate to the neck or jaw or may be referred to the back. The pain typically worsens when the patient bends over, strains, or lies down. Patients may come to the emergency department (ED) fearing that they are having a myocardial infarction (“heart attack”).

With severe GERD, the pain occurs after each meal and lasts for 20 minutes to 2 hours. Patients usually obtain prompt relief by drinking fluids, taking antacids, or maintaining an upright posture.

Regurgitation (backward flow into the throat) of food particles or fluids is common. The patient feels warm fluid traveling up the throat without nausea. If the fluid reaches the level of the pharynx, he or she notes a sour or bitter taste in the mouth. This problem can even occur in an upright position. The danger of aspiration is increased if regurgitation occurs when the patient is lying down.

Eructation (belching), **flatulence** (gas), and bloating after eating are other common manifestations. Nausea and vomiting rarely occur, and unplanned weight loss is not common.

Assess for crackles in the lung, which can be an indication of associated aspiration. Assess the patient for coughing, hoarseness, or wheezing at night. Bronchitis may occur in those who have long-term regurgitation.

A reflex salivary hypersecretion known as **water brash** occurs in response to reflux. Water brash is different from regurgitation. The patient reports a sensation of fluid in the throat, but unlike with regurgitation, there is no bitter or sour taste.

Chronic GERD can cause **dysphagia** (difficulty swallowing). Dysphagia usually indicates a narrowing of the esophagus because of stricture or inflammation. Assess the patient for:

- The degree of dysphagia
- Whether dysphagia occurs when ingesting solids, liquids, or both
- Whether dysphagia is intermittent or occurs with each swallowing effort

Odynophagia (painful swallowing) can also occur with chronic GERD, but it is rare in people with uncomplicated reflux disease. Severe and long-lasting chest pain may be present if spasms occurring in the esophagus cause the muscle to contract with excess force. The resulting pain can be agonizing and may last for hours.

Other manifestations include chronic cough that occurs mostly at night or when the patient is lying down, asthma, and atypical chest pain. Cough and symptoms of asthma occur when refluxed acid is spilled over into the tracheobronchial tree. *Atypical chest pain* is thought to be caused by stimulation of pain receptors in the esophageal wall and by esophageal spasm. This type of chest pain can mimic angina and needs to be carefully distinguished from cardiac pain.

CONSIDERATIONS FOR OLDER ADULTS

In the older adult, the incidence of heartburn decreases in those with gastroesophageal reflux (GERD). Instead, the more severe complications of the disease are more frequent in this population, including atypical chest pain; ear, nose, and throat infections; and pulmonary problems, such as aspiration pneumonia, sleep apnea, and asthma. Barrett’s esophagus and esophageal erosions are also more common in older adults. The cause for these differences is not known (Chait, 2010).

Diagnostic Assessment

The most accurate method of diagnosing GERD is *24-hour ambulatory esophageal pH monitoring*. This test involves placing a small catheter through the nose into the distal esophagus. The patient is asked to keep a diary of activities and symptoms, and the pH is continuously monitored and recorded. Ambulatory pH monitoring is especially useful in diagnosing patients with atypical symptoms. A wireless monitoring device may be used to promote patient comfort.

Esophagogastroduodenoscopy (EGD) is useful in diagnosing or evaluating reflux esophagitis or in monitoring complications such as Barrett’s esophagus. This test requires the use of moderate sedation during the procedure, and patients must have someone accompany them home after recovery. During the procedure, tissue samples can be obtained for biopsy and strictures can be dilated (see Chapter 55).

Although not as common, *esophageal manometry*, or motility testing, may be performed when the diagnosis is uncertain. Water-filled catheters are inserted in the patient’s nose or mouth and slowly withdrawn while measurements of LES pressure and peristalsis are recorded. When used alone, manometry is not sensitive or specific enough to establish a diagnosis of GERD.

INTERVENTIONS

Nonsurgical Management

The purpose of treatment for GERD is to relieve symptoms, treat esophagitis, and prevent complications such as strictures or Barrett’s esophagus. For most patients, GERD can be controlled by nutrition therapy, lifestyle changes, and drug therapy. *The most important role of the nurse is patient and family education. Teach the patient that GERD is a chronic disorder that requires ongoing management. The disease should be treated more aggressively in older adults (Chait, 2010).*

Nonpharmacologic Interventions. Nutrition therapy is used to relieve symptoms in patients with relatively mild GERD. Ask about the patient’s basic meal patterns and food preferences. Coordinate with the dietitian, patient, and family about how to adapt to changes in eating that may decrease reflux symptoms.

Teach the patient to limit or eliminate foods that decrease LES pressure, such as chocolate, alcohol, fatty foods (especially fried), caffeine, and carbonated beverages. The patient should also restrict spicy and acidic foods (e.g., orange juice, tomatoes) until esophageal healing can occur, because these foods irritate the inflamed tissue and cause heartburn. Peppermint may also aggravate symptoms.

Large meals increase the volume of and pressure in the stomach and delay gastric emptying. Therefore remind the patient to eat four to six small meals each day rather than three large ones. Encourage patients to eat no food for at least 3 hours before going to bed. Reflux episodes are most damaging at night. Patients may have the most difficulty restricting evening snacks. Advise the patient to eat slowly and chew thoroughly to facilitate digestion and prevent eructation (belching).

The control of GERD involves *lifestyle changes* to promote health and control reflux (Chart 57-2). Teach the patient to elevate the head by 6 to 12 inches for sleep to prevent nighttime reflux. This can be done by placing blocks under the head of the bed or by using a large, wedge-style pillow instead of a standard pillow.

CHART 57-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Health Promotion and Lifestyle Changes to Control Reflux

- Eat four to six small meals a day.
- Limit or eliminate fatty foods, coffee, tea, cola, and chocolate.
- Reduce or eliminate from your diet any food or spice that increases gastric acid and causes pain.
- Limit or eliminate alcohol and tobacco.
- Do not snack in the evening, and take no food for 2 to 3 hours before you go to bed.
- Eat slowly and chew your food thoroughly to reduce belching.
- Remain upright for 1 to 2 hours after meals, if possible.
- Elevate the head of your bed 6 to 12 inches using wooden blocks, or elevate your head using a foam wedge. Never sleep flat in bed.
- If you are overweight, lose weight.
- Do not wear constrictive clothing.
- Avoid heavy lifting, straining, and working in a bent-over position.
- Chew “chewable” antacids thoroughly, and follow with a glass of water.

Teach the patient to sleep in the right side-lying position to decrease the effects of nighttime episodes of reflux. Nighttime reflux is extremely common, and infrequent swallowing in combination with a supine position impairs esophageal clearance. Smoking and alcohol cause decreased LES pressure. Explore the possibility and methods for smoking cessation, and make appropriate referrals. Ask the patient about his or her use of alcoholic beverages. If appropriate, assist the patient in finding alcohol-cessation programs.

Assist the patient in examining approaches to weight reduction. Decreasing intra-abdominal pressure often reduces reflux symptoms. Teach the patient to avoid wearing constrictive clothing, lifting heavy objects or straining, and working in a bent-over or stooped position. Emphasize that these general adaptations are an essential and effective part of disease management and can produce prompt results in uncomplicated cases.

Obese patients often have obstructive sleep apnea, as well as GERD. Those who receive continuous positive airway pressure (CPAP) treatment report improved sleeping and decreased episodes of reflux at night. See [Chapter 31](#) for a discussion of CPAP.

Some drugs lower LES pressure and *cause* reflux, such as oral contraceptives, anticholinergic agents, sedatives, NSAIDs (e.g., ibuprofen), nitrates, and calcium channel blockers. The possibility of eliminating those drugs causing reflux should be explored with the health care provider.

Drug Therapy. Drug therapy for GERD management includes three major types—antacids, histamine blockers, and proton pump inhibitors. These drugs have one or more of these functions ([Chart 57-3](#)):

- Inhibit gastric acid secretion
- Accelerate gastric emptying
- Protect the gastric mucosa

In uncomplicated cases of GERD, *antacids* may be effective for *occasional* episodes of heartburn. Antacids act by elevating the pH level of the gastric contents, thereby deactivating pepsin. They are not helpful in controlling frequent

symptoms because their length of action is too short and their nighttime effectiveness is minimal. These drugs also *increase* LES pressure and therefore are not given for long-term use.

Antacids containing aluminum hydroxide or magnesium hydroxide may be used. Maalox and Mylanta consist of a combination of these two agents. Patients often tolerate them better because they produce fewer side effects, such as constipation and diarrhea. Teach the patient to take the antacid 1 hour before and 2 to 3 hours after each meal. Some antacids are prepared as double-strength (DS) suspensions or tablets. The advantage of DS preparations is that a smaller amount of the drug is required. For example, 30 mL of regular Mylanta equals 15 mL of Mylanta-II (DS preparation).

Gaviscon, a combination of alginic acid and sodium bicarbonate, is often a very effective drug for GERD. It forms a thick foam that floats on top of the gastric contents and theoretically decreases the incidence of reflux. If reflux occurs, the foam enters the esophagus first and buffers the acid in the refluxed material. Remind the patient to take this drug when food is in the stomach.

Histamine receptor antagonists, commonly called *histamine blockers*, such as famotidine (Pepcid), ranitidine (Zantac), and nizatidine (Axid), decrease acid. With low-dose forms of these drugs available over the counter (OTC) and widely advertised for heartburn, many patients self-medicate before seeking professional assistance from their health care provider. When patients who have self-medicated with OTC preparations have uncontrolled symptoms, the health care provider usually prescribes a *higher* dose.

Ranitidine and the other preparations are long acting, allowing less-frequent dosing. They also appear to produce fewer side effects and may be safe for long-term use. Although these drugs do not affect the occurrence of reflux directly, they do reduce gastric acid secretion, improve symptoms, and promote healing of inflamed esophageal tissue.

Proton pump inhibitors (PPIs), such as omeprazole (Prilosec), rabeprazole (Aciphex), pantoprazole (Protonix), and esomeprazole (Nexium), are the *main* treatment for more severe GERD. Some PPIs are available as OTC drugs. These agents provide effective, long-acting inhibition of gastric acid secretion by affecting the proton pump of the gastric parietal cell. PPIs reduce gastric acid secretion and can be given in a single daily dose. If once-a-day dosing fails to control symptoms, twice-daily dosing may be used. A newer PPI, omeprazole/sodium bicarbonate (Zegerid), is the first immediate-release PPI and is designed for short-term use. Another newer PPI, dexlansoprazole (Kapidex), is a dual-release (delayed-release) drug that is available in several dosages but tends to be associated with more side and adverse effects than some of the other PPIs.

Some PPIs, such as Nexium and Protonix, may be administered in IV form for short-term use to treat or to prevent stress ulcers that can result from surgery. PPIs promote rapid tissue healing, but recurrence is common when the drug is stopped. Long-term use may mask reflux symptoms, and stopping the drug determines if reflux has been resolved. Long-term use may also cause community-acquired pneumonia and GI infections.

Research has also found that long-term use of proton pump inhibitors may increase the risk for hip fracture, especially in older adults. PPIs can interfere with calcium

CHART 57-3 COMMON EXAMPLES OF DRUG THERAPY

Gastroesophageal Reflux Disease (GERD)

DRUG/USUAL DOSAGE	PURPOSE FOR DRUG	NURSING INTERVENTIONS	RATIONALES
Antacids			
Aluminum or magnesium salts (Mylanta, Maalox) 30 mL orally between meals and as needed (PRN) throughout the day and at bedtime (Also see Chart 58-3 in Chapter 58)	Increases pH of gastric contents by deactivating pepsin	Give 1 hr before meals, 2-3 hr after meals, and at bedtime. Observe the patient for constipation or diarrhea. Suggest the use of combination mixtures or alternating use of aluminum and magnesium products.	These drugs work best if the stomach is empty. If given after meals, hydrogen ion load is high in food. Aluminum products produce constipation, and magnesium products induce diarrhea. Balancing their effects is important for patient adherence.
Alginic acid and sodium bicarbonate (Gaviscon), 1 tablet or 10-20 mL orally throughout the day and at bedtime	Buffers acid in stomach	Give after meals and at bedtime.	Alginic acid forms a viscous foam that floats on top of the gastric contents, impeding reflux or buffering its effects when it occurs.
Histamine Receptor Antagonists			
Ranitidine (Zantac) 150 mg orally twice daily Famotidine (Pepcid) 40 mg orally daily or 20 mg orally twice daily Nizatidine (Axiid) 150 mg orally twice daily	Decreases gastric acid secretions by blocking histamine receptors in parietal cells	Administer with meals and at bedtime. Use cautiously and in reduced dosages in patients with renal disease. Observe for dysrhythmias. Do not mix with tomato-based, mixed-vegetable juices; apple juice is the preferred choice.	Ranitidine and famotidine are more potent, longer-acting drugs but produce fewer side effects. Patients need an adequate creatinine clearance to prevent drug toxicity. Dysrhythmias are common adverse effects of the drug. Nizatidine may be less potent when mixed with tomato-based, mixed-vegetable juices.
Prokinetic Drugs			
Metoclopramide (Reglan) 10 mg orally three or four times daily	Increases gastric emptying	Instruct the patient to take the drug before meals. Teach the patient to report any neurologic or psychotropic side effects, such as restlessness, anxiety, ataxia, or hallucinations.	This drug increases the rate of gastric emptying. Long-term drug use produces adverse effects in up to one third of patients. <i>Therefore this drug is not commonly used.</i>
Proton Pump Inhibitors			
Omeprazole (Prilosec, Losec) 20-30 mg orally daily Lansoprazole (Prevacid) 15 mg orally daily for gastroesophageal reflux disease (GERD); up to 60 mg orally for GI ulcers or Zollinger-Ellison syndrome Rabeprazole (Aciphex) 60 mg orally daily (may increase to 120 mg in two divided doses) Pantoprazole (Protonix, Protonix IV) 40 mg orally daily or 40 mg IV daily for 7-10 days given in 15-min or 2-min infusions Esomeprazole (Nexium) 20-40 mg orally daily; 20-40 mg IV daily for 7-10 days given between 10 and 30 min (do not run less than 3 minutes)	Decreases gastric acid production (long-acting)	Instruct the patient to take the drug before meals. Observe the patient for typical side effects: abdominal cramping, diarrhea, headache. For the patient who has difficulty swallowing or has a nasogastric tube, open the capsule and mix granules in apple juice (or applesauce if not tube-fed). Do not crush, break, or chew delayed-release tablets. Teach patient to wear sunscreen. Do not crush, break, or chew delayed-release tablets. Do not give Protonix IV with other IV drugs. Do not administer with digoxin, rabeprazole, or iron salts. Do not crush, break, or chew this delayed-release oral drug. Do not give IV Nexium with other IV drugs.	Gastric acid suppression is greater than 90%. Action is prolonged, but GI effects are severe in some patients. Same as for omeprazole. The drug is safe to administer by opening (not crushing) the capsule. This form of the drug is released slowly into the body throughout the day. The drug predisposes the patient to burns. This form of the drug is released slowly into the body throughout the day. Protonix IV is not compatible with most other IV drugs. This drug may alter the effect and absorption of these agents. The oral form of the drug is released slowly throughout the day. IV Nexium is not compatible with most other drugs.

CHART 57-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Postoperative Instructions for Patients Having Endoscopic Therapies for Gastroesophageal Reflux Disease (e.g., Stretta Procedure)

- Remain on clear liquids for 24 hours after the procedure.
- After the first day, consume a soft diet, such as custard, pureed vegetables, mashed potatoes, and applesauce.
- Avoid nonsteroidal anti-inflammatory drugs and aspirin for 10 days.
- Continue drug therapy as prescribed, usually proton pump inhibitors.
- Use liquid medications whenever possible.
- Do not allow nasogastric tubes for at least 1 month because the esophagus could be perforated.
- Contact the health care provider immediately if these problems occur:
 - Chest or abdominal pain
 - Bleeding
 - Dysphagia
 - Shortness of breath
 - Nausea or vomiting

absorption and protein digestion and therefore reduce available calcium to bone tissue. Decreased calcium makes bones more brittle and likely to fracture, especially as people age (Chait, 2010).

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client with gastroesophageal reflux disease (GERD) is newly diagnosed by the nurse practitioner, who prescribes pantoprazole (Protonix) 40 mg. What teaching will the nurse provide for this client about this drug?

- "Be sure to take this drug every day until you feel better."
- "Do not take the drug with tomato-based foods or drinks."
- "Be aware that this drug can cause anxiety and restlessness."
- "Do not crush the drug because it has a delayed release."

Endoscopic Therapies. In the past 15 years, several non-invasive endoscopic procedures have been approved for severe GERD. Two techniques used are the Stretta procedure and endoluminal gastroplication. These nonsurgical methods are becoming more popular and may often replace surgery for GERD when other measures are not effective. Patients who are very obese or have severe symptoms may not be candidates for these procedures.

In the Stretta procedure, the physician applies radiofrequency (RF) energy through the endoscope using needles placed near the gastroesophageal junction. The RF energy decreases vagus nerve activity, thus reducing discomfort for the patient. This nonsurgical procedure has also been approved for patients with Barrett's esophagus (Bulsiewicz & Shaheen, 2011).

In the gastroplication procedure, the physician tightens the LES through the endoscope using sutures near the sphincter. Chart 57-4 outlines discharge instructions for endoscopic therapies.

The advantages of endoscopic therapies compared with surgery include:

- Use of light or moderate sedation (rather than general anesthesia)
- Ambulatory care procedure (rather than an inpatient stay)
- Short procedure (45 minutes versus several hours)
- 1 to 2 days absence from work (rather than 2 to 3 weeks)
- No antibiotics and lower complication rate, including fewer deaths

Surgical Management

A very small percentage of patients with GERD require anti-reflux surgery. It is usually indicated for otherwise healthy patients who have failed to respond to medical treatment or have developed complications related to GERD. Various surgical procedures may be used through conventional open techniques or laparoscope.

Laparoscopic Nissen fundoplication (LNF) is a minimally invasive surgery (MIS) and is the gold standard for surgical management. A discussion of this procedure can be found in the next section (Hiatal Hernia) in the Surgical Management discussion. Patients who have surgery are encouraged to continue following the basic anti-reflux regimen of antacids and nutritional therapy because the rate of recurrence is high.

HIATAL HERNIA

Hiatal hernias, also called *diaphragmatic hernias*, involve the protrusion of the stomach through the esophageal hiatus of the diaphragm into the chest. The esophageal hiatus is the opening in the diaphragm through which the esophagus passes from the thorax to the abdomen. Most patients with hiatal hernias are asymptomatic, but some may have daily symptoms similar to those with GERD (McCance et al., 2010).

Pathophysiology

The two major types of hiatal hernias are sliding hernias and paraesophageal (rolling) hernias. *Sliding hernias* are the most common type. The esophagogastric junction and a portion of the fundus of the stomach slide upward through the esophageal hiatus into the chest, usually as a result of weakening of the diaphragm (Fig. 57-1). The hernia generally moves freely and slides into and out of the chest during changes in position or intra-abdominal pressure. Although **volvulus** (twisting) and obstruction do occur rarely, the major concern for a sliding hernia is the development of esophageal reflux and its complications (see Gastroesophageal Reflux Disease section earlier in this chapter). The development of reflux is related to chronic exposure of the lower esophageal sphincter (LES) to the low pressure of the thorax, which significantly reduces the effectiveness of the LES. Symptoms associated with decreased LES pressure are worsened by positions that favor reflux, such as bending or lying supine. Coughing, obesity, and ascites also increase reflux symptoms.

With *rolling hernias*, also known as *paraesophageal hernias*, the gastroesophageal junction remains in its normal intra-abdominal location but the fundus (and possibly portions of the stomach's greater curvature) rolls through the esophageal hiatus and into the chest beside the esophagus (see Fig. 57-1). The herniated portion of the stomach may be small or quite large. In rare cases, the stomach completely inverts into the chest. Reflux is not usually present because the LES remains

FIG. 57-1 A comparison of the normal stomach and sliding and paraesophageal (rolling) hiatal hernias.

anchored below the diaphragm. However, the risks for volvulus (twisting), obstruction (blockage), and strangulation (stricture) are high. The development of iron deficiency anemia is common because slow bleeding from venous obstruction causes the gastric mucosa to become engorged and ooze. Significant bleeding or hemorrhage is rare.

Rolling hernias are thought to develop from an anatomic defect occurring when the stomach is not properly anchored below the diaphragm rather than from muscle weakness. They can also be caused by previous esophageal surgeries, including sliding hernia repair.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Ask the patient if he or she has heartburn, regurgitation (backward flow of food into the throat), pain, dysphagia (difficulty swallowing), and eructation (belching). Assess general physical appearance and nutritional status. Note the location, onset, duration, and quality of pain, as well as factors that relieve it or make it worse. The primary symptoms of sliding hiatal hernias are associated with reflux. Auscultate the lungs because pulmonary symptoms similar to asthma may be triggered by episodes of aspiration, particularly at night. A detailed history is crucial in attempting to differentiate angina from noncardiac chest pain caused by reflux. Symptoms resulting from hiatal hernia typically worsen after a meal or when the patient is in a supine position (Chart 57-5).

In those with rolling hernias, assess for symptoms related to the stretching or displacement of thoracic contents by the hernia. Patients may report a feeling of fullness after eating or have breathlessness or a feeling of suffocation if the hernia interferes with breathing. Some may experience chest pain associated with reflux that mimics angina.

The *barium swallow study with fluoroscopy* is the most specific diagnostic test for identifying hiatal hernia. Rolling

CHART 57-5 KEY FEATURES

Hiatal Hernias

Sliding Hiatal Hernias

- Heartburn
- Regurgitation
- Chest pain
- Dysphagia
- Belching

Paraesophageal Hernias

- Feeling of fullness after eating
- Breathlessness after eating
- Feeling of suffocation
- Chest pain that mimics angina
- Worsening of manifestations in a recumbent position

hernias are usually clearly visible, and sliding hernias can often be observed when the patient moves through a series of positions that increase intra-abdominal pressure. To visualize sliding hernias, an esophagogastroduodenoscopy (EGD) may be performed to view both the esophagus and gastric lining (see Chapter 55).

INTERVENTIONS

Patients with hiatal hernias may be managed either medically or surgically. Collaborative care is based on the severity of symptoms and the risk for serious complications. Sliding

! NURSING SAFETY PRIORITY

Action Alert

The most important role of the nurse in caring for a patient with a hiatal hernia is health teaching. Encourage the patient to avoid eating in the late evening and to avoid foods associated with reflux. Teach the patient and family that the patient should follow a restricted diet and exercise to reduce body weight if overweight. Obesity increases intra-abdominal pressure and worsens both the hernia and the symptoms of reflux. Teach about positioning, including:

- Sleep at night with the head of the bed elevated 6 inches
- Remain upright for several hours after eating
- Avoid straining or excessive vigorous exercise
- Refrain from wearing clothing that is tight or constrictive around the abdomen

hiatal hernias are most commonly treated medically. Large rolling hernias can become strangulated or obstructed. Therefore early surgical repair is preferred.

Nonsurgical Management

The collaborative interventions for patients with hiatal hernia are similar to those for GERD and include drug therapy, nutrition therapy, and lifestyle changes. The health care provider typically prescribes antacids and histamine receptor antagonists, such as ranitidine (Zantac), in an attempt to control reflux and its symptoms. Nutrition therapy is also important and follows the guidelines discussed earlier for GERD.

Surgical Management

Surgery may be required when the risk for complications is high or when damage from chronic reflux becomes severe.

Preoperative Care. If the surgery is not urgent, the surgeon instructs patients who are overweight to lose weight before surgery. They are also advised to quit or significantly reduce smoking. As part of preoperative teaching, reinforce the surgeon's instructions and prepare the patient for what to expect after surgery.

Laparoscopic Nissen fundoplication (LNF) is the minimally invasive surgery commonly used for hiatal hernia repair. Complications after LNF occur less frequently compared with those seen in patients having the more traditional open surgical approach.

A small percentage of patients are not candidates for LNF and therefore require a conventional open fundoplication. Teach patients having this procedure what to expect after surgery. For example, for the trans-thoracic surgical approach, teach the patient about chest tubes. Inform the patient that a nasogastric tube will be inserted during surgery and will remain in place for several days. Oral intake is started gradually with clear liquids after peristalsis is re-established or to stimulate peristalsis. Instruct the patient how to deep breathe and use the incentive spirometer. These measures are essential to prevent postoperative respiratory complications. The high incision makes deep breathing extremely painful. Teach the patient about postoperative pain, and assure him or her that adequate postoperative analgesic will be given promptly. Pain levels must be continuously monitored.

Operative Procedures. Although several hiatal hernia repair procedures are used, each involves reinforcement of the lower esophageal sphincter (LES) by fundoplication. The surgeon wraps a portion of the stomach fundus around the distal esophagus to anchor it and reinforce the LES (Fig. 57-2). In laparoscopic surgery, the repair is performed through several ½-inch incisions in the abdomen. For the conventional open procedure, the surgeon typically uses a high trans-thoracic approach that requires a large chest incision for access to the surgical area.

Postoperative Care. Patients having the LNF procedure are at risk for bleeding and infection, although these problems are not common. *The nursing care priority is to observe for these complications and provide health teaching as described in Chart 57-6.*

Postoperative care after *conventional open repair* closely follows that required after any esophageal surgery. Complications after open surgery are more common and potentially serious. Carefully assess for complications of open

FIG. 57-2 Open surgical approach for Nissen fundoplication for gastroesophageal reflux disease or hiatal hernia repair.

CHART 57-6 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Postoperative Instructions for Patients Having Laparoscopic Nissen Fundoplication (LNF)

- Stay on a soft diet for about a week, including mashed potatoes, puddings, custard, and milkshakes; avoid carbonated beverages, tough foods, and raw vegetables that are difficult to swallow.
- Remain on antireflux medications as prescribed for at least a month.
- Do not drive for a week after surgery; do not drive if taking opioid pain medication.
- Walk every day, but do not do any heavy lifting.
- Remove small dressings 2 days after surgery, and shower; do not remove Steri-Strips until 10 days after surgery.
- Wash incisions with soap and water, rinse well, and pat dry; report any redness or drainage from the incisions to your surgeon.
- Report fever above 101° F (38.3° C), nausea, vomiting, or uncontrollable bloating or pain. For patients older than 65 years, report elevations above 100° F (37.8° C).
- Schedule an appointment for follow-up with your surgeon in 3 to 4 weeks.

fundoplication surgery, described next, and report any complications to the health care provider (Chart 57-7).

! NURSING SAFETY PRIORITY

Action Alert

The primary focus of care after conventional surgery for a hiatal hernia repair is the prevention of respiratory complications. Elevate the head of the patient's bed at least 30 degrees to lower the diaphragm and promote lung expansion. Assist the patient out of bed and begin ambulation as soon as possible. Be sure to support the incision during coughing to reduce pain and to prevent excessive strain on the suture line, especially with obese patients.

CHART 57-7 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE**Assessment of Postoperative Complications Related to Fundoplication Procedures**

COMPLICATION	ASSESSMENT FINDINGS
Temporary dysphagia	The patient has difficulty swallowing when oral feeding begins.
Gas bloat syndrome	The patient has difficulty belching to relieve distention.
Atelectasis, pneumonia	The patient experiences dyspnea, chest pain, or fever.
Obstructed nasogastric tube	The patient experiences nausea, vomiting, or abdominal distention. The nasogastric tube does not drain.

Incentive spirometry and deep breathing are routinely used after surgery to maintain patency of the airways and lung expansion. Adequate pain control with analgesics is essential for postoperative deep breathing and coughing. Patients with a smoking history or chronic airway limitation (e.g., chronic obstructive pulmonary disease, asthma) require more aggressive management by the respiratory therapist to prevent atelectasis and pneumonia. Patients with large hiatal hernias are at the highest risk for developing respiratory complications.

The patient having the conventional surgery usually has a large-bore (diameter) nasogastric (NG) tube to prevent the fundoplication wrap from becoming too tight around the esophagus. Initially the NG drainage should be dark brown with old blood but should become normal yellowish green within the first 8 hours after surgery. Check the NG tube every 4 to 8 hours for proper placement in the stomach. The tube should be properly anchored so it is not displaced, because re-insertion could perforate the fundoplication. Follow the surgeon's requests for care of the patient with an NG tube.

Monitor patency of the NG tube to keep the stomach decompressed. This prevents retching or vomiting, which can strain or rupture the stomach sutures. The NG tube is irritating. Therefore provide frequent oral hygiene to increase comfort. Assess the patient's hydration status regularly, including accurate measures of intake and output. Adequate fluid replacement helps thin respiratory secretions.

After open fundoplication, the patient may begin clear fluids when peristalsis is re-established or in an effort to stimulate peristalsis. Some surgeons create a temporary gastrostomy for feeding to allow for undisturbed healing of the repair. The patient gradually progresses to a near-normal diet during the first 4 to 6 weeks. Some foods, especially caffeinated or carbonated beverages and alcohol, are either restricted or eliminated. The food storage area of the stomach is reduced by the surgery, and meals need to be both smaller and more frequent.

Carefully supervise the first oral feedings because temporary dysphagia is common. Continuous dysphagia usually indicates that the fundoplication is too tight, and dilation may be required.

Another common complication of this surgery is the **gas bloat syndrome**, in which patients are unable to voluntarily

eructate (belch). The syndrome is usually temporary but may persist, even in those who have the laparoscopic approach. Teach the patient to avoid drinking carbonated beverages and to avoid eating gas-producing foods (especially high-fat foods), chewing gum, and drinking with a straw.

Other patients have **aerophagia** (air swallowing) from attempting to reverse or clear acid reflux. Teach them to relax consciously before and after meals, to eat and drink slowly, and to chew all food thoroughly. Air in the stomach that cannot be removed by belching can be extremely uncomfortable. Frequent position changes and ambulation are often effective interventions for eliminating air from the GI tract. If gas pain is still present, patients are taught to take simethicone, 80 mg four times daily as needed. Be sure to remind the patient to crush and dissolve the medication in water before taking.

Community-Based Care

Patients undergoing one of the open surgical repairs require activity restrictions during the 3- to 6-week postoperative recovery period. For laparoscopic surgery, activity is typically restricted for a shorter time and the patient can return to his or her usual lifestyle more quickly, usually in a few days to a week.

For long-term management, teach the patient and family about appropriate nutritional modifications. The use of stool softeners or bulk laxatives is recommended for the first postoperative weeks until healing is complete. Instruct the patient to avoid straining and to prevent constipation. Teach him or her to inspect the healing incision daily and to notify the health care provider if swelling, redness, tenderness, discharge, or fever occurs. Advise the patient to avoid contact with people with respiratory infections and to contact the health care provider if symptoms of a cold or influenza develop. Continuous coughing can cause the incision or the fundoplication to dehiscence ("break open"). Advise the patient to avoid smoking. Provide information about smoking-cessation methods, if appropriate.

If needed, collaborate with the dietitian to educate the patient and family about dietary changes. Encourage the patient to eat smaller and more frequent meals. Few ongoing diet restrictions are needed, but overeating or eating the wrong types of foods can produce discomfort if the patient cannot belch. Instruct the patient to report reflux symptoms to the health care provider.

Although severe surgical complications are rare, conditions such as gas bloat syndrome and dysphagia may continue. Prepare the patient for these problems and for the potential that reflux may not be completely controlled or may occur again. Although surgery controls the condition, a cure is rare and lifestyle modifications need to be ongoing.

ESOPHAGEAL TUMORS

Pathophysiology

Although esophageal tumors can be benign, most are usually malignant (cancerous) and the majority arise from the epithelium. Squamous cell carcinomas of the esophagus are located in the upper two thirds of the esophagus. Adenocarcinomas are more commonly found in the distal third and at the gastroesophageal junction and are now the most common type of esophageal cancer (McCance et al., 2010). Esophageal

tumors grow rapidly because there is no serosal layer to limit their extension. Because the esophageal mucosa is richly supplied with lymph tissue, there is early spread of tumors to lymph nodes. Esophageal tumors can protrude into the esophageal lumen and can cause thickening or invade deeply into surrounding tissue. In rare cases, the lesion may be confined to the epithelial layer (in situ). In most cases, the tumor is large and well established on diagnosis. More than half of esophageal cancers **metastasize** (spread throughout the body).

The two primary risk factors associated with the development of squamous cell carcinoma of the esophagus are tobacco use and heavy alcohol intake. The compounds in tobacco smoke may be responsible for the genetic mutations seen in many esophageal tumors. A smoker has two to six times the risk for eventually developing esophageal cancer than does a nonsmoker (American Cancer Society [ACS], 2010). Many alcoholic beverages contain potent carcinogens that may be responsible for the development of esophageal tumors. Smoking and excessive alcohol can act together in causing esophageal cancer. Obesity and malnutrition are also risk factors.

Long-term, untreated *gastroesophageal reflux disease (GERD)* can lead to esophageal adenocarcinoma. For people with Barrett's esophagus, the risk for developing esophageal cancer also greatly increases. **Barrett's esophagus** results from exposure to acid and pepsin, which leads to the replacement of normal distal squamous mucosa with columnar epithelium as a response to tissue injury. This tissue undergoes

dysplasia (cell appearance changes) and, ultimately, becomes cancerous. In parts of the world where esophageal cancer is more common, the incidence of squamous cell carcinoma appears to be linked to high levels of nitrosamines (which are found in pickled and fermented foods) and foods high in nitrate. Diets that are chronically deficient in fresh fruits and vegetables have also been implicated in the development of squamous cell carcinoma.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Assess for risk factors related to the development or symptoms of esophageal cancer, such as racial and ethnic background, age, gender, history of alcohol consumption, tobacco use, dietary habits, and other esophageal problems (e.g., dysphagia, reflux). Esophageal cancer (squamous cell) occurs most often in middle-aged and older adults and tends to occur more in black males, although the exact cause for racial differences is not known. White males are more predisposed to esophageal adenocarcinoma. Ask the patient about consumption of smoked pickled foods, changes in appetite, changes in taste, or weight loss. *Cancer of the esophagus is a silent tumor in its early stages, with few observable signs. By the time the tumor causes symptoms, it usually has spread extensively.*

Physical Assessment/Clinical Manifestations

Dysphagia (difficulty swallowing) is the most common symptom of esophageal cancer, but it may not be present until the esophageal opening has gotten much smaller. Dysphagia is both persistent and progressive when **stricture** (narrowing) occurs. It is initially associated with swallowing solids, particularly meat, and then progresses rapidly over a period of weeks or months to difficulty in swallowing soft foods and liquids. Late in the disease, even saliva can induce choking. Patients usually report a sensation that food is sticking in the throat or in the substernal area. Careful assessment of the dysphagia is an important part of the diagnosis because dysphagia associated with other esophageal disorders is not usually continuous. Weight loss often accompanies dysphagia and can be more than 20 pounds over several months.

Odynophagia (painful swallowing) is reported by many patients as a steady, dull, substernal pain that may radiate. It occurs most often when the patient drinks cold liquids. The presence of severe or persistent pain often indicates tumor invasion of the mediastinal structures. Assess for regurgitation, vomiting, **halitosis** (foul breath), and chronic hiccups, which often accompany advanced disease. In most patients, pulmonary problems develop. Assess for chronic cough, increased secretions, and a history of recent infections. Tumors in the upper esophagus may involve the larynx and thus cause hoarseness. **Chart 57-8** summarizes the common clinical manifestations of esophageal tumors.

Psychosocial Assessment

The diagnosis of esophageal cancer causes high patient anxiety. The disease is accompanied by distressing symptoms and is often terminal. The fear of choking can place unusual

GENETIC/GENOMIC CONSIDERATIONS

Certain genetic factors may have a role in the development of esophageal cancers. It is thought that these cancers result from mutations in tumor suppressor genes. Tumor suppressor genes are normal genes that control cell growth and division. When this type of gene is mutated and does not work properly, cells are unable to stop growing and dividing and tumors can result. (See **Chapter 23** for a more complete discussion.)

Overexpression and mutations of the *Tp53*, *Tp16*, and *Tp17* tumor suppressor genes have been found in people with esophageal cancer (Nussbaum et al., 2007). In addition, the presence of the mutated *Tp53* gene may be an indication of advanced disease, especially in patients with adenocarcinomas.

Overexpression of *cyclin D1*, a protein that promotes cell growth and division, has also been found in patients with esophageal squamous cell cancers. Cyclins are products of oncogenes, which are normal genes involved in cell division and are controlled by suppressor genes. Prolonged exposure to carcinogens, such as tobacco, can cause oncogenes to escape the control of suppressor genes, leading to overexpression of cyclins and uncontrolled cell growth (cancer).

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A client has a history of gastroesophageal reflux disease and is worried about getting cancer of the esophagus. What health teaching about ways to decrease the risk for cancer will the nurse provide?

Select all that apply.

- "Consider dieting and exercise because you are overweight."
- "Drink a glass of red wine every night because it provides antioxidants."
- "Join a good smoking-cessation program as soon as possible."
- "Eat plenty of fruits and vegetables instead of so much junk food."
- "Sleep with two pillows every night to prevent reflux when sleeping."

stress, especially at mealtimes. The loss of pleasure and social aspects of eating may affect relationships with family and friends. Assess the patient's response to the diagnosis and prognosis. Ask about his or her usual coping strengths and resources. Assess the impact of the disease on the patient's usual daily activity routine. Determine the availability of support systems and the potential financial impact of the disease and its treatment. Refer the patient and family members to psychological counseling, pastoral care, and/or the social worker or case manager as needed. [Chapter 9](#) describes end-of-life care for patients in the terminal stage of the disease.

Diagnostic Assessment

A barium swallow study with fluoroscopy is usually the first diagnostic test requested to evaluate dysphagia. In a barium swallow, the margins of a tumor may be seen. The definitive diagnosis of esophageal cancer is made by *esophageal ultrasound (EUS)* with fine needle aspiration to examine the tumor tissue. An esophagogastroduodenoscopy (EGD) may also be performed to inspect the esophagus and obtain tissue specimens for cell studies and disease staging. A complete cancer staging workup is performed to determine the extent of the disease and plan appropriate therapy.

Positron emission tomography (PET) may identify metastatic disease with more accuracy than a computed tomography (CT) scan. PET can also help evaluate response to chemotherapy to treat the cancer.

ANALYSIS

The most specific common problem for patients with esophageal cancer is *decreased nutritional intake related to impaired swallowing and possible metastasis*. Many patients with cancer also have pain and are fearful due to the diagnosis of cancer. [Chapter 24](#) describes problems that are typically seen with any patient with cancer.

PLANNING AND IMPLEMENTATION

Promoting Nutrition

Planning: Expected Outcomes. The major concern for a patient with esophageal cancer is weight loss secondary to dysphagia. Therefore he or she is expected to maintain adequate nutrient intake and weight either orally or via an alternative method.

Interventions. Interventions to maintain or improve nutritional status focus on treatments that remove or shrink the obstructive tumor. Methods to reduce the effects of

treatment that can impact nutrition are also a priority. Surgery is the most definitive intervention for esophageal cancer.

Nonsurgical treatment options for cancer of the esophagus that can assist in both disease and nutrition management include:

- Nutrition therapy
- Swallowing therapy
- Chemotherapy
- Radiation therapy
- Chemoradiation
- Targeted therapies
- Photodynamic therapy
- Esophageal dilation
- Endoscopic therapies

Nonsurgical Management. The treatment of esophageal cancer often involves a combination of the therapies just mentioned. Patients with cancer of the esophagus experience many physical problems, and symptom management becomes essential.

The purpose of nutrition therapy is to administer food and fluids to support the patient who is malnourished or at high risk for becoming malnourished. Conduct a screening assessment to provide information about the patient's nutritional status. The dietitian determines the caloric needs of the patient to meet daily requirements. Be sure the patient is weighed daily. Careful positioning is essential for a patient who is experiencing frequent reflux or who has tubes to keep the esophagus patent. Teach the patient to remain upright for several hours after meals and to avoid lying completely flat. Remind unlicensed assistive personnel (UAP) and other health care team members to keep the head of the bed elevated to a 30-degree angle or more to prevent reflux.

Semisoft foods and thickened liquids are preferred because they are easier to swallow. Record the amount of food and fluid intake every day to monitor progress in meeting desired nutritional outcomes. Liquid nutritional supplements (e.g., Boost, Ensure) are used between feedings to increase caloric intake. Ongoing efforts are made to preserve the ability to swallow, but enteral feedings (tube feedings) may be needed temporarily when dysphagia is severe. In patients with complete esophageal obstruction or life-threatening fistulas, the surgeon may create a gastrostomy or jejunostomy for feeding. Encourage the patient and family to meet with the dietitian for diet teaching and planning. [Chapter 63](#) describes care for patients receiving enteral feeding.

Collaborate with the speech-language pathologist (SLP) to assist the patient with oral exercises to improve swallowing (*swallowing therapy*). Ask the patient to suck on a lollipop to enhance tongue strength. Teach the patient to reach for food particles on the lips or chin using the tongue. In preparation

CHART 57-8 KEY FEATURES

Esophageal Tumors

- Persistent and progressive dysphagia (most common feature)
- Feeling of food sticking in the throat
- Odynophagia (painful swallowing)
- Severe, persistent chest or abdominal pain or discomfort
- Regurgitation
- Chronic cough with increasing secretions
- Hoarseness
- Anorexia
- Nausea and vomiting
- Weight loss (often more than 20 pounds)
- Changes in bowel habits (diarrhea, constipation, bleeding)

! NURSING SAFETY PRIORITY

Critical Rescue

When the patient with an esophageal tumor is eating or drinking, monitor for signs and symptoms of aspiration, such as choking or coughing! Food aspiration can cause airway obstruction, pneumonia, or both, especially in older adults. In coordination with the SLP, teach family members and caregivers how to feed the patient, if needed. Teach them how to monitor for aspiration and implement appropriate measures if choking occurs.

for swallowing, remind the patient to position the head in forward flexion (chin tuck). Then tell him or her to place food at the back of the mouth. Monitor him or her for sealing of the lips and for tongue movements while eating. Check for pocketing of food in the cheeks after swallowing.

The use of *chemotherapy* in the treatment of esophageal cancer has been only moderately effective. It can be given as a primary treatment if the patient is not a candidate for surgery or for palliation (control of symptoms). In most cases, though, chemotherapy is given in combination with radiation therapy to provide the patient the best chance of cure. The rationale for this approach is to shrink the tumor and eliminate any other tumor that may be in the local lymph nodes, improving the odds for a complete surgical resection. The two most commonly used chemotherapeutic agents have traditionally been 5-fluorouracil (5-FU) and a platinum-based agent, such as cisplatin (Platinol), carboplatin (Paraplatin), and oxaliplatin (Eloxatin). These drugs make the tumor cells more sensitive to the effects of radiation. Other drugs have been tried successfully for treatment of esophageal cancer, including paclitaxel (Taxol), docetaxel (Taxotere), and irinotecan (Camptosar). Because chemotherapeutic drugs affect healthy cells as well as cancer cells, they have many side effects that cause discomfort to the patient. [Chapter 24](#) describes chemotherapy in detail and discusses the role of the nurse in caring for patients receiving these drugs.

Radiation therapy to manage esophageal cancer is only moderately effective and can be used alone or in combination with other treatments. Radiation alone can provide palliation of symptoms by shrinking the tumor. It is contraindicated for patients with tracheoesophageal fistula, mediastinitis, mediastinal hemorrhage, or infiltration of the cancer to the trachea or bronchus. Normal esophageal tissue is very sensitive to the effects of radiation. Although high doses of radiation demonstrate the best results for tumor shrinkage, esophageal stricture or stenosis can result in many patients, which then requires esophageal dilation. [Chapter 24](#) describes radiation methods and the general nursing care for the patient having radiation therapy.

Chemoradiation is a treatment for esophageal cancer that involves the use of chemotherapy at the same time as radiation therapy. One cycle of chemotherapy is given during the first week of radiation and another is delivered during the fifth week of radiation. Additional drug cycles are given after radiation therapy is complete.

The newest addition to the treatment of esophageal cancer is targeted therapies, used in combination with radiation and chemotherapy. Unlike chemotherapy, these therapies interfere with cancer cell growth in a variety of ways with less impact on healthy cells. Many of these drugs focus on proteins that are involved in signaling cells when to grow and divide. A key to success with targeted therapy is that the cancer cells must overexpress the targeted protein. Thus each patient's cancer cells are first examined for the overexpression to determine if targeted therapy is appropriate and which drug to use. A number of agents have been approved for other GI cancers but are still used experimentally for esophageal cancer. For example, cetuximab (Erbix) is a monoclonal antibody that targets the epithelial growth factor receptor (EGFR) on the surface of cancer cells. EGFR is often overexpressed in esophageal tumors. Other targeted therapies, such

as trastuzumab (Herceptin), gefitinib (Iressa), and erlotinib (Tarceva), have also been used. [Chapter 24](#) describes targeted therapies in detail, including nursing implications for patient safety and quality care.

Photodynamic therapy (PDT) was originally used for the treatment of skin cancer but is now used also as a palliative treatment for patients with advanced esophageal cancer who are not candidates for surgery. It may be used also as a cure for patients who have very small, localized tumors. The patient is injected with porfimer sodium (Photofrin), a light-sensitive drug that collects in cancer cells. Two days after the injection, a fiberoptic probe with a light at the tip is threaded into the esophagus through an endoscope. The light activates the Photofrin, destroying only cancer cells. PDT is far less invasive than surgery and is performed on an ambulatory care basis under moderate sedation.

The side effects of Photofrin are rare but include nausea, fever, and constipation. Before the procedure, the patient is given written guidelines concerning photosensitivity measures. Remind the patient to avoid exposure to sunlight for 1 to 3 months. Sunglasses and protective clothing that covers all exposed body areas are essential. The patient may experience chest pain secondary to tissue damage and will require pain relief with opioid analgesics for a short time. Teach the patient to follow a clear liquid diet for 3 to 5 days after the procedure and advance to full liquids as tolerated. Warn the patient that tissue particles may release from the tumor site and be present in the sputum. [Chapter 24](#) describes in detail the health teaching needed to promote patient safety associated with PDT.

Esophageal dilation may be performed as necessary throughout the course of the disease to achieve temporary but immediate relief of dysphagia. It is usually performed on an ambulatory care basis. Dilators are used to tear soft tissue, thereby widening the esophageal lumen (opening). In most cases, malignant tumors can be dilated safely, but perforation remains a significant risk. Large metal stents may be used to keep the esophagus open for longer periods. A stent covered with graft material can be used to seal a perforation. Bacteremia can also occur. To reduce the risk for endocarditis, antibiotics are given. The treatment is repeated as often as needed to preserve the patient's ability to swallow.

When patients are not candidates for surgery or the tumor is too large to remove surgically, laser therapy or electrocoagulation using endoscopy may be performed as a palliative measure. Both of these methods destroy some cancer cells and reduce tumor size to improve swallowing. The procedures are done in ambulatory care settings or same-day surgery centers using moderate sedation.

Surgical Management. The purposes of surgical resection vary from palliation to cure. **Esophagectomy** is the removal of all or part of the esophagus. An **esophagogastrectomy** involves the removal of part of the esophagus and proximal stomach. The remaining stomach may be "pulled up" to take the place of the esophagus, or a section of the jejunum or colon may be placed as a conduit. Conventional open surgical techniques are lengthy and are associated with many complications or death. Fistula formation between the trachea and esophagus, abscess, and respiratory complications are common.

For patients with early-stage cancer, a laparoscopic-assisted **minimally invasive esophagectomy (MIE)** may be

FIG. 57-3 Open surgical approaches to the treatment of esophageal cancer.

performed. However, most patients require the conventional open surgery because of tumor size and metastasis by the time they are diagnosed with the disease.

Preoperative Care. Preoperative preparation for patients undergoing esophagectomy or esophagogastrectomy can be quite extensive, especially before conventional techniques. Advise the patient to stop smoking 2 to 4 weeks before surgery to enhance pulmonary function. Patient preparation may include 5 days to 2 to 3 weeks of nutritional support to decrease the risk for postoperative complications. Ideally this supplementation is given orally, but many patients require tube feeding or parenteral nutrition. Teach the patient and family to monitor the patient's weight and intake and output. A preoperative evaluation may be required to treat dental disease. Teach the patient to use meticulous oral care four times daily to decrease the risk for postoperative infection.

Preoperative nursing care focuses on teaching and on psychological support regarding the surgical procedure and preoperative and postoperative instructions. Teach the patient about:

- The number and sites of all incisions and drains
- The placement of a jejunostomy tube for initial enteral feedings
- The need for chest tubes if the pleural space is entered
- The purpose of the nasogastric tube
- The need for IV infusion

Teach the patient about routines for turning, coughing, deep breathing, and chest physiotherapy. Emphasize the crucial nature of postoperative respiratory care. If colon interposition (resecting a piece of colon and creating an esophagus) is planned, the patient also has a complete bowel preparation before surgery.

The patient facing a serious illness and extensive surgery can be expected to have feelings of grief and anxiety. Encourage the patient to talk about personal feelings and fears, and involve the family or significant others in all preoperative teaching and discussions. A social worker or case manager

can be extremely helpful in providing continuity of care and support to the entire family.

Operative Procedures. In the MIE procedure, the surgeon makes four or five small incisions in the chest and abdomen using a video-assisted thoracoscope and laparoscope. The lower esophagus and gastric fundus are removed. The remaining portion of the esophagus is then anastomosed (reconnected) to the stomach.

For most patients, the surgeon performs an open subtotal or total esophagectomy because tumors are often large and involve distant lymph nodes. For a subtotal (partial) removal, the diseased portion of the esophagus is removed and the cervical portion is anastomosed (connected) to the stomach (Fig. 57-3). A **pyloromyotomy** is done by cutting and suturing the pylorus. Finally, a jejunostomy tube may be placed for postoperative enteral feeding.

For patients with early-stage tumors of the lower third of the esophagus, a transhiatal esophagectomy is the preferred surgical approach. The surgery is performed through an upper midline cervical incision. With this approach, the pleural space is not entered, reducing respiratory complications. For patients with tumors in the upper esophagus, a radical neck dissection and laryngectomy may also be needed if the disease has spread to the larynx. **Chapter 31** discusses the care of patients having these procedures.

The surgeon may perform a **colon interposition** when the tumor involves the stomach or the stomach is otherwise unsuitable for anastomosis. A section of right or left colon is removed and brought up into the thorax to substitute for the esophagus (see Fig. 57-3).

Postoperative Care. The patient requires intensive postoperative care and is at risk for multiple serious complications. The patient having an MIE has the same risk for postoperative complications as one having the open procedure. The advantages of MIE, though, include:

- Less blood loss during surgery; fewer blood transfusions

- Decreased healing and recovery time
- Decreased trauma to the body
- No large incisions
- Less postoperative pain
- Shorter hospital stay (5 to 7 days rather than 7 to 10 days)

! NURSING SAFETY PRIORITY

Action Alert

Respiratory care is the highest postoperative priority for patients having an esophagectomy. For those who had traditional surgery, intubation with mechanical ventilation is needed for at least the first 16 to 24 hours. Pulmonary complications include atelectasis and pneumonia. The risk for postoperative pulmonary complications is increased in the patient who has received preoperative radiation. Once the patient is extubated, begin deep breathing, turning, and coughing every 1 to 2 hours. Assess the patient for decreased breath sounds and shortness of breath every 1 to 2 hours. Provide incisional support and adequate analgesia for effective coughing.

Remind nursing and other staff to keep the patient in a semi-Fowler's or high Fowler's position to support ventilation and prevent reflux. The health care provider prescribes prophylactic antibiotics and supplemental oxygen. *Ensure the patency of the chest tube drainage system, and monitor for changes in the volume or color of the drainage.*

Cardiovascular complications, particularly hypotension during surgery, can occur as a result of pressure placed on the posterior heart and usually respond well to IV fluid administration.

! NURSING SAFETY PRIORITY

Action Alert

Monitor for manifestations of fluid volume overload, particularly in older patients and in those who have undergone lymph node dissection. Assess for edema, crackles in the lungs, and increased jugular venous pressure. In the immediate postoperative phase, the patient is often admitted to the intensive care unit. Critical care nurses assess hemodynamic parameters such as cardiac output, cardiac index, and systemic vascular resistance every 2 hours to monitor for myocardial ischemia. Observe for atrial fibrillation that results from irritation of the vagus nerve during surgery, and manage according to agency protocol.

The patient with poor nutrition or prior radiation or chemotherapy is at risk for infection. For those who undergo more radical surgical procedures, there is a serious risk for leakage at the anastomosis (surgical connection) sites. This situation is especially true with colon interpositions because several sites are stressed by the effects of tension, poor blood supply, and delayed healing. *Mediastinitis* (inflammation of the mediastinum) resulting from an anastomotic leak can lead to fatal sepsis.

Wound management is another major postoperative concern for conventional surgery because the patient typically has multiple incisions and drains. *Provide direct support to the incision during turning and coughing to prevent dehiscence.* Wound infection can occur 4 to 5 days after surgery. Leakage from the site of anastomosis is a dreaded complication that can appear 2 to 10 days after surgery. If an anastomotic leak occurs, all oral intake is discontinued and is not resumed until the site of the leak has healed.

! NURSING SAFETY PRIORITY

Critical Rescue

After esophageal surgery, carefully assess for fever, fluid accumulation, general signs of inflammation, and symptoms of early shock (e.g., tachycardia, tachypnea). Report any of these findings to the surgeon OR Rapid Response Team immediately!

A nasogastric (NG) tube is placed intraoperatively to decompress the stomach to prevent tension on the suture line. Monitor the NG tube for patency, and carefully secure the tube to prevent dislodgment, which can disrupt the sutures at the anastomosis. *Do not irrigate or reposition the NG tube in patients who have undergone esophageal surgery unless requested by the surgeon!* The initial nasogastric drainage is bloody but should change to a greenish yellow color by the end of the first postoperative day. The continued presence of blood may indicate internal bleeding at the suture line. Provide oral hygiene for the patient every 2 to 4 hours while the tube is in place, or delegate and supervise this activity (Chart 57-9).

The nutritional management of the patient who has undergone esophageal surgery is an early postoperative concern. After conventional surgery, on the second postoperative day, initial feedings usually begin through the jejunostomy tube (J tube). The feedings are slowly increased over the next several days. Feeding by this method can be discontinued once the patient is taking adequate oral nutrition. However, some patients may require J-tube feedings for about 1 month if large amounts of residual feeding are aspirated.

Before beginning oral feedings, a cine-esophagram study is performed to detect any anastomotic leaks, strictures, or signs of aspiration. If no leaks are seen, a liquid diet is started. If liquids are well tolerated, the patient's diet is advanced to include semisolid foods and then solid foods.

Place the patient in an upright position, and supervise all initial swallowing efforts. The food storage area of the stomach has been radically decreased, and gravity is the only defense against reflux. *Teach the patient and/or family the importance of the patient eating six to eight small meals per day. Fluids should be taken between, rather than with, meals to*

CHART 57-9 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Managing the Patient with a Nasogastric Tube After Esophageal Surgery

- Check for tube placement every 4 to 8 hours.
- Ensure that the tube is patent (open) and draining; drainage should turn from bloody to yellowish green by the end of the first postoperative day.
- Secure the tube well to prevent dislodgment.
- Do not irrigate or reposition the tube without a physician's request.
- Provide meticulous oral and nasal hygiene every 2 to 4 hours.
- Keep the head of the bed elevated to at least 30 degrees.
- When the patient is permitted to have a small amount of water, place him or her in an upright position and observe for dysphagia (difficulty swallowing).
- Observe for leakage from the anastomosis site, as indicated by fever, fluid accumulation, and manifestations of early shock (tachycardia, tachypnea, altered mental status).

prevent diarrhea. Diarrhea can occur 20 minutes to 2 hours after eating and can be managed with loperamide (Imodium) before meals. The diarrhea is thought to be the result of **vagotomy syndrome**, which develops as a result of interrupted vagal fibers to the abdominal organs during surgery.

Community-Based Care

Patients with esophageal cancer have many challenges to face once they are discharged home. The combination treatment regimens cause long-lasting side effects, such as fatigue and weakness. These complex treatments also require the patient and family to be knowledgeable about symptom management and to know when to report concerns to the health care provider.

Home Care Management

Once the patient is discharged to home, ongoing respiratory care remains a priority. Give the patient and family instructions for ambulation and incentive spirometer use. Encourage the patient to be as active as possible and to avoid excessive bedrest because this can lead to complications of immobility. Teach the family to protect the patient from infection and to contact the health care provider immediately if signs of respiratory infection develop. Patients should stay away from people with infections and avoid large crowds.

Teaching for Self-Management

Remind the patient and family to wash their hands frequently, and teach them to inspect the incisions daily for redness, tenderness, swelling, odor, and discharge because proper wound healing is still a concern at the time of discharge. Instruct them to report a temperature greater than 101° F (38.3° C), or 100° F (37.8° C) for older adults. Prepare written instructions about the signs of anastomosis leakage. *Teach the patient or family to immediately report to the health care provider the presence of fever and a swollen, painful neck incision.*

Nutritional support also remains a concern. Encourage the patient to continue increasing oral feedings as tolerated. Remind him or her to eat small, frequent meals containing high-calorie, high-protein foods that are soft and easily swallowed. Teach the value of using supplemental egg-nogs and milkshakes between meals, and instruct the patient to eat slowly. Lactose-free products should be used if the patient cannot tolerate dairy foods. Patients who have undergone esophageal resection can lose up to 10% of their body weight. Teach the patient to monitor his or her weight at home and to report a weight loss of 5 pounds or more in 1 month. If sufficient oral intake is not possible, the family may need instruction about tube feedings or parenteral nutrition at home.

Emphasize the importance of remaining upright after meals. Dysphagia or odynophagia may recur because of stricture, reflux, or cancer recurrence. These symptoms should be promptly reported to the health care provider. Despite radical surgery, the patient with cancer of the esophagus often still has a terminal illness and a relatively short life expectancy. Emphasis is placed on maximizing quality of life. Realistic planning is important as the patient's condition eventually worsens, and the patient and family are assisted to plan for the future together. Assist family members in exploring formal and informal sources of support. Help the family or significant others arrange for hospice care when it is needed. **Chapter 9** describes end-of-life care, including hospice.

Health Care Resources

Referrals to community or home care organizations assist the family in providing care in the home. The patient may need transportation to the radiation treatment center five times per week for up to 6 weeks. Oncology nursing care may be needed to monitor and evaluate the patient who is receiving chemotherapy at home through venous access devices or portable infusion pumps. Inform the patient and family about the services available through the American Cancer Society (www.cancer.org), including support groups and transportation. Familiarize the family with area hospice services for future planning. Coordinate resource referrals with the case manager or home care agency.

EVALUATION: EXPECTED OUTCOMES

Evaluate the care of the patient with esophageal cancer based on the identified priority patient problems. The major expected outcome is that the patient will be able to consume adequate nutrition and maintain a stable weight.

DECISION-MAKING CHALLENGE

Teamwork and Collaboration; Safety; Evidence-Based Practice

A 58-year-old patient is admitted for a partial esophagectomy. He has a history of alcoholism and says he quit drinking when he found out about his diagnosis. He has not smoked in 35 years. You are assigned to care for the patient after he returns from the postanesthesia care unit (PACU).

1. What is the priority for care for this patient after surgery? What position will you place the patient in and why? Locate one or two sources of current evidence supporting your answer.
2. For what postoperative complications will you monitor, and why could they occur after this surgery?
3. The patient has a nasogastric (NG) tube in place after surgery. What nursing care will you provide for the patient related to the NG tube?
4. The patient's life partner tells you that he is worried that the patient may not be able to return to his job as a family practice physician. How might you respond to his concern?
5. With what members of the health care team might you collaborate and why?

ESOPHAGEAL DIVERTICULA

Diverticula are sacs resulting from the herniation of esophageal mucosa and submucosa into surrounding tissue. They may develop anywhere along the length of the esophagus. No environmental risk factors are known to be involved in their development. The incomplete or late opening of swallowing muscles can cause high pressure in the hypopharynx and lead to *Zenker's diverticula*, the most common form. This type occurs most often in older adults. Patients report dysphagia (difficulty swallowing), regurgitation (reflux), nocturnal cough, and halitosis (bad breath). They can also be at risk for perforation because the mucosa is without the protection of the normal esophageal muscle layer.

Esophageal diverticula are diagnosed most often by esophagogastroduodenoscopy (EGD). This procedure must be performed with strict care because of the risk for perforation. Nutrition therapy and positioning are the major interventions for controlling symptoms related to diverticula. Collaborate with the dietitian to assist the patient in exploring variations in the size and frequency of meals and in food

texture and consistency. Semisoft foods and smaller meals are often best tolerated and may reduce or relieve the symptoms of pressure and reflux. Nocturnal reflux associated with diverticula is managed by teaching the patient to sleep with the head of the bed elevated and to avoid the supine position for at least 2 hours after eating. Advise the patient to avoid vigorous exercise after meals. Teach him or her to avoid restrictive clothing and frequent stooping or bending.

Surgical management is aimed at removing the diverticula. Postoperatively, the patient is NPO for several days to promote healing. During that period, the patient receives IV fluids for hydration, tube feedings, and then oral fluid and food. Provide pain relief measures, and monitor for complications such as bleeding or perforation. *A nasogastric (NG) tube is placed during surgery for decompression and is not irrigated or repositioned unless specifically requested by the surgeon.*

Community-based care includes teaching the patient and family about:

- Nutritional therapy
- Positioning guidelines to prevent reflux
- Warning signs of complications, such as bleeding or infection

ESOPHAGEAL TRAUMA

Trauma to the esophagus can result from blunt injuries, chemical burns, surgery or endoscopy, or the stress of continuous severe vomiting (Table 57-2). Trauma may affect the esophagus directly, impairing swallowing and nutrition, or it may create problems in related structures such as the lungs or mediastinum. The incidence of most forms of esophageal trauma is low in adults. When excessive force is exerted on the esophageal mucosa, it may perforate or rupture, allowing

TABLE 57-2 COMMON CAUSES OF ESOPHAGEAL PERFORATION

• Straining	• Instrument or tubes
• Seizures	• Chemical injury
• Trauma	• Complications of esophageal surgery
• Foreign objects	• Ulcers

the caustic acid secretions to enter the mediastinal cavity. These tears are associated with a high mortality rate related to shock, respiratory impairment, or sepsis.

Chemical injury is usually a result of the accidental or intentional ingestion of caustic substances. The damage to the mouth and esophagus is rapid and severe. Acid burns tend to affect the superficial mucosal lining, whereas alkaline substances cause deeper penetrating injuries. Strong alkalis can cause full perforation of the esophagus within 1 minute. Additional problems may include aspiration pneumonia and hemorrhage. Esophageal strictures may develop as scar tissue forms.

Patients with esophageal trauma are initially evaluated and treated in the emergency department. Assessment focuses on the nature of the injury and the circumstances surrounding it. *Assess for airway patency, breathing, chest pain, dysphagia, vomiting, and bleeding as the priorities for patient care.* If the risk for extending the damage is not excessive, an x-ray or endoscopic study may be requested to evaluate tears or perforation. A CT scan of the chest can be done to assess for the presence of mediastinal air.

After the injury, keep the patient NPO to prevent further leakage of esophageal secretions. Esophageal and gastric suction can be used for drainage and to rest the esophagus. Esophageal rest is maintained for more than a week after injury to allow for initial healing of the mucosa. Total parenteral nutrition (TPN) is prescribed to provide calories and protein for wound healing while the patient is not eating.

To prevent sepsis, the health care provider prescribes broad-spectrum antibiotics. High-dose corticosteroids may be administered to suppress inflammation and prevent strictures (esophageal narrowing). In addition, opioid and non-opioid analgesics are prescribed for pain management. When caustic burns involve the mouth, topical agents such as lidocaine (Xylocaine Viscous) may be used for analgesia and local anti-inflammatory action.

If nonsurgical management is not effective in healing traumatized esophageal tissue, the patient may need surgery to remove the damaged tissue. Those with severe injuries may require resection of part of the esophagus with a gastric pull-through and repositioning or replacement by a bowel segment.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient has inadequate digestion and nutrition as a result of chronic esophageal problems?

- Dysphagia (difficulty swallowing)
- Odynophagia (painful swallowing)
- Dyspepsia (indigestion or “heartburn”)
- Regurgitation (reflux)
- Eructation (belching)
- Chronic cough
- Choking
- Halitosis (foul breath)
- Weight loss

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate digestion and nutrition as a result of chronic esophageal problems?

Perform and interpret focused physical findings, including:

- Assess ability to chew and swallow food.
- Assess chest pain (dyspepsia) for quality, location, and intensity.
- Assess body weight change.
- Auscultate lungs.
- Assess readiness to learn.

Respond by:

- Providing semi-solid or thickened liquids if solid foods cannot be swallowed comfortably
- Collaborating with the dietitian and occupational therapist (OT) for swallowing evaluation and training
- Monitoring for aspiration of secretions or food

NURSING CONCEPT REVIEW—cont'd

- Teaching lifestyle changes, such as foods to avoid, smoking and alcohol cessation, weight reduction (if obese), and importance of drug therapy to control symptoms
- Monitoring weight
- Monitoring for increased dysphagia
- Monitor for manifestations of aspiration.
- Observe patient for improvement in GI symptoms.
- Evaluate effectiveness of health teaching.
- Think about what else you might do to promote digestion and nutrition.

On what should you REFLECT?

- Evaluate for rapid weight changes (decrease if obese, and increase if severe weight loss has occurred).

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Consult with the dietitian, patient, and family regarding nutritional restrictions for patients with GERD.
- Collaborate with the health care team for the patient with impaired swallowing and/or limited nutrition.
- Teach the patient and family to recognize the symptoms of dysphagia.
- Remain with the dysphasic patient during meals to prevent or assist with choking episodes.

Health Promotion and Maintenance

- Teach the patient oral exercises aimed at improving swallowing.
- Stress the importance of recognizing and controlling reflux through nutrition therapy and medications to avoid further esophageal damage that could lead to Barrett's esophagus.
- Teach the patient to elevate the head of the bed by 6 inches for sleep to prevent nighttime reflux.
- Instruct the patient to sleep in the right side-lying position to minimize the effects of nighttime episodes of reflux.
- Teach the patient with esophageal cancer to monitor his or her body weight and to notify the health care provider for a loss of 5 pounds or greater within 1 month.
- Teach the patient to avoid alcoholic beverages, smoking, and other substances as listed in [Chart 57-2](#) because they lead to increased gastroesophageal reflux.
- Teach the patient to prevent gas bloat syndrome by avoiding drinking carbonated beverages, eating gas-producing foods, chewing gum, and drinking with a straw.
- Review postprocedure instructions for patients having endoscopic therapies for GERD as outlined in [Chart 57-4](#).

Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety regarding the diagnosis of esophageal cancer and related treatment regimen of surgery, chemotherapy, and radiation.
- Explain all procedures, restrictions, drug therapy, and follow-up care to the patient and family.
- Refer the patient or family members to psychological counseling, hospice, pastoral care, and the case manager as needed.

Physiological Integrity

- For patients with GERD, teach the importance of strict adherence to antireflux agents in preventing esophageal damage (see [Chart 57-3](#)).
- Be aware that laparoscopic Nissen fundoplication (LNF) is the most common surgical procedure for patients with GERD and hiatal hernia.
- Assess for complications and provide postoperative care for patients having the LNF procedure, as described in [Charts 57-6 and 57-7](#).
- Be sure to frequently monitor the nutritional status of the patient with esophageal cancer.
- Teach the patient having open conventional esophageal surgery about incisions, drains, and jejunostomy tube placement before he or she undergoes surgery for esophageal cancer.
- For the patient with a nasogastric (NG) tube, check the NG tube every 4 to 8 hours for proper placement and anchorage; follow guidelines as outlined in [Chart 57-9](#).
- Assess the patient after esophageal surgery for pulmonary and cardiac complications of surgery, and report changes to the health care provider.
- Assess patients for key features of esophageal tumors as listed in [Chart 57-8](#).

CHAPTER

58

Care of Patients with Stomach Disorders

Donna D. Ignatavicius

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Describe the importance of collaborating with members of the health care team when caring for patients with stomach disorders.
2. Identify community resources for patients with gastric disorders.

Health Promotion and Maintenance

3. Develop a teaching plan for patients about complementary and alternative therapies that have been used to help manage gastritis and peptic ulcer disease (PUD).
4. Plan interventions to promote GI health and prevent gastritis.

Psychosocial Integrity

5. Identify the need for end-of-life care for patients with advanced gastric cancer.

Physiological Integrity

6. Compare etiologies and assessment findings of acute and chronic gastritis.

7. Identify risk factors for gastritis.
8. Compare and contrast assessment findings associated with gastric and duodenal ulcers.
9. Identify the most common medical complications that can result from PUD.
10. Describe the purpose and adverse effects of drug therapy for gastritis and PUD.
11. Monitor patients with PUD and gastric cancer for signs of upper GI bleeding.
12. Prioritize interventions for patients with upper GI bleeding.
13. Plan individualized care for the patient having gastric surgery.
14. Explain the purpose and procedure for gastric lavage.
15. Evaluate the impact of gastric disorders on the nutrition status of the patient.
16. Develop a preoperative and postoperative plan of care for the patient undergoing gastric surgery.
17. Identify risk factors for gastric cancer.

Although only a few diseases affect the stomach, they can be very serious and in some cases life threatening. The most common disorders include gastritis, peptic ulcer disease, and gastric cancer. Each of these health problems can result in impaired or altered *digestion* and *nutrition*. The stomach is part of the upper GI system that is responsible for a large part of the digestive process. Patient-centered collaborative care

for stomach disorders often includes therapies to meet the patient's *need for adequate nutrition*.

GASTRITIS

Gastritis is the inflammation of gastric mucosa (stomach lining). It can be scattered or localized and can be classified

according to cause, cellular changes, or distribution of the lesions. Gastritis can be erosive (causing ulcers) or non-erosive. Although the mucosal changes that result from *acute* gastritis typically heal after several months, this is not true for *chronic* gastritis.

Pathophysiology

Prostaglandins provide a protective mucosal barrier that prevents the stomach from digesting itself by a process called acid **autodigestion**. If there is a break in the protective barrier, mucosal injury occurs. The resulting injury is worsened by histamine release and vagus nerve stimulation. Hydrochloric acid can then diffuse back into the mucosa and injure small vessels. This back-diffusion causes edema, hemorrhage, and erosion of the stomach's lining. The pathologic changes of gastritis include vascular congestion, edema, acute inflammatory cell infiltration, and degenerative changes in the superficial epithelium of the stomach lining.

Types of Gastritis

Inflammation of the gastric mucosa or submucosa after exposure to local irritants or other cause can result in **acute gastritis**. The early pathologic manifestation of gastritis is a thickened, reddened mucous membrane with prominent **rugae**, or folds. Various degrees of mucosal necrosis and inflammatory reaction occur in acute disease. The diagnosis cannot be based solely on clinical symptoms. Complete regeneration and healing usually occur within a few days. If the stomach muscle is not involved, complete recovery usually occurs with no residual evidence of gastric inflammatory reaction. If the muscle is affected, hemorrhage may occur during an episode of acute gastritis.

Chronic gastritis appears as a patchy, diffuse (spread out) inflammation of the mucosal lining of the stomach. As the disease progresses, the walls and lining of the stomach thin and atrophy. With progressive gastric atrophy from chronic mucosal injury, the function of the parietal (acid-secreting) cells decreases and the source of intrinsic factor is lost. The intrinsic factor is critical for absorption of vitamin B₁₂. When body stores of vitamin B₁₂ are eventually depleted, **pernicious anemia** results. The amount and concentration of acid in stomach secretions gradually decrease until the secretions consist of only mucus and water.

Chronic gastritis is associated with an increased risk for gastric cancer. The persistent inflammation extends deep into the mucosa, causing destruction of the gastric glands and cellular changes. Chronic gastritis may be categorized as type A, type B, or atrophic.

Type A (nonerosive) chronic gastritis refers to an inflammation of the glands, as well as the fundus and body of the stomach. Type B chronic gastritis usually affects the glands of the antrum but may involve the entire stomach. In atrophic chronic gastritis, diffuse inflammation and destruction of deeply located glands accompany the condition. Chronic atrophic gastritis affects all layers of the stomach, thus decreasing the number of cells. The muscle thickens, and inflammation is present. Chronic atrophic gastritis is characterized by total loss of fundal glands, minimal inflammation, thinning of the gastric mucosa, and intestinal metaplasia (abnormal tissue development). These cellular changes can lead to peptic ulcer disease (PUD) and gastric cancer (McCance et al., 2010).

Etiology and Genetic Risk

Acute Gastritis. The onset of infection with *Helicobacter pylori* can result in acute gastritis. *H. pylori* is a gram-negative bacterium that penetrates the mucosal gel layer of the gastric epithelium. Although less common, other forms of bacterial gastritis from organisms such as staphylococci, streptococci, *Escherichia coli*, or salmonella can cause life-threatening problems such as sepsis and extensive tissue necrosis (death).

Long-term NSAID use creates a high risk for acute gastritis. NSAIDs inhibit prostaglandin production in the mucosal barrier. Other risk factors include alcohol, caffeine, and corticosteroids. Acute gastritis is also caused by local irritation from radiation therapy and accidental or intentional ingestion of corrosive substances, including acids or alkalis (e.g., lye and drain cleaners). Emotional stress and acute anxiety may also contribute to gastritis.

Chronic Gastritis. **Type A gastritis** has been associated with the presence of antibodies to parietal cells and intrinsic factor. Therefore an autoimmune cause for this type of gastritis is likely. Parietal cell antibodies have been found in most patients with pernicious anemia and in more than one half of those with type A gastritis. A genetic link to this disease, with an autosomal dominant pattern of inheritance, has been found in the relatives of patients with pernicious anemia (McCance et al., 2010).

The most common form of the disease is **type B gastritis**, caused by *H. pylori* infection. A direct correlation exists between the number of organisms and the degree of cellular abnormality present. The host response to the *H. pylori* infection is activation of lymphocytes and neutrophils. Release of inflammatory cytokines, such as interleukin (IL)-1, IL-8, and tumor necrosis factor (TNF)-alpha, damages the gastric mucosa (McCance et al., 2010).

Chronic local irritation and toxic effects caused by alcohol ingestion, radiation therapy, and smoking have been linked to chronic gastritis. Surgical procedures that involve the pyloric sphincter, such as a pyloroplasty, can lead to gastritis by causing reflux of alkaline secretions into the stomach. Other systemic disorders such as Crohn's disease, graft-versus-host disease, and uremia can also precipitate the development of chronic gastritis.

Atrophic gastritis is a type of chronic gastritis that is seen most often in older adults. It can occur after exposure to toxic substances in the workplace (e.g., benzene, lead, nickel) or *H. pylori* infection, or it can be related to autoimmune factors.

Health Promotion and Maintenance

Gastritis is a very common health problem in the United States. Yet, a balanced diet, regular exercise, and stress-reduction techniques can help prevent it (**Chart 58-1**). A balanced diet includes following the recommendations of the U.S. Department of Agriculture (USDA) and limiting intake of foods and spices that can cause gastric distress, such as caffeine, chocolate, mustard, pepper, and other strong or hot spices. Alcohol and tobacco consumption should also be avoided. Regular exercise maintains peristalsis, which helps prevent gastric contents from irritating the gastric mucosa. Stress-reduction techniques can include aerobic exercise, meditation, reading, and/or yoga, depending on individual preferences. Psychotherapy may also be considered.

Excessive use of aspirin and other NSAIDs should also be avoided. If a family member has *H. pylori* infection or has had

CHART 58-1 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Gastritis Prevention

- Eat a well-balanced diet.
- Avoid drinking excessive amounts of alcoholic beverages.
- Use caution in taking large doses of aspirin, other NSAIDs (e.g., ibuprofen), and corticosteroids.
- Avoid excessive intake of caffeine-containing beverages, especially coffee and tea.
- Be sure that foods and water are safe, to avoid contamination.
- Manage stress levels using complementary and alternative therapies, such as relaxation and meditation techniques.
- Stop smoking.
- Protect yourself against exposure to toxic substances in the workplace, such as lead and nickel.
- Seek medical treatment if you are experiencing symptoms of esophageal reflux (see Chapter 57).

CHART 58-2 KEY FEATURES

Gastritis

Acute Gastritis

- Rapid onset of epigastric pain or discomfort
- Nausea and vomiting
- Hematemesis (vomiting blood)
- Gastric hemorrhage
- Dyspepsia (heartburn)
- Anorexia

Chronic Gastritis

- Vague report of epigastric pain that is relieved by food
- Anorexia
- Nausea or vomiting
- Intolerance of fatty and spicy foods
- Pernicious anemia

it in the past, patient testing should be considered. This test can identify the bacteria before they cause gastritis.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Symptoms of *acute* gastritis range from mild to severe. The patient may report epigastric discomfort, anorexia, cramping, nausea, and vomiting (Chart 58-2). Assess for abdominal tenderness and bloating, **hematemesis** (vomiting blood), or **melen** (traces of blood in the stool). Symptoms last only a few hours or days and vary with the cause. Aspirin/NSAID-related gastritis may result in **dyspepsia** (heartburn). Gastritis or food poisoning caused by endotoxins, such as staphylococcal endotoxin, has an abrupt onset. Severe nausea and vomiting often occur within 5 hours of ingestion of the contaminated food. *In some cases, gastric hemorrhage is the presenting symptom, which is a life-threatening emergency.*

Chronic gastritis causes few symptoms unless ulceration occurs. Patients may report nausea, vomiting, or upper abdominal discomfort. Periodic epigastric pain may occur after a meal. Some patients have anorexia (see Chart 58-2).

Several blood tests are available to detect *H. pylori* if gastritis or an ulcer is suspected. Examples of these tests are described on p. 1228 in the Peptic Ulcer Disease section of this chapter. One of the most common methods is a blood test to detect IgG or IgM anti-*H. pylori* antibodies.

Esophagogastroduodenoscopy (EGD) via an endoscope with biopsy is the gold standard for diagnosing gastritis. The physician takes a biopsy to establish a definitive diagnosis of the type of gastritis. If lesions are patchy and diffuse, biopsy of several suspicious areas may be necessary to avoid misdiagnosis. A *cytologic examination* of the biopsy specimen is performed to confirm or rule out gastric cancer. Tissue samples can also be taken to detect *H. pylori* using *rapid urease testing*. As the name implies, this test provides quick results unlike the more traditional tissue culture that takes several weeks to determine if the bacteria are present. The results of these tests are more reliable if the patient has discontinued taking antacids for at least a week (Pagana & Pagana, 2010).

INTERVENTIONS

Patients with gastritis are not often seen in the acute care setting unless they have an exacerbation (“flare up”) of acute or chronic gastritis that results in fluid and electrolyte imbalance or bleeding. Collaborative care is directed toward supportive care for relieving the symptoms and removing or reducing the cause of discomfort.

Acute gastritis is treated symptomatically and supportively because the healing process is spontaneous, usually occurring within a few days. When the cause is removed, pain and discomfort usually subside. If bleeding is severe, a blood transfusion may be necessary. Fluid replacement is prescribed for patients with severe fluid loss. Surgery, such as partial gastrectomy, pyloroplasty, and/or vagotomy, may be needed for patients with major bleeding or ulceration. Treatment of *chronic* gastritis varies with the cause. The approach to management includes the elimination of causative agents, treatment of any underlying disease (e.g., uremia, Crohn’s disease), avoidance of toxic substances (e.g., alcohol, tobacco), and health teaching.

Eliminating the causative factors, such as *H. pylori* infection if present, is the primary treatment approach. Drugs and nutritional therapy are also used. In the *acute* phase, the health care provider prescribes drugs that block and buffer gastric acid secretions to relieve pain.

H₂-receptor antagonists, such as famotidine (Pepcid) and nizatidine (Axid), are typically used to block gastric secretions. Sucralfate (Carafate, Sulcrate ) is a *mucosal barrier fortifier*, may also be prescribed. *Antacids* used as buffering agents include aluminum hydroxide combined with magnesium hydroxide (Maalox) and aluminum hydroxide combined with simethicone and magnesium hydroxide (Mylanta). Antisecretory agents (**proton pump inhibitors [PPIs]**) such as omeprazole (Prilosec) or pantoprazole (Protonix) may be prescribed to suppress gastric acid secretion (Chart 58-3).

! NURSING SAFETY PRIORITY

Drug Alert

Teach the patient to monitor for symptom relief and side effects of drugs to treat gastritis and to notify the health care provider of any adverse effects or worsening of gastric distress. The dose, frequency, or type of drug may need to be changed if symptoms of gastric irritation appear or persist. *Remind patients not to take additional over-the-counter (OTC) drugs such as Pepcid AC if they are taking similar prescribed drugs.*

CHART 58-3 COMMON EXAMPLES OF DRUG THERAPY

Peptic Ulcer Disease

DRUG AND USUAL DOSAGE	PURPOSE OF DRUG	NURSING INTERVENTIONS	RATIONALES
Antacids			
Magnesium hydroxide with aluminum hydroxide (Maalox, Mylanta) 50-80 mEq orally 1 hr and 3 hr after meals and at bedtime	Increases pH of gastric contents by deactivating pepsin	Give 2 hr after meals and at bedtime. Use liquid rather than tablets. Do not give other drugs within 1-2 hr of antacids. Assess patients for a history of renal disease. Assess the patient for a history of heart failure. Observe the patient for the side effect of diarrhea. Give 1 hr after meals and at bedtime. Use liquid rather than tablets if palatable. Do not give other drugs within 1-2 hr of antacids. Observe patients for the side effect of constipation. If constipation occurs, consider alternating with magnesium antacid. Use for patients with renal failure.	Hydrogen ion load is high after ingestion of foods. Suspensions are more effective than chewable tablets. Antacids interfere with absorption of other drugs. Hypermagnesemia may result. These antacids have a high sodium content. These antacids contain magnesium, which cannot be excreted by poorly functioning kidneys, thus causing toxicity. Inadequate renal perfusion from heart failure decreases the ability of the kidneys to excrete magnesium, thus causing toxicity. Magnesium often causes diarrhea. Hydrogen ion load is high after ingestion of food. Suspensions are more effective than chewable tablets. Antacids interfere with absorption of other drugs. Aluminum causes constipation, and magnesium has a laxative effect. Aluminum binds with phosphates in the GI tract. This antacid does not contain magnesium.
Aluminum hydroxide (Amphojel) 50-80 mEq orally 1 hr and 3 hr after meals and at bedtime			
H₂ Antagonists			
Ranitidine (Zantac) 150 mg orally twice daily or 300 mg orally at bedtime; 50 mg IV every 6 hr or 8 mg/hr IV (continuous)	Decreases gastric acid secretions by blocking histamine receptors in parietal cells	Give single dose at bedtime for treatment of GI ulcers. NOTE: IV ranitidine may also be given to prevent surgical stress ulcers. NOTE: IV famotidine may also be given to prevent surgical stress ulcers.	Bedtime administration suppresses nocturnal acid production.
Famotidine (Pepcid) 40 mg orally once daily or in two divided doses; 20 mg IV every 12 hr			
Nizatidine (Axid) 150 mg orally twice daily or 300 mg at bedtime			

Continued

CHART 58-3 COMMON EXAMPLES OF DRUG THERAPY

Peptic Ulcer Disease—cont'd

DRUG AND USUAL DOSAGE	PURPOSE OF DRUG	NURSING INTERVENTIONS	RATIONALES
Mucosal Barrier Fortifiers			
Sucralfate (Carafate, Sulcrate) 1 g orally four times daily or 2 g twice daily	Binds with bile acids and pepsin to protect stomach mucosa	Give 1 hr before and 2 hr after meals, and at bedtime. Do not give within 30 min of giving antacids or other drugs.	Food may interfere with drug's adherence to mucosa. Antacids may interfere with effect.
Proton Pump Inhibitors			
Omeprazole (Prilosec, Losec) 20 mg orally twice daily or 40 mg at bedtime	Suppresses H ₂ K-ATPase enzyme system of gastric acid secretion	Have patients take capsule whole; do not crush (unless giving Zegerid, a fast-acting form of the drug). Give single dose at bedtime for ulcer disease.	Delayed-release capsules allow absorption after granules leave the stomach. Bedtime administration suppresses nocturnal acid production.
Lansoprazole (Prevacid) 15 or 30 mg orally at bedtime		Give single dose at bedtime for ulcer disease; do not crush.	Bedtime administration suppresses nocturnal acid production.
Rabeprazole (Aciphex) 20 mg orally once daily		Take after the morning meal. Do not crush capsule.	Drug promotes healing and symptom relief of duodenal ulcers. Drug is a sustained-release capsule.
Pantoprazole (Protonix) 40 mg orally or IV daily for 7-10 days		Do not crush. IV form must be given with filter and in a separate line. Do not give Protonix IV with other IV drugs.	Drug is enteric-coated. Given IV, drug precipitates easily.
Esomeprazole (Nexium) 20 or 40 mg orally daily (or IV daily for 7-10 days)		Give 1 hr before meals. Assess for hepatic impairment. Do not give Nexium IV with other IV drugs.	The IV form is not compatible with most other drugs. Food decreases absorption. Patients with severe hepatic problems need a low dose. The IV form is not compatible with most other drugs.
Prostaglandin Analogs			
Misoprostol (Cytotec) 200 mcg orally four times daily	Decreases gastric secretions and enhances resistance to mucosal injury when patient is taking NSAIDs	Take with food. Avoid magnesium-containing antacids.	Drug protects against NSAID-induced ulcers. Both misoprostol and magnesium-containing antacids can cause diarrhea.
Antimicrobials			
Clarithromycin (Biaxin) 500 mg orally three times daily Amoxicillin (Amoxil) 1 g orally twice daily Tetracycline 500 mg orally four times daily Metronidazole (Flagyl) 250 mg orally three times daily and at bedtime	Treats <i>Helicobacter pylori</i>	Antimicrobials should be given as part of therapy to eradicate <i>H. pylori</i> infection. The selection of the specific drug depends on its effectiveness, side effects, and drug interactions.	<i>H. pylori</i> is a gram-negative bacterium implicated in the development of peptic ulcer disease (PUD).

Patients with *chronic* gastritis may require vitamin B₁₂ for prevention or treatment of pernicious anemia. If *H. pylori* is found, the health care provider treats the infection. Current practice for infection treatment is described on p. 1229 in the discussion of Drug Therapy in the Peptic Ulcer Disease section.

The nurse, health care provider, or pharmacist teaches patients to avoid drugs and other irritants that are associated with gastritis episodes, if possible. These drugs include corticosteroids, erythromycin (E-Mycin, Erythromid ) , and NSAIDs, such as naproxen (Naprosyn) and ibuprofen (Motrin, Advil, Amersol ) , Novo-Profen ) . NSAIDs are also available as OTC drugs and should not be used. Teach patients to read all OTC drug labels because many preparations contain aspirin or other NSAID.

Instruct the patient to limit intake of any foods and spices that cause distress, such as those that contain caffeine or high acid content (e.g., tomato products, citrus juices) or those that are heavily seasoned with strong or hot spices. Bell peppers and onions are also commonly irritating foods. Most patients seem to progress better with a bland, non-spicy diet and smaller, more frequent meals. Alcohol and tobacco should also be avoided.

Assist the patient with various techniques that reduce stress and discomfort, such as progressive relaxation, cutaneous stimulation, guided imagery, and distraction. Other complementary and alternative therapies that have been used are listed in Table 58-1. Chapter 2 describes these therapies in detail.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A client with a recent diagnosis of acute gastritis needs health teaching about nutrition therapy. Which foods and beverages should the nurse teach the client to avoid? **Select all that apply.**

- A. Potatoes
- B. Onions
- C. Apples
- D. Milk
- E. Orange juice
- F. Tomato juice

TABLE 58-1 COMMONLY USED COMPLEMENTARY AND ALTERNATIVE THERAPIES FOR GASTRITIS AND PEPTIC ULCER DISEASE (PUD)

Herbs and Vitamins

- Gamma-linolenic acid (GLA)
- Probiotics
- Vitamin B₁₂
- Bromelain
- Vitamin A
- Vitamin C
- Astragalus
- Barberry
- Chamomile
- Cranberry
- Dandelion

- Ginger
- Green tea
- Licorice
- Slippery elm
- Turmeric
- Yarrow

Homeopathy

- Pulsatilla
- Ipecacuanha
- Carbo vegetabilis
- Nux vomica

PEPTIC ULCER DISEASE

A **peptic ulcer** is a mucosal lesion of the stomach or duodenum. **Peptic ulcer disease (PUD)** results when mucosal defenses become impaired and no longer protect the epithelium from the effects of acid and pepsin.

Pathophysiology

Types of Ulcers

Three types of ulcers may occur: gastric ulcers, duodenal ulcers, and stress ulcers (less common). Most gastric and duodenal ulcers are caused by *H. pylori* infection, which is transmitted via the fecal-oral route and thought to be acquired in childhood. It can also be transmitted from contaminated endoscopic equipment (Pagana & Pagana, 2010). About half of the world's population is infected with the bacterium (Fromm, 2009).

As a response to the bacteria, cytokines, neutrophils, and other substances are activated and cause epithelial cell necrosis. Urease, a substance secreted by the *H. pylori* bacterium, produces ammonia and creates a more alkaline environment (McCance et al., 2010). Hydrogen ions are then released in response to the presence of ammonia and contribute further to mucosal damage. Urease can be detected through laboratory testing to confirm the *H. pylori* infection.

Gastric ulcers usually develop in the antrum of the stomach near acid-secreting mucosa. When a break in the mucosal barrier occurs (such as that caused by *H. pylori* infection), hydrochloric acid injures the epithelium. Gastric ulcers may then result from back-diffusion of acid or dysfunction of the pyloric sphincter (Fig. 58-1). Without normal functioning of the pyloric sphincter, bile refluxes (backs up) into the stomach. This reflux of bile acids may break the integrity of the mucosal barrier and produce hydrogen ion back-diffusion, which leads to mucosal inflammation. Toxic agents and bile then destroy the membrane of the gastric mucosa.

Gastric emptying is often delayed in patients with gastric ulceration. This causes regurgitation of duodenal contents, which worsens the gastric mucosal injury. Decreased blood flow to the gastric mucosa may also alter the defense barrier and thereby allow ulceration to occur. Gastric ulcers are deep and penetrating, and they usually occur on the lesser curvature of the stomach, near the pylorus (Fig. 58-2).

Most *duodenal ulcers* occur in the upper portion of the duodenum. They are deep, sharply demarcated lesions that penetrate through the mucosa and submucosa into the muscularis propria (muscle layer). The floor of the ulcer consists of a necrotic area residing on granulation tissue and surrounded by areas of fibrosis.

The main feature of a duodenal ulcer is high gastric acid secretion, although a wide range of secretory levels is found. In patients with duodenal ulcers, pH levels are low (excess acid) in the duodenum for long periods. Protein-rich meals, calcium, and vagus nerve excitation stimulate acid secretion. Combined with hypersecretion, a rapid emptying of food from the stomach reduces the buffering effect of food and delivers a large acid bolus to the duodenum (see Fig. 58-1). Inhibitory secretory mechanisms and pancreatic secretion may be insufficient to control the acid load.

Many patients with duodenal ulcer disease have confirmed *H. pylori* infection. These bacteria produce substances that

Conditions favoring the development of **gastric ulcers** are normal gastric acid secretion and delayed stomach emptying with *increased diffusion of gastric acid back into the stomach tissues*.

Conditions favoring the development of **duodenal ulcers** are normal diffusion of acid back into stomach tissues with *increased secretion of gastric acid and increased stomach emptying*.

FIG. 58-1 The pathophysiology of peptic ulcer.

damage the mucosa. Urease produced by *H. pylori* breaks down urea into ammonia.

Stress ulcers are acute gastric mucosal lesions occurring after an acute medical crisis or trauma, such as head injury and sepsis. In the patient who is NPO for major surgery, gastritis may lead to **stress ulcers**, which are multiple shallow erosions of the stomach and occasionally the proximal duodenum. Patients who are critically ill, especially those with extensive burns (**Curling's ulcer**), sepsis (ischemic ulcer), or increased intracranial pressure (**Cushing's ulcer**), are also susceptible to these ulcers.

Bleeding caused by gastric erosion is the main manifestation of acute stress ulcers. Multifocal lesions associated with stress ulcers occur in the stomach and proximal duodenum. These lesions begin as areas of ischemia and evolve into erosions

FIG. 58-2 The most common sites for peptic ulcers.

FIG. 58-3 Common causes of upper GI bleeding.

and ulcerations that may progress to massive hemorrhage. Little is known of the exact etiology of stress ulcers. However, in the presence of elevated levels of hydrochloric acid, ischemic areas can progress to erosive gastritis and subsequent ulcerations. Stress ulcers are associated with lengthened hospital stay and increased mortality rates.

Complications of Ulcers

The most common complications of PUD are hemorrhage, perforation, pyloric obstruction, and intractable disease. Hemorrhage is the most serious complication (Fig. 58-3). It

CHART 58-4 KEY FEATURES

Upper GI Bleeding

- Bright red or coffee-ground vomitus (hematemesis)
- Tarry stools or frank (bright red) blood in stools
- Melena (occult blood) (especially in older adults)
- Decreased blood pressure
- Increased weak and thready pulse
- Decreased hemoglobin and hematocrit
- Vertigo
- Acute confusion (in older adults)
- Dizziness
- Syncope

tends to occur more often in patients with *gastric* ulcers and in older adults. Many patients have a second episode of bleeding if underlying infection with *H. pylori* remains untreated or if therapy does not include an H_2 antagonist. With massive bleeding, the patient vomits bright red or coffee-ground blood (**hematemesis**). Hematemesis usually indicates bleeding at or above the duodenojejunal junction (upper GI bleeding) (Chart 58-4).

Minimal bleeding from ulcers is manifested by occult blood in a tarry stool (**melena**). Melena may occur in patients with gastric ulcers but is more common in those with duodenal ulcers. Gastric acid digestion of blood typically results in a granular dark vomitus (*coffee-ground appearance*). The digestion of blood within the duodenum and small intestine may result in a black stool.

Gastric and duodenal ulcers can perforate and bleed. *Perforation* occurs when the ulcer becomes so deep that the entire thickness of the stomach or duodenum is worn away. The stomach or duodenal contents can then leak into the peritoneal cavity. Sudden, sharp pain begins in the mid-epigastric region and spreads over the entire abdomen. The amount of pain correlates with the amount and type of GI contents spilled. The classic pain causes the patient to be apprehensive. The abdomen is tender, rigid, and boardlike (**peritonitis**). The patient assumes the knee-chest (“fetal”) position to decrease the tension on the abdominal muscles. He or she can become severely ill within hours. Bacterial septicemia and hypovolemic shock follow. Peristalsis diminishes, and paralytic ileus develops. *Peptic ulcer perforation is a surgical emergency and can be life threatening!*

Pyloric (gastric outlet) obstruction (blockage) occurs in a small percentage of patients and is manifested by vomiting caused by stasis and gastric dilation. Obstruction occurs at the pylorus (the gastric outlet) and is caused by scarring, edema, inflammation, or a combination of these factors.

Symptoms of obstruction include abdominal bloating, nausea, and vomiting. When vomiting persists, the patient may have hypochloremic (metabolic) alkalosis from loss of large quantities of acid gastric juice (hydrogen and chloride ions) in the vomitus. Hypokalemia may also result from the vomiting or metabolic alkalosis.

Many patients with ulcers have a single episode with no recurrence. However, *intractability* may develop from complications of ulcers, excessive stressors in the patient's life, or an inability to adhere to long-term therapy. He or she no longer responds to conservative management, or recurrences of symptoms interfere with ADLs. In general, the patient continues to have recurrent pain and discomfort despite treatment. Those who fail to respond to traditional

treatments or who have a relapse after discontinuation of therapy are referred to a gastroenterologist.

Etiology and Genetic Risk

Peptic ulcer development is associated primarily with bacterial infection with *H. pylori* and NSAIDs. NSAIDs (e.g., ibuprofen) break down the mucosal barrier and disrupt the mucosal protection mediated systemically by cyclooxygenase (COX) inhibition. COX-2 inhibitors (celecoxib [Celebrex]) are less likely to cause mucosal damage but place patients at high risk for cardiovascular events, such as myocardial infarction. In addition, NSAIDs cause decreased endogenous prostaglandins, resulting in local gastric mucosal injury. GI complications from NSAID use can occur at any time, even after long-term uncomplicated use. NSAID-related ulcers are difficult to treat, even with long-term therapy, because these ulcers have a high rate of recurrence.

Certain substances may contribute to gastroduodenal ulceration by altering gastric secretion, producing localized damage to mucosa and interfering with the healing process. For example, corticosteroids (e.g., prednisone), theophylline (Theo-Dur), and caffeine stimulate hydrochloric acid production. Patients receiving radiation therapy may also develop GI ulcers. Other risk factors for PUD are the same as for gastritis (see Chart 58-1).

Genetic factors may be important. *H. pylori* infection tends to occur in people who are genetically susceptible. Those with a family history of PUD are at higher risk for having PUD than those without a family history (McCance et al., 2010).

Incidence/Prevalence

PUD affects millions of people across the world. However, health care provider visits, hospitalizations, and the mortality rate for PUD have decreased in the past few decades. The use of proton pump inhibitors and *H. pylori* treatment may explain these declines. Duodenal ulcers are increasing in “baby boomers,” however, which may be the result of increased NSAID use for arthritic pain as they age.

Health Promotion and Maintenance

Health promotion and illness prevention practices are the same as for gastritis (see Chart 58-1). For critically ill patients, health care providers prescribe drug therapy to prevent stress ulcers as described on p. 1229 in the Drug Therapy section.

PATIENT-CENTERED COLLABORATIVE CARE**ASSESSMENT****History**

Collect data related to the causes and risk factors for peptic ulcer disease (PUD). Question the patient about factors that can influence the development of PUD, including alcohol intake and tobacco use. Note if certain foods such as tomatoes or caffeinated beverages precipitate or worsen symptoms. Information regarding actual or perceived daily stressors should also be obtained.

A history of current or past medical conditions focuses on GI problems, particularly any history of diagnosis or treatment for *H. pylori* infection. Review all prescription and OTC

drugs that the patient is taking. Specifically inquire whether the patient is taking corticosteroids, chemotherapy, or NSAIDs. Also ask whether he or she has ever undergone radiation treatments. Assess whether the patient has had any GI surgeries, especially a partial gastrectomy, which can cause chronic gastritis.

A history of GI upset, pain and its relationship to eating and sleep patterns, and actions taken to relieve pain are also important. Inquire about any changes in the character of the pain, because this may signal the development of complications. For example, if pain that was once intermittent and relieved by food and antacids becomes constant and radiates to the back or upper quadrant, the patient may have ulcer perforation. However, many people with active duodenal or gastric ulcers report having no ulcer symptoms.

Physical Assessment/Clinical Manifestations

Physical assessment findings may reveal epigastric tenderness, usually located at the midline between the umbilicus and the xiphoid process. *If perforation into the peritoneal cavity is present, the patient has a rigid, boardlike abdomen accompanied by rebound tenderness and pain.* Initially, auscultation of the abdomen may reveal hyperactive bowel sounds, but these may diminish with progression of the disorder.

Dyspepsia (*indigestion*) is the most commonly reported symptom associated with PUD. It is typically described as sharp, burning, or gnawing. Some patients may perceive discomfort as a sensation of abdominal pressure or of fullness or hunger. Specific differences between gastric and duodenal ulcers are listed in Table 58-2.

Gastric ulcer pain often occurs in the upper epigastrium with localization to the left of the midline and is aggravated by food. Duodenal ulcer pain is usually located to the right of the epigastrium. The pain associated with a duodenal ulcer occurs 90 minutes to 3 hours *after* eating and often awakens the patient at night. Pain may also be exacerbated (made worse) by certain foods (e.g., tomatoes, hot spices, fried foods, onions, alcohol, caffeine drinks) and certain drugs (e.g., NSAIDs, corticosteroids). Perform a comprehensive pain assessment that includes:

- Location
- Characteristics
- Onset/duration
- Frequency
- Quality
- Severity
- All precipitating and alleviating factors

Nausea and vomiting may be symptoms accompanying ulcer disease, most commonly with pyloric sphincter dysfunction. It results from gastric stasis associated with pyloric obstruction. Appetite is generally maintained in patients with a peptic ulcer unless pyloric obstruction is present. Some health care agencies use a 0-to-5 nausea scale to rate the degree of the patient's report of nausea (Halpin et al., 2010).

To assess for fluid volume deficit that occurs from bleeding, take orthostatic blood pressures and monitor for signs and symptoms of dehydration. Orthostatic changes are present if there is a decrease of more than 20 mm Hg in systolic blood pressure, a decrease of 10 mm Hg in diastolic blood pressure, and/or an increase in pulse when the patient rises from a lying to an erect (sitting or, if possible, standing) position. Also assess for dizziness, especially when the patient

TABLE 58-2 DIFFERENTIAL FEATURES OF GASTRIC AND DUODENAL ULCERS

FEATURE	GASTRIC ULCER	DUODENAL ULCER
Age	Usually 50 yr or older	Usually 50 yr or older
Gender	Male/female ratio of 1.1 : 1	Male/female ratio of 1 : 1
Blood group	No differentiation	Most often type O
General nourishment	May be malnourished	Usually well nourished
Stomach acid production	Normal secretion or hyposecretion	Hypersecretion
Occurrence	Mucosa exposed to acid-pepsin secretion	Mucosa exposed to acid-pepsin secretion
Clinical course	Healing and recurrence	Healing and recurrence
Pain	Occurs 30-60 min after a meal; at night: rarely Worsened by ingestion of food	Occurs 1½-3 hr after a meal; at night: often awakens patient between 1 and 2 AM Relieved by ingestion of food
Response to treatment	Healing with appropriate therapy	Healing with appropriate therapy
Hemorrhage	Hematemesis more common than melena	Melena more common than hematemesis
Malignant change	Perhaps in less than 10%	Rare
Recurrence	Tends to heal, and recurs often in the same location	60% recur within 1 yr; 90% recur within 2 yr
Surrounding mucosa	Atrophic gastritis	No gastritis

is upright, because this is a symptom of fluid volume deficit. Older adults often experience dizziness when they get out of bed and are at risk for falls.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

When taking a history of a client diagnosed with a duodenal ulcer, which assessment finding does the nurse expect?

- A. Severe weight loss
- B. Pain while eating
- C. Hematemesis after eating
- D. Waking at night with pain

Psychosocial Assessment

Assess the impact of ulcer disease on the patient's lifestyle, occupation, family, and social and leisure activities. Evaluate the impact that lifestyle changes will have on the patient and family. This assessment may reveal information about the patient's ability to adhere to the prescribed treatment regimen and to obtain the needed social support to alter his or her lifestyle.

Laboratory Assessment

Serologic testing for IgG anti-*H. pylori* antibody is the most common noninvasive method to confirm *H. pylori* infection. IgA and IgM anti-*H. pylori* antibody testing may also be performed. Serologic immune testing methods, such as the

enzyme-linked immunosorbent assay (ELISA), may be done several months after the diagnosis of infection to determine the effectiveness of treatment. A negative result indicates that treatment was successful.

Although *H. pylori* does not survive in the stool, an ELISA may detect its presence. A breath test to detect urease may also be performed as a screening tool, but it is not reliable as the serologic testing method.

Patients who have venous bleeding from a peptic ulcer may have decreased hemoglobin and hematocrit values. The stool may also be positive for occult (not seen) blood if bleeding is present.

Imaging Assessment

In the past, upper GI series with barium follow-through was the typical test for diagnosing peptic ulcers. However, this procedure is not the most reliable way to visualize any lesions. If perforation is suspected, the health care provider may request a chest and abdomen x-ray series.

Other Diagnostic Assessment

The major diagnostic test for PUD is esophagogastroduodenoscopy (EGD), which is the most accurate means of establishing a diagnosis. Direct visualization of the ulcer crater by EGD allows the health care provider to take specimens for *H. pylori* testing and for biopsy and cytologic studies for ruling out gastric cancer. The rapid urease test can confirm a quick diagnosis because urease is produced by the bacteria in the gastric mucosa. EGD may be repeated at 4- to 6-week intervals while the health care provider evaluates the progress of healing in response to therapy. Chapter 55 describes this test in more detail.

GI bleeding may be tested using a nuclear medicine GI bleeding study. No special preparation is required for this scan. The patient is injected with a contrast medium (usually Tc99m), and the GI system is scanned for the presence of bleeding after a waiting period. A second scan may be done 1 to 2 days after the bleeding is treated to determine if the interventions were effective.

ANALYSIS

The priority patient problems for patients with peptic ulcer disease (PUD) are:

1. Acute or Chronic Pain related to gastric and/or duodenal ulceration
2. Potential for upper GI bleeding

PLANNING AND IMPLEMENTATION

Managing Acute Pain or Chronic Pain

Planning: Expected Outcomes. The patient with PUD is expected to report pain control as evidenced by no more than a 3 on a 0-10 pain intensity scale.

Interventions. PUD causes significant discomfort that impacts many aspects of daily living. Interventions to manage pain focus on drug therapy and dietary changes. One of the primary purposes for drug therapy is to decrease pain by eliminating *H. pylori* infection and promoting healing of gastric mucosa.

Drug Therapy. The primary purposes of drug therapy in the treatment of PUD are to (1) provide pain relief, (2) eliminate *H. pylori* infection, (3) heal ulcerations, and (4) prevent recurrence. Several different regimens can be used. In

selecting a therapeutic drug regimen, the health care provider must consider the efficacy of the treatment, the anticipated side effects, the ability of the patient to adhere to the regimen, and the cost of the treatment.

Although numerous drugs have been evaluated for the treatment of *H. pylori* infection, no single agent has been used successfully against the organism. A common drug regimen for *H. pylori* infection is PPI-triple therapy, which includes a proton pump inhibitor (PPI) such as lansoprazole (Prevacid) plus two antibiotics such as metronidazole (Flagyl, Novonidazol) and tetracycline (Ala-Tet, Panmycin, Nu-Tetra) or clarithromycin (Biaxin, Biaxin XL) and amoxicillin (Amoxil, Amoxi) for 7 to 14 days. Seven-day therapy is also effective when a PPI, levofloxacin (Levaquin), and either amoxicillin or clarithromycin are used (Schrauwen et al., 2009).

CONSIDERATIONS FOR OLDER ADULTS

Many older adults have *H. pylori* infection that is undiagnosed because of vague symptoms associated with physiologic changes of aging and comorbidities that mask dyspepsia. Teach older adults about the importance of *H. pylori* screening because early detection and aggressive treatment can prevent PUD and gastric cancer (Fromm, 2009).

Hyposecretory drugs reduce gastric acid secretions and are therefore used for both peptic ulcer disease (PUD) and gastritis management. The primary prescribed drugs include proton pump inhibitors and H₂-receptor antagonists (see Chart 58-3).

Proton pump inhibitors (PPIs) are the drug class of choice for treating patients with acid-related disorders. Examples include omeprazole (Prilosec), lansoprazole (Prevacid), rabeprazole (Aciphex), pantoprazole (Protonix), and esomeprazole (Nexium). These drugs suppress the H,K-ATPase enzyme system of gastric acid production, and several of them are available as over-the-counter (OTC) drugs.

Omeprazole, lansoprazole, and esomeprazole are each available as delayed-release capsules designed to release their contents after they pass through the stomach. Omeprazole and lansoprazole may be dissolved in a sodium bicarbonate solution and given through any feeding tube. Bicarbonate protects the dissolved omeprazole and lansoprazole granules in gastric acid. Therefore the drugs are still absorbed correctly. These capsules can also be opened. The enteric-coated capsules can be put in apple juice or orange juice and given through a large-bore feeding tube. Rabeprazole (Aciphex) and pantoprazole (Protonix) are enteric-coated tablets that quickly dissolve after the tablet has moved through the stomach and should not be crushed before giving them. Several of the PPIs are also available in an IV form, which may be helpful for patients who are NPO. A new faster-acting form of omeprazole combined with sodium bicarbonate (Zegerid) can be purchased OTC and is prescribed most often for active duodenal ulcers for a 4- to 8-week period.

Some patients use these PPIs for years and perhaps a lifetime. However, these drugs should not be used for a prolonged period because, over time, they may contribute to osteoporotic-related fractures, especially spinal fractures in older women (Kwok et al., 2010). Omeprazole (Prilosec and Prilosec OTC) reduce the effect of clopidogrel (Plavix), an antiplatelet drug. Teach patients to tell their health care provider if they are taking clopidogrel.

H₂-receptor antagonists are drugs that block histamine-stimulated gastric secretions. These drugs may also be used for indigestion and gastritis. Lower-dose forms are available in over-the-counter (OTC) products. *H₂-receptor antagonists* block the action of the *H₂* receptors of the parietal cells, thus inhibiting gastric acid secretion. Two of the most common drugs are famotidine (Pepcid) and nizatidine (Axid) and are available as Pepcid OTC and Axid AR in OTC form. These drugs are typically administered in a single dose at bedtime and are used for 4 to 6 weeks in combination with other therapy.

Antacids buffer gastric acid and prevent the formation of pepsin. They may help small duodenal ulcers heal but are usually not used alone as drug therapy. Liquid suspensions are the most therapeutic form, but tablets may be more convenient and enhance adherence. The most widely used preparations are mixtures of aluminum hydroxide and magnesium hydroxide. This combination overcomes the unpleasant GI side effects of either of these preparations when used alone. Mylanta and Maalox are examples of this type of combination antacid formulation. The aluminum and magnesium hydroxide combination products neutralize well at small doses. These products must be administered cautiously to patients with renal impairment because elimination is reduced and excessive amounts are retained in the body.

! NURSING SAFETY PRIORITY

Drug Alert

Teach the patient that to achieve a therapeutic effect, sufficient antacid must be ingested to neutralize the hourly production of acid. For optimal effect, take antacids about 2 hours after meals to reduce the hydrogen ion load in the duodenum. Antacids may be effective from 30 minutes to 3 hours after ingestion. If taken on an empty stomach, they are quickly evacuated. Thus the neutralizing effect is reduced.

Calcium carbonate (Tums) is a potent antacid, but it triggers gastrin release, causing a rebound acid secretion. Therefore its use in acid inhibition is not recommended.

Antacids can interact with certain drugs such as phenytoin (Dilantin), tetracycline (Ala-Tet, Nu-Tetra 🍁), and ketoconazole (Nizoral) and interfere with their effectiveness. Ask what other drugs the patient is using before a specific antacid is prescribed. Other drugs are given 1 to 2 hours before or after the antacid. Inform the patient that flavored antacids, especially wintergreen, should be avoided. The flavoring increases the emptying time of the stomach. Thus the desired effect of the antacid is negated.

Teach the patient with past or present heart failure to avoid antacids with high sodium content, such as aluminum hydroxide, magnesium hydroxide, sodium bicarbonate, and simethicone combination products (Gelusil and Mylanta). Magaldrate (Riopan) has the lowest sodium concentration.

Sucralfate (Carafate) is a *mucosal barrier fortifier* (protector) that forms complexes with proteins at the base of a peptic ulcer. This protective coat prevents further digestive action of both acid and pepsin. Sucralfate does not inhibit acid secretion. Rather, it binds bile acids and pepsins, reducing injury from these substances. The drug may be used in conjunction with *H₂-receptor antagonists* and antacids but should not be administered within 1 hour of the antacid. Sucralfate is given on an empty stomach 1 hour before each meal and at bedtime. The main side effect of this drug is constipation.

Nutrition Therapy. The role of diet in the management of ulcer disease is controversial. There is no evidence that dietary restriction reduces gastric acid secretion or promotes tissue healing, although a bland diet may assist in relieving symptoms. Food itself acts as an antacid by neutralizing gastric acid for 30 to 60 minutes. An increased rate of gastric acid secretion, called *rebound*, may follow.

! NURSING SAFETY PRIORITY

Action Alert

Teach the patient with peptic ulcer disease to avoid substances that increase gastric acid secretion. This includes caffeine-containing beverages (coffee, tea, cola). Both caffeinated and decaffeinated coffees should be avoided, because coffee contains peptides that stimulate gastrin release.

Teach the patient to exclude any foods that cause discomfort. A bland, nonirritating diet is recommended during the acute symptomatic phase. Bedtime snacks are avoided because they may stimulate gastric acid secretion. Eating six smaller daily meals may help, but this regimen is no longer a regular part of therapy. No evidence supports the theory that eating six daily meals promotes healing of the ulcer. This practice may actually stimulate gastric acid secretion. Patients should avoid alcohol and tobacco because of their stimulatory effects on gastric acid secretion.

Complementary and Alternative Therapies. Teach patients about complementary and alternative therapies that can reduce stress, including hypnosis and imagery. For example, the use of yoga and meditation techniques has demonstrated a beneficial effect on anxiety disorders. Many have suggested that GI disorders result from the dysfunction of both the GI tract itself and the brain. This means that emotional stress is thought to worsen GI disorders such as peptic ulcer disease. Yoga is thought to alter the activities of the central and autonomic nervous systems.

Many herbs, such as powders of slippery elm and marshmallow root, quercetin, and licorice, are used commonly by patients with gastritis and PUD. These herbs are thought to heal inflamed tissue and increase blood flow to the gastric mucosa. Other substances include zinc, vitamin C, essential fatty acids, acidophilus, vitamins E and A, and glutamine. All of these substances enhance healing. Table 58-1 provides a more complete list of therapies that have been used. Many of them have been scientifically supported in animal studies. Additional research using humans is being conducted.

Managing Upper GI Bleeding

Planning: Expected Outcomes. The patient with upper GI bleeding (often called *upper GI hemorrhage* or *UGH*) is expected to have vital signs within normal limits.

Interventions. Blood loss from PUD results in high morbidity and mortality. Fluid volume loss secondary to vomiting can lead to dehydration and electrolyte imbalances. Monitoring and early recognition of complications are critical to the successful management of PUD. Interventions aimed at managing complications associated with PUD include prevention and/or management of bleeding, perforation, and gastric outlet obstruction. In some cases, surgical treatment of complications becomes necessary.

Nonsurgical Management. Because prevention or early detection of complications is needed to obtain a positive

clinical outcome, monitor the patient carefully and immediately report changes to the health care provider. The type of intervention selected will depend on the type and severity of the complication.

Emergency: Upper GI Bleeding. The patient who is actively bleeding has a life-threatening emergency. He or she needs supportive therapy to prevent hypovolemic shock and possible death.

! NURSING SAFETY PRIORITY

Critical Rescue

*The first priority for care of the patient with upper GI bleeding is to maintain **a**irway, **b**reathing, and **c**irculation (ABCs). Provide oxygen and other ventilatory support as needed. Start two large-bore IV lines for replacing fluids and blood. Monitor vital signs, hematocrit, and oxygen saturation.*

The purpose of managing hypovolemia is to expand intravascular fluid in a patient who is volume depleted. Carefully monitor the patient's fluid status, including intake and output. *Fluid replacement in older adults should be closely monitored to prevent fluid overload.* Serum electrolytes are also assessed because depletions from vomiting or nasogastric suctioning must be replaced. Volume replacement with isotonic solutions (e.g., 0.9% normal saline solution, lactated Ringer's solution) should be started immediately. The health care provider may prescribe blood products such as packed red blood cells to expand volume and correct a low hemoglobin and hematocrit. For patients with active bleeding, fresh frozen plasma may be given if the prothrombin time is 1.5 times higher than the midrange control value.

Continue to monitor the patient's hematocrit, hemoglobin, and coagulation studies for changes from the baseline measurements. With mild bleeding (less than 500 mL), slight feelings of weakness and mild perspiration may be present. When blood loss exceeds 1 L/24 hr, manifestations of shock may occur, such as hypotension, chills, palpitations, diaphoresis, and a weak, thready pulse.

A combination of several different treatments, including nasogastric tube (NGT) placement and lavage, endoscopic therapy, interventional radiologic procedures, and acid suppression, can be used to control acute bleeding and prevent rebleeding. If the patient is actively bleeding at home, he or she is usually admitted to the emergency department for GI lavage. If the patient is already a patient in the hospital, lavage can be done at the bedside. After the bleeding has stopped, H₂-receptor antagonists, proton pump inhibitors, and antacids are the primary drugs used.

Nasogastric Tube Placement and Lavage. Upper GI bleeding often requires the health care provider or nurse to insert a large-bore nasogastric tube (NGT) to:

- Determine the presence or absence of blood in the stomach
- Assess the rate of bleeding
- Prevent gastric dilation
- Administer lavage

Patients who have upper GI bleeding often have discomfort, nausea, and/or vomiting, which can be worsened by inserting an NGT. Therefore several methods are available to prevent these problems, such as applying lidocaine gel or spray before the tube is placed. Some health care providers do not use any

of these methods to promote patient comfort, even though they have been shown to be effective.

Once the NGT is placed, proper positioning of the tube is confirmed by x-ray examination. Irrigate the NGT to maintain its patency and prevent obstruction with clotted blood (Chart 58-5).

Gastric lavage requires the insertion of a large-bore NGT with instillation of a room-temperature solution in volumes of 200 to 300 mL. There is no evidence that sterile saline or sterile water is better than tap water for this procedure. Follow agency protocol for the solution that is required. The solution and blood are repeatedly withdrawn manually until returns are clear or light pink and without clots. Instruct the patient to lie on the left side during this procedure to limit the flow of the lavage solution out of the stomach. The NGT may remain in place for a few days or be removed after lavage.

Endoscopic Therapy. Endoscopic therapy via an esophagogastroduodenoscopy (EGD) can assist in achieving homeostasis during an acute hemorrhage by isolating the bleeding artery to embolize (clot) it. Octreotide (Sandostatin) or terlipressin (Novapressin) may be given IV as adjuvant therapy. These drugs are synthetic GI hormones (somatostatin analogs) that suppress gastric acid secretion.

Pre-EGD nursing care involves inserting one or two large-bore IV catheters if they are not in place. A large catheter allows the patient to receive IV moderate sedation (e.g., midazolam [Versed] and an opioid) and possibly a blood transfusion. Keep the patient NPO 4 to 6 hours before the procedure. This prevents the risk for aspiration and allows the endoscopist to view and treat the ulcer. A patient must sign a consent form before the EGD *after* the physician informs him or her about the procedure. During the EGD, a specialized endoscopy nurse and technician assist the physician with the procedure.

! NURSING SAFETY PRIORITY

Action Alert

*After esophagogastroduodenoscopy (EGD), monitor vital signs, heart rhythm, and oxygen saturation frequently until they return to baseline. In addition, frequently assess the patient's ability to swallow saliva. The patient's gag reflex may initially be absent after an EGD because of anesthetizing (numbing) the throat with a spray before the procedure. **After the procedure, do not allow the patient to have food or liquids until the gag reflex is intact!***

Endoscopic therapy is beneficial for most patients with active bleeding. However, ulcers that continue to bleed or continue to rebleed despite endoscopic therapy may require an interventional radiologic procedure or surgical repair.

Interventional Radiologic Procedures. For patients with persistent, massive upper GI bleeding or those who are not surgical candidates, catheter-directed embolization may be performed. This endovascular procedure is usually done if endoscopic procedures are not successful or available. A femoral approach is most often used, but brachial access may be used. An arteriogram is performed to identify the arterial anatomy and find the exact location of the bleeding. A liquid substance is used to clot the bleeding artery. Nursing care of patients having this procedure is similar to the care required for patients undergoing arteriography (Loffroy & Guiu, 2009).

Acid Suppression. Aggressive acid suppression is used to prevent rebleeding. When acute bleeding is stopped and clot

CHART 58-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Nasogastric Tubes

1. Inform the patient about the procedure and its potential discomfort.
2. Position the patient with pillows behind the shoulders.
3. Lubricate the tube with a water-soluble lubricant.
4. Measure the length of the tube to be passed:
 - a. Measure from the bridge of the nose to the earlobe to the xiphoid process.
 - b. Indicate this length with a piece of tape on the tube.

5. Determine which nostril is more patent.
6. Encourage the patient to swallow or drink water if the level of consciousness and treatment plan permit.
7. Insert the tube:
 - a. Pass the tube gently into the nasopharynx. Ask the patient to swallow repeatedly while the tube is advanced.
 - b. If resistance is met, rotate the tube slowly, aiming downward and toward the closer ear.
 - c. In the intubated or semiconscious patient, flex the head toward the chest while passing the tube.
8. Withdraw the tube immediately if any change is noted in respiratory status.
9. Test for tube placement by using these techniques:
 - a. Obtain a sample of the gastric contents by aspirating with a 50-mL catheter-tipped syringe.
 - b. Test the pH of the gastric contents (should be between 1 and 3.5).
 - c. Obtain a request for an x-ray study to confirm placement.
10. Connect the tube to suction at low pressure:
 - a. The Levin tube is connected to intermittent low suction.
 - b. The Salem sump or Anderson tube is connected to continuous low suction.
11. Secure the tube to the patient's nose and to his or her gown:
 - a. Tie a slipknot around the tube with a rubber band.
 - b. Pin the rubber band to the gown.
12. Check intake and output every 4 hr or more often, as indicated.
13. Observe the patient for nausea, vomiting, abdominal fullness, or distention.
14. If irrigation is indicated, use only a normal saline solution.
15. Observe the patient for alterations in fluid and electrolyte balance.
16. If indicated, instruct the patient about movement that will not dislodge the tube and cause nasal irritation.
17. Remove the tape securing the tube to the nose daily and PRN to clean skin; reapply tape.

formation has taken place within the ulcer crater, the clot remains in contact with gastric contents. Acid-suppressive agents are used to stabilize the clot by raising the pH level of gastric contents. Several types of drugs are used. H_2 -receptor antagonists prevent acid from being produced by parietal cells. Proton pump inhibitors prevent the transport of acid across the parietal cell membrane, whereas antacids buffer acid produced in the stomach.

Perforation is managed by immediately replacing fluid, blood, and electrolytes, administering antibiotics, and keeping the patient NPO. Maintain nasogastric suction to drain gastric secretions and thus prevent further peritoneal spillage. Carefully monitor intake and output and check vital signs at least hourly. Monitor the patient for clinical manifestations of septic shock, such as fever, pain, tachycardia, lethargy, or anxiety.

Pyloric obstruction is caused by edema, spasm, or scar tissue. Symptoms of obstruction related to difficulty in emptying the stomach include feelings of fullness, distention, or nausea after eating, as well as vomiting copious amounts of undigested food.

Treatment of obstruction is directed toward restoring fluid and electrolyte balance and decompressing the dilated stomach. Obstruction related to edema and spasm generally responds to medical therapy. First, the stomach must be decompressed with nasogastric suction. Next, interventions are directed at correcting metabolic alkalosis and dehydration. The NGT is clamped after about 72 hours. Check the patient for retention of gastric contents. If the amount retained is not more than 50 mL in 30 minutes, the health care provider may allow oral fluids. In some cases, surgical intervention may be required to treat PUD.

Surgical Management. Evidence-based guidelines for the treatment of PUD that include *H. pylori* treatment and the development of nonsurgical means of controlling bleeding have led to a decline in the need for surgical intervention. In PUD, surgical intervention may be used to:

- Treat patients who do not respond to medical therapy or other nonsurgical procedures
- Treat a surgical emergency that develops as a complication of PUD, such as perforation

Two general surgical approaches are available for PUD—minimally invasive surgery and conventional open surgery.

Minimally invasive surgery (MIS) via laparoscopy (a type of endoscope) is occasionally used to remove a chronic gastric ulcer or treat hemorrhage from perforation. Several small incisions allow access to the stomach and duodenum. The patient may have partial stomach removal (subtotal gastrectomy), pyloroplasty (to open the pylorus) and/or a vagotomy (vagus nerve cutting) to control acid secretion (Fig. 58-4). The advantages of MIS over traditional procedures include a shorter hospital stay, fewer complications, less pain, and better, quicker recovery. MIS is discussed in more detail in Chapter 17. Conventional surgery is performed using an open approach. This procedure is discussed on p. 1235 under Surgical Management in the Gastric Cancer section.

Community-Based Care

Patients may be discharged from the hospital as long as there is no evidence of ongoing bleeding, orthostatic changes, or cardiopulmonary distress or compromise. Those discharged after treatment for peptic ulcer disease (PUD) and/

FIG. 58-4 Various types of vagotomies.

CHART 58-6 HOME CARE ASSESSMENT

The Patient with Ulcer Disease

Assess gastrointestinal and cardiovascular status, including:

- Vital signs, including orthostatic vital signs
- Skin color
- Presence of abdominal pain (location, severity, character, duration, precipitating factors, and relief measures)
- Character, color, and consistency of stools
- Changes in bowel elimination pattern
- Hemoglobin and hematocrit
- Bowel sounds; palpate for areas of tenderness

Assess nutritional status, including:

- Dietary patterns and habits
- Intake of caffeine and alcohol
- Relationship of food to symptoms

Assess medication history:

- Use of steroids
- Use of NSAIDs
- Use of over-the-counter medications

Assess patient's coping style:

- Recent stressors
- Past coping style

Assess patient's understanding of illness and ability to adhere to the therapeutic regimen:

- Symptoms to report to health care provider
- Expected and side effects of medications
- Food and drug interactions
- Need for smoking cessation

or complications secondary to the disease must face several challenges to manage the disease successfully. Long-term adherence to drug therapy may require the patient to take several drugs each day. Permanent lifestyle alterations in nutrition habits must also be made.

Home Care Management

Most patients are discharged to the home to continue their recovery. Those who have had major surgery or have had complications, such as hemorrhage, may require one or two visits from a home care nurse to assess clinical progress, especially if the patient is an older adult (Chart 58-6).

Teaching for Self-Management

The primary focus of home care preparation is patient and family teaching regarding risk factors for the recurrence of PUD. Teach them how to recognize new complications and what to do if they occur, especially abdominal pain; nausea and vomiting; black, tarry stools; and weakness or dizziness.

Teach the patient and family about risk factors for recurring peptic ulcers. Help them plan ways to make needed lifestyle changes. For postsurgical patients, especially those who have undergone partial stomach removal, a smaller meal may be required. Other postoperative nutrition changes are described on p. 1238 in the discussion of Teaching for Self-Management in the Gastric Cancer section.

! NURSING SAFETY PRIORITY

Action Alert

Teach the patient who has had surgery for PUD to avoid any OTC product containing aspirin or other NSAID. Emphasize the importance of following the treatment regimen for treating *H. pylori* infection and healing the ulcer. Emphasize the importance of keeping all follow-up appointments. Help the patient identify situations that cause stress, describe feelings during stressful situations, and develop a plan for coping with stressors. Encourage the patient to learn and use relaxation techniques, such as exercise, biofeedback, humor, and imagery. Psychotherapy may be indicated to cope with excessive anxiety or stress.

Health Care Resources

If needed, refer the patient and family to the National Digestive Diseases Information Clearinghouse (www.acg.gi.org/patients/gitract/nddic.asp). This group provides information and support to patients who have digestive disorders.

EVALUATION: OUTCOMES

Evaluate the care of the patient with peptic ulcer disease (PUD) based on the identified priority patient problems. The expected outcomes are that the patient:

- Does not have active PUD or associated complications
- Verbalizes pain relief or control
- Adheres to the drug regimen and lifestyle changes to prevent recurrence and heal the ulcer

ZOLLINGER-ELLISON SYNDROME

Zollinger-Ellison syndrome (ZES) is a rare disease that is manifested by upper GI tract ulceration, increased gastric acid secretion, and one or more duodenal or pancreatic tumors, called **gastrinomas**. About two thirds of these tumors are malignant. Although most of these tumors grow slowly, a small portion of patients have tumors that develop rapidly and metastasize widely. Metastasis occurs mainly in the liver and regional lymph nodes.

Pathophysiology

ZES is caused by gastrin-secreting tumors that stimulate the acid-secreting cells of the stomach to maximal activity. This large quantity of acid causes GI ulceration. In the early course of the disease, symptoms are similar to those of peptic ulcer disease (PUD). However, these symptoms tend to progress and respond poorly to traditional ulcer therapy. Diarrhea occurs in almost half of patients. It may be associated with

large amounts of hydrochloric acid secreted into the proximal duodenum. **Steatorrhea** (an excessive amount of fat in the feces) results from the inactivation of pancreatic lipase secondary to the large concentrations of acid and decreased amounts of bile acids.

In some patients, gastrinoma results from an autosomal dominant disorder called *multiple endocrine neoplasia type 1 (MEN-1) syndrome*, in which there is a mutation in the *MEN-1* suppressive gene. Gastrinomas contain multiple hormones, but adrenocorticotrophic hormone (ACTH) is most commonly found (McCance et al., 2010).

PATIENT-CENTERED COLLABORATIVE CARE

Patients may report PUD symptoms and may have diarrhea and/or steatorrhea. Ask whether any relatives have had ZES. Radiographic and endoscopic findings for ZES are similar to those for PUD. *However, infection with H. pylori is usually absent.* The diagnosis is usually made by radioimmunoassay studies that reveal *increased serum gastrin levels* in conjunction with the clinical features of the disease.

The aim of therapy is to suppress acid secretion to control symptoms. Proton pump inhibitors (PPIs), such as lansoprazole (Prevacid) and omeprazole (Prilosec, Losec ) are the drugs of choice to reduce gastric acid secretion and heal the ulcers. High doses of H₂-receptor antagonists are also effective in reducing gastric acid and providing symptom relief.

The tumor requires complete surgical resection as a curative treatment. In some patients, a radical pancreaticoduodenectomy (Whipple procedure) is performed. Chapter 62 in the discussion of Surgical Management in the Pancreatic Cancer section describes this procedure and nursing care in detail. Patients with aggressive disease can also be treated with chemotherapeutic agents such as 5-fluorouracil, doxorubicin, and streptozocin to reduce tumor size and control symptoms before surgery. Octreotide (Sandostatin) may also be used.

GASTRIC CANCER

Most cancers of the stomach are adenocarcinomas. This type of cancer develops in the mucosal cells that form the innermost lining of any portion or all of the stomach. Often there are no symptoms in the early stages and the disease is advanced when detected.

Pathophysiology

Gastric cancer usually begins in the glands of the stomach mucosa. Atrophic gastritis and intestinal metaplasia (abnormal tissue development) are precancerous conditions. Inadequate acid secretion in patients with atrophic gastritis creates an alkaline environment that allows bacteria (especially *H. pylori*) to multiply. This infection causes mucosa-associated lymphoid tissue (MALT) lymphoma, which starts in the stomach (McCance et al., 2010).

Gastric cancers spread by direct extension through the gastric wall and into regional lymphatics, which carry tumor deposits to lymph nodes. Direct invasion of and adherence to adjacent organs (e.g., the liver, pancreas, and transverse colon) may also result. Hematogenous spread via the portal vein to the liver and via the systemic circulation to the lungs and bones is the most common mode of metastasis. Peritoneal

seeding of cancer cells from the tumor areas to the omentum, peritoneum, ovary, and pelvic cul-de-sac can also occur.

In people with *advanced* gastric cancer, there is invasion of the muscularis (stomach muscle) or beyond. These lesions are not cured by surgical resection. The overall 5-year survival rate of people with stomach cancer in the United States is poor because most patients have no symptoms until the disease advances.

Etiology and Genetic Risk

Infection with H. pylori is the largest risk factor for gastric cancer because it carries the cytotoxin-associated antigen A (CagA) gene. Patients with pernicious anemia, gastric polyps, chronic atrophic gastritis, and **achlorhydria** (absence of secretion of hydrochloric acid) are two to three times more likely to develop gastric cancer.

The disease also seems to be positively correlated with eating pickled foods, nitrates from processed foods, and salt added to food. The ingestion of these foods over a long period can lead to atrophic gastritis, a precancerous condition. A low intake of fruits and vegetables is also a risk factor for cancer (McCance et al., 2010).

Gastric surgery seems to increase the risk for gastric cancer because of the eventual development of atrophic gastritis, which results in changes to the mucosa. Patients with Barrett's esophagus from prolonged or severe gastroesophageal reflux disease (GERD) have an increased risk for cancer in the cardia (at the point where the stomach connects to the esophagus).

Incidence/Prevalence

Men appear to have a slightly greater risk than women. Asians and Asian Americans are at an especially high risk because of preferences for salted and smoked fish. The average age for developing gastric cancer is 70 years (National Cancer Institute, 2010).

CULTURAL AWARENESS

Minority groups in the United States have a greater incidence of gastric cancer than Euro-Americans (whites), probably because of diets higher in salt and pickled foods. Asian/Pacific Islanders, American Indians/Alaska Natives, and blacks are the most at-risk groups (National Cancer Institute, 2010).

Health Promotion and Maintenance

Teach patients with gastritis and/or *H. pylori* infection to follow the treatment regimen to ensure that gastritis heals and *H. pylori* infection is eliminated. *Stress the need for eating a well-balanced diet and limiting pickled foods, salted foods, and processed foods to help prevent gastric cancer.*

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

The nurse assesses a client for the risk for gastric cancer. Which of these factors would likely increase the client's risk? **Select all that apply.**

- A. Having a history of untreated gastroesophageal reflux disease
- B. Being an adult between 20 and 40 years of age
- C. Eating a diet high in smoked and pickled foods
- D. Eating a diet with high-fiber foods
- E. Eating a diet high in salt and adding salt to food

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Question the patient about known risk factors for the development of gastric cancer. Ask about preferred foods, especially pickled, salted, or smoked foods. Inquire whether the patient has ever been diagnosed with or treated for *H. pylori* infection, gastritis, or pernicious anemia. Note whether he or she has a history of gastric surgery or polyps. Also ask whether any of the patient's immediate relatives have gastric cancer.

Although patients with *early* gastric cancer may be asymptomatic, indigestion (heartburn) and abdominal discomfort are the *most* common symptoms (Chart 58-7). These symptoms are often ignored, however, or a change in diet or use of antacids relieves them. As the tumor grows, these symptoms become more severe and do not respond to nutrition changes or antacids. Epigastric or back pain is also an early symptom that may go unrecognized.

In *advanced* gastric cancer, progressive weight loss, nausea, and vomiting can occur. Vomiting represents pronounced dilation, thickening of the stomach wall, or pyloric obstruction. Obstructive symptoms appear earlier with tumors located near the pylorus than with fundic lesions. Patients with advanced disease may have weakness, fatigue, and anemia. Physical assessment findings in advanced disease may be absent, or a palpable epigastric mass may suggest hepatomegaly (liver enlargement) from metastatic disease. Hard, enlarged lymph nodes in the left supraclavicular chain, left axilla, or umbilicus result from metastasis from gastric cancer. Masses on the right suggest metastasis in the perigastric lymph nodes or liver.

In patients with advanced disease, anemia is evidenced by *low hematocrit* and hemoglobin values. Patients may have macrocytic or microcytic anemia associated with decreased iron or vitamin B₁₂ absorption. *The stool may be positive for occult blood. Hypoalbuminemia and abnormal results of liver tests* (e.g., bilirubin and alkaline phosphatase) occur with

advanced disease and with hepatic metastasis. *The level of carcinoembryonic antigen (CEA) is elevated in advanced cancer of the stomach.*

The health care provider uses esophagogastroduodenoscopy (EGD) with biopsy for definitive diagnosis of gastric cancer. The lesion can be viewed directly, and biopsies of all visible lesions can be obtained to determine the presence of cancer cells. During the endoscopy, an endoscopic (endoluminal) ultrasound (EUS) of the gastric mucosa can also be performed. This technology allows the health care provider to evaluate the depth of the tumor and the presence of lymph node involvement, which permits more accurate staging of the disease. Computed tomography (CT), positron emission tomography (PET), and magnetic resonance imaging (MRI) scans of the chest, abdomen, and pelvis are used in determining the extent of the disease and planning therapy.

INTERVENTIONS

Management of gastric cancer includes drug therapy, radiation, and/or surgery. Drug therapy and radiation may be used instead of surgery or as an adjunct before and/or after surgery.

Nonsurgical Management

The treatment of gastric cancer depends highly on the stage of the disease. Radiation and chemotherapy commonly prolong survival of patients with advanced gastric disease.

Combination *chemotherapy* with multiple cycles of drugs such as cisplatin and epirubicin before and after surgery may be given. Bone marrow suppression, nausea, and vomiting are common adverse drug effects. Chapter 24 discusses the general nursing care of patients receiving chemotherapy.

Although gastric cancers are somewhat sensitive to the effects of radiation, the use of this treatment is limited because the disease is often widely spread to other abdominal organs on diagnosis. Organs such as the liver, kidneys, and spinal cord can endure only a limited amount of radiation. Intraoperative radiotherapy (IORT) is available in large tertiary care health care systems. Radiation may be used for palliative management when surgery is not an option.

The most common side effects of radiation include impaired skin integrity, fatigue, and anorexia. Nausea, vomiting, and diarrhea may occur about 1 week after treatment is initiated and diminish a month or more after treatment ends. (See Chapter 24 for more information on radiation therapy.)

Surgical Management

Surgical resection by removing the tumor is the preferred method for treating gastric cancer. The primary surgical procedures for the treatment of gastric cancer are total gastrectomy and subtotal (partial) gastrectomy. In early stages, laparoscopic surgery (minimally invasive surgery [MIS]) plus adjuvant chemotherapy or radiation may be curative. Patients having MIS have less pain, shorter hospital stays, rare postoperative complications, and quicker recovery. However, MIS is seldom performed because very few patients are diagnosed in the early stage of the disease.

Most patients with advanced disease are candidates for palliative surgical treatment. Metastasis in the supraclavicular lymph nodes, inguinal lymph nodes, liver, umbilicus, or perirectal wall indicates that the opportunity for cure by resection has been lost. Palliative resection may significantly improve

CHART 58-7 KEY FEATURES

Early Versus Advanced Gastric Cancer

Early Gastric Cancer*

- Indigestion
- Abdominal discomfort initially relieved with antacids
- Feeling of fullness
- Epigastric, back, or retrosternal pain

Advanced Gastric Cancer

- Nausea and vomiting
- Obstructive symptoms
- Iron deficiency anemia
- Palpable epigastric mass
- Enlarged lymph nodes
- Weakness and fatigue
- Progressive weight loss
- Signs of distant metastasis:
 - Virchow's nodes
 - Blumer's shelf
 - "Sister Mary Joseph nodes"
 - Krukenberg's tumor

*Note: Many patients with early gastric cancer have no clinical manifestations.

FIG. 58-5 Total gastrectomy with anastomosis of the esophagus to the jejunum (esophagojejunostomy) is the principal surgical intervention for extensive gastric cancer.

the quality of life for a patient suffering from obstruction, hemorrhage, or pain.

Preoperative Care. Before conventional open-approach surgery, a nasogastric tube (NGT) is inserted and connected to suction to remove secretions and empty the stomach. This allows surgery to take place without contamination of the peritoneal cavity by gastric secretions. [Chart 58-5](#) describes the procedure for inserting the NGT and nursing care associated with maintenance. The NGT remains in place for a few days *postoperatively* to prevent the accumulation of secretions, which may lead to vomiting or GI distention and pressure on the incision.

Because weight loss is problematic for patients with gastric cancer, nutrition therapy is a vital aspect of preoperative and postoperative management. Preoperatively, compression by the tumor can prevent adequate nutritional intake. To correct malnutrition before surgery, the health care provider may prescribe enteral supplements to the diet and/or total parenteral nutrition (TPN). Vitamin, mineral, iron, and protein supplements are essential to correct nutritional deficits.

Other preoperative nursing measures for the patient undergoing open gastric surgery are the same as those for any patient undergoing abdominal surgery and general anesthesia (see [Chapter 16](#)).

Operative Procedures. The surgeon usually removes part or all of the stomach to take out the tumor. When the tumor is located in the mid-portion or distal (lower) portion of the stomach, a subtotal (partial) gastrectomy is typically performed. The omentum, spleen, and relevant nodes are also removed.

For the patient with a removable growth in the proximal (upper) third of the stomach, a total gastrectomy is performed ([Fig. 58-5](#)). In this procedure the surgeon removes the entire stomach along with the lymph nodes and omentum. The surgeon sutures the esophagus to the duodenum or jejunum to reestablish continuity of the GI tract. More radical surgery involving removal of the spleen and distal pancreas

is controversial, although the Whipple procedure may be used to prolong life. However, the complications of this drastic surgery are very serious and common. For patients with advanced disease, total gastrectomy is performed only when gastric bleeding or obstruction is present.

Patients with tumors at the gastric outlet who are not candidates for subtotal or total gastrectomy may undergo gastroenterostomy for palliation. The surgeon creates a passage between the body of the stomach and the small bowel, often the duodenum.

Postoperative Care. Provide the usual postoperative care for patients who have had general anesthesia to prevent atelectasis, paralytic ileus, and wound infection (see [Chapter 18](#)). In addition, monitor the patient for the development of complications that are specific to gastric surgery.

Auscultate the lungs for adventitious sounds (crackles or reduced breath sounds), and monitor for the return of bowel sounds. Take vital signs as appropriate to detect signs of infection or bleeding. Aggressive pulmonary exercises and early ambulation can help prevent respiratory complications and deep vein thrombosis. Also inspect the operative site every shift for the presence of redness, swelling, or drainage, which indicates wound infection. Keep the head of the bed elevated to prevent aspiration from reflux.

Decreased patency caused by a clogged NGT can result in *acute gastric dilation* after surgery. This problem is manifested by epigastric pain and a feeling of fullness, hiccups, tachycardia, and hypotension. Irrigation or replacement of the NGT by request of the surgeon can relieve these symptoms.

Dumping syndrome is a term that refers to a group of vasomotor symptoms that occur after eating. This syndrome is believed to occur as a result of the rapid emptying of food contents into the small intestine, which shifts fluid into the gut causing abdominal distention. Observe for *early* manifestations of this syndrome, which typically occurs within 30 minutes of eating. Symptoms include vertigo, tachycardia, syncope, sweating, pallor, palpitations, and the desire to lie down. Report these manifestations to the surgeon, and encourage the patient to lie down. Monitor the patient for late symptoms.

Late dumping syndrome, which occurs 90 minutes to 3 hours after eating, is caused by a release of an excessive amount of insulin. The insulin release follows a rapid rise in the blood glucose level that results from the rapid entry of high-carbohydrate food into the jejunum. Observe for manifestations, including dizziness, light-headedness, palpitations, diaphoresis, and confusion.

Dumping syndrome is managed by nutrition changes that include decreasing the amount of food taken at one time and eliminating liquids ingested with meals. In collaboration with the dietitian, teach the patient to eat a high-protein, high-fat, low- to moderate-carbohydrate diet ([Table 58-3](#)). Acarbose may be used to decrease carbohydrate absorption. A somatostatin analog, octreotide (Sandostatin), 50 mcg subcutaneously 2 to 3 times daily 30 minutes before meals may be prescribed in severe cases. This drug decreases gastric and intestinal hormone secretion and slows stomach and intestinal transit time.

Alkaline reflux gastropathy, also known as *bile reflux gastropathy*, is a complication of gastric surgery in which the pylorus is bypassed or removed. Endoscopic examination reveals regurgitated bile in the stomach and mucosal

TABLE 58-3 DIET FOR DUMPING SYNDROME

FOOD GROUP	FOODS ALLOWED OR ENCOURAGED	FOODS TO USE WITH CAUTION	FOODS THAT MUST BE EXCLUDED
Soups		Fluids 1 hr before and after meals	Spicy soups
Meat and meat substitutes	8 oz or more per day: fish, poultry, beef, pork, veal, lamb, eggs, cheese, and peanut butter		Spicy meats or meat substitutes
Potato and substitutes	Potato, rice, pasta, starchy vegetables (small amount)		Highly spiced potatoes or substitutes
Bread and cereal	White bread, rolls, muffins, crackers, and cereals (small amount)	Whole-grain bread, rolls, crackers, and cereals	Breads with frosting or jelly, sweet rolls, and coffee cake
Vegetables	Two or more cooked vegetables	Gas-producing vegetables, such as cabbage, onions, broccoli, or raw vegetables	
Fruits	Limit three per day: unsweetened cooked or canned fruits	Unsweetened juice or fruit drinks 30-45 min after meals; fresh fruit	Sweetened fruit or juice
Beverages	Dietetic drinks	Limit to 1 hr after meals; caffeine-containing beverages, such as coffee, tea, and cola; if tolerated, diet carbonated beverages	Milk shakes, malts, and other sweet drinks; regular carbonated beverages and alcohol
Fats	Margarine, oils, shortening, butter, bacon, and salad dressings	Mayonnaise	Any fats with milk products
Desserts	Fruit (see Fruits)	Sugar-free gelatin, pudding, and custard	All sweets, cakes, pies, cookies, candy, ice cream, and sherbet
Seasonings and miscellaneous	Diet jelly, diet syrups, sugar substitutes	Excessive amounts of salt	Excessive amounts of spices, sugar, jelly, honey, syrup, or molasses

General Principles

- Several small meals daily
- Relatively high fat and protein content
- Low roughage
- Relatively low carbohydrate content
- No milk, sweets, or sugars
- Liquid between meals *only*

hyperemia. Symptoms include early satiety (satisfied quickly with little food), abdominal discomfort, and vomiting.

Delayed gastric emptying is often present after gastric surgery and usually resolves within 1 week. Edema at the anastomosis (surgical connection areas) or adhesions (scar tissue) obstructing the distal loop may cause mechanical blockage. Metabolic causes (e.g., hypokalemia, hypoproteinemia, or hyponatremia) should be considered. The edema is resolved with nasogastric suction, maintenance of fluid and electrolyte balance, and proper nutrition.

Afferent loop syndrome may occur when the duodenal loop is partially obstructed after radical surgery. Pancreatic and biliary secretions fill the intestinal loop, which becomes distended. Painful contractions attempt to propel these secretions from the loop. Teach patients to report abdominal bloating and pain 20 to 60 minutes after eating, often followed by nausea and vomiting. Treatment consists of surgical correction of the incomplete loop obstruction.

Several problems related to *nutrition* develop as a result of partial removal of the stomach, including deficiencies of vitamin B₁₂, folic acid, and iron; impaired calcium metabolism; and reduced absorption of calcium and vitamin D. These problems are caused by a reduction of intrinsic factor. The decrease results from the resection and from inadequate absorption because of rapid entry of food into the bowel. In the absence of intrinsic factor, clinical manifestations of pernicious anemia may occur. Assess for the development of atrophic glossitis secondary to vitamin B₁₂

deficiency. In atrophic glossitis, the tongue takes on a shiny, smooth, and “beefy” appearance. The patient may also have signs of anemia secondary to folic acid and iron deficiency. Monitor the complete blood count (CBC) for signs of megaloblastic anemia and leukopenia (low red blood cell [RBC] and white blood cell [WBC] levels). These manifestations are corrected by the administration of vitamin B₁₂. The health care provider may also prescribe folic acid or iron preparations.

DECISION-MAKING CHALLENGE

Patient-Centered Care

A 58-year-old patient had a partial gastrectomy for gastric cancer yesterday and has a nasogastric tube connected to suction. When you meet him to perform your initial assessment, he tells you that he is a family physician who is one of few health care providers in a rural town and is worried about who will care for his patients during his postoperative recovery and treatment. He is also concerned about who will “look after” his older life partner who has been living with him for 21 years.

1. How will you respond to the patient’s concerns?
2. What priority care will you plan to provide for him today and why?
3. For what complications is he at risk and why? How would you know if he has abdominal bleeding?
4. Conduct an electronic data-based search for current evidence related to health teaching for this patient. How will you determine the strength of the evidence? How will you conduct an analysis and draw conclusions about the data you find?

Community-Based Care

Patients who have undergone total gastrectomy and those who are debilitated with advanced gastric cancer are discharged to home with maximal assistance and support or to a transitional care unit or skilled nursing facility. Patients who have undergone subtotal gastrectomy and are not debilitated may be discharged to home with partial assistance for ADLs. Recurrence of cancer is common, and patients need regular follow-up examinations and imaging assessments. Collaborate with the case manager (CM) to ensure continuity of care and thorough follow-up with diagnostic testing.

Home Care Management

Gastric cancer is a life-threatening illness. Therefore the patient and family members require physical and emotional care. Assess their ability to cope with the disease and the possible need for end-of-life care. The adverse effects of gastric cancer treatment can be debilitating, and patients need to learn symptom management strategies. Hospice programs can help both the patient and the family cope with these physical and emotional needs.

Patients may fear returning home because of their inability for self-management. Enlisting family and health care resources for the patient may ease some of this anxiety. Provide the family with adequate information about community support systems to make the transition to home care easier. If the prognosis is poor, they need continued professional support from case managers, social workers, and/or nurses to cope with death and dying. (See [Chapter 9](#) for a discussion of end-of-life care.)

Teaching for Self-Management

Educate the patient and family about any continuing needs, drug therapy, and nutrition therapy. If patients are discharged to home with surgical dressings, teach the patient and family

how to change them. Review the manifestations of incisional infection (e.g., fever, redness, and drainage) that they should report to their surgeon.

Patients who will be receiving radiation therapy or chemotherapy require instructions related to the side effects of these treatments. Nausea and vomiting are common side effects of chemotherapy, and instruction in the use of prescribed antiemetics may be needed. (See [Chapter 24](#) for health teaching for patients receiving chemotherapy or radiation therapy.)

In collaboration with the dietitian, teach the patient and family about the type and quantity of foods that will provide optimal nutritional value. Interventions to minimize dumping syndrome and decrease gastric stimulants are also emphasized (see [Table 58-3](#)). Remind the patient to:

- Eat small, frequent meals
- Avoid drinking liquids with meals
- Avoid foods that cause discomfort
- Eliminate caffeine and alcohol consumption
- Begin a smoking-cessation program, if needed
- Receive B₁₂ injections, as prescribed
- Lie flat after eating for a short time

Health Care Resources

A home care referral provides continued assessment, assistance, and encouragement to the patient and family. A home care nurse can help with care procedures and provide valuable psychological support. Additional referrals to a dietitian, professional counselor, or clergy/spiritual leader may be necessary. Referral to a hospice agency can be of great assistance for the patient with advanced disease. Hospice care may be delivered in the home or in an institutional setting. Appropriate support groups (e.g., I Can Cope, provided by the American Cancer Society) can be a major resource.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing impaired digestion and nutrition as a result of a stomach disorder?

- Report of epigastric pain or indigestion before or after a meal
- Report of inability to tolerate certain foods
- Nausea and/or vomiting (with or without blood)
- Melena or frank blood in stools

What should you INTERPRET and how should you RESPOND to a patient experiencing impaired digestion and nutrition as a result of a stomach disorder?

Perform and interpret physical assessment, including:

- Taking vital signs
- Observing and documenting assessment findings
- Preparing for gastric lavage if hematemesis is present

- Interpreting laboratory values and other diagnostic findings:

- Presence of *H. pylori*
- Decreased hemoglobin and hematocrit

Respond by:

- Maintaining airway, breathing, and circulation (ABCs)
- Placing patient in sitting position or on left side to prevent aspiration if vomiting
- Preparing to assist with gastric lavage if hematemesis is present

On what should you REFLECT?

- Think about what else you could do to care for this patient.
- Consider with whom you should collaborate to improve or maintain digestion and nutrition for this patient.
- After patient interventions, monitor for changes in vital signs, hematocrit, and hemoglobin.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Provide information about organizations for digestive disorders to receive information and support; refer the patient to the American Cancer Society if gastric cancer is the diagnosis.

Health Promotion and Maintenance

- Identify patients at risk for gastritis and PUD, especially older adults who take large amounts of NSAIDs and those with *H. pylori*.
- Teach patients behaviors to prevent PUD, such as avoiding large consumption of caffeine, alcohol, coffee, aspirin, and other NSAIDs. Also teach them to avoid contaminated foods and water and smoking (see [Chart 58-1](#)).
- Teach patients about various complementary and alternative therapies that are currently used for gastritis and PUD.

Psychosocial Integrity

- Allow patients with gastric cancer to express feelings of grief, fear, and anxiety.
- For patients with advanced gastric cancer, identify the need for end-of-life care, including referral to hospice care.

Physiological Integrity

- Teach patients the importance of adhering to *H. pylori* treatment to prevent the risk for gastric cancer.
- For patients who have undergone a gastrectomy, collaborate with the dietitian and instruct the patient regarding diet changes to avoid abdominal distention and dumping syndrome.
- Teach patients with abnormal symptoms (e.g., abdominal tenderness, abdominal pain that is relieved by food or pain

that becomes worse 3 hours after eating, dyspepsia, melena, and/or distention) to consult with their physician immediately for a prompt diagnosis and treatment.

- Teach patients that hematemesis is a medical emergency and that they should go to the emergency department for prompt treatment.
- Teach the proper administration of antacids (one to two after meals). Tell patients that antacids can interfere with the effectiveness of certain drugs, such as phenytoin (Dilantin).
- Teach the proper administration of H₂ antagonists. Explain that they should be given on an empty stomach (see [Chart 58-3](#)).
- Teach the proper administration of antisecretory agents, noting that most cannot be crushed because they are sustained-release or enteric-coated tablets.
- Assess patients for clinical manifestations of gastritis.
- Monitor patients with ulcers for any of the signs and symptoms of GI bleeding that are listed in [Chart 58-4](#). Report any of these symptoms if noted to a physician immediately.
- Insert a nasogastric tube (NGT) as outlined in [Chart 58-5](#).
- After an EGD, monitor the patient's vital signs, heart rhythm, and oxygen saturation frequently until they return to baseline. To prevent aspiration, assess the gag reflex and ensure that it is intact before giving the patient food.
- Observe the patient for signs and symptoms of dumping syndrome after gastric surgery; teach the manifestations and management of this syndrome. Advise the patient to eat six small meals per day and to consume a diet high in protein and fat but low in carbohydrate-rich foods. Liquids should not be taken with meals.

Care of Patients with Noninflammatory Intestinal Disorders

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Prioritize nursing care for the patient with abdominal trauma.
2. Identify community-based resources for patients with colorectal cancer (CRC).
3. Describe the importance of collaborating with health care team members to provide care for patients with CRC.

Health Promotion and Maintenance

4. Teach patients health promotion practices to prevent CRC.
5. Plan health teaching for patients to promote self-management when caring for a colostomy.

Psychosocial Integrity

6. Assess patient and family response to a diagnosis of CRC.

Physiological Integrity

7. Develop a teaching-learning plan for patients with irritable bowel syndrome (IBS).
8. Differentiate the most common types of hernias.
9. Develop a plan of care for a patient undergoing a minimally invasive inguinal hernia repair.
10. Identify risk factors for CRC.
11. Interpret assessment findings for patients with CRC.
12. Explain the role of the nurse in managing the patient with CRC.
13. Develop a perioperative plan of care for a patient undergoing a colon resection and colostomy.
14. Explain the differences between small-bowel and large-bowel obstructions.
15. Develop a plan of care for a patient with an intestinal obstruction to promote elimination.
16. Describe the postoperative care for a patient having a hemorrhoid surgical procedure.
17. Explain the pathophysiology of malabsorption syndrome.

Intestinal health problems may be inflammatory or non-inflammatory. This chapter describes those disorders that are noninflammatory in origin. Noninflammatory intestinal problems often cause rectal bleeding, changing bowel patterns, and abdominal pain. If not diagnosed and managed early, some intestinal problems can lead to inadequate absorption of vital nutrients and therefore affect the need for *nutrition* and *elimination*.

IRRITABLE BOWEL SYNDROME

Pathophysiology

Irritable bowel syndrome (IBS) is a functional GI disorder that causes chronic or recurrent diarrhea, constipation, and/or abdominal pain and bloating. It is sometimes referred to as *spastic colon*, *mucous colon*, or *nervous colon* (Fig. 59-1). IBS is the most common digestive disorder seen in clinical

FIG. 59-1 Spastic contractions of the colon as they occur with irritable bowel syndrome.

practice and may affect as many as one in five people in the United States.

In most patients, no actual pathophysiologic bowel changes occur. However, microscopic inflammatory changes have recently been found in some patients with the disease due to bacterial overgrowth and subsequent infection.

In patients with IBS, bowel motility changes and increased or decreased bowel transit times result in changes in the normal *bowel elimination* pattern to one of these classifications: diarrhea (IBS-D), constipation (IBS-C), alternating diarrhea and constipation (IBS-A), or a mix of diarrhea and constipation (IBS-M). Symptoms of the disease typically begin to appear in young adulthood and continue throughout the patient's life.

The etiology of IBS remains unclear. Recent research suggests that a combination of environmental, immunologic, genetic, hormonal, and stress factors play a role in the development and course of the disease. Examples of environmental factors include foods and fluids like caffeinated or carbonated beverages and dairy products. Infectious agents have also been identified. Several recent studies have found that patients with IBS often have small-bowel bacterial overgrowth, which causes bloating and abdominal distention. Multiple normal flora and pathogenic agents have been identified, including *Pseudomonas aeruginosa* (Kerckhoffs et al., 2011). Other researchers believe that these agents are less causative and serve as measurable biomarkers for the disease (Malinen et al., 2010).

Immunologic and genetic factors have also been associated with IBS, especially cytokine genes, including proinflammatory interleukins (IL) such as IL-6 and tumor necrosis factor (TNF)-alpha (Barkhordari et al., 2010). These findings may provide the basis of targeted drug therapy for the disease.

In the United States, women are two times more likely to have IBS than men. This difference may be the result of hormonal differences. However, in other areas of the world, this distribution pattern may not occur. For example, researchers found that there is not a female predominance for the disease in Asian countries (Gwee et al., 2010).

Considerable evidence relates the role of stress and mental or behavioral illness, especially anxiety and depression, to IBS. Many patients diagnosed with IBS meet the criteria for at least one primary mental health disorder. Some researchers suggest that psychosocial problems may be a cause for IBS (Nicholl et al., 2008). However, the pain and other chronic symptoms of the disease may lead to secondary mental health disorders. For example, when diarrhea is predominant, patients fear that there will be no bathroom facilities available and can become very anxious. The long-term nature of dealing with a chronic disease for which there is no cure can lead to secondary depression in some patients.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Ask the patient about a history of weight change, fatigue, malaise, abdominal pain, changes in the bowel pattern (constipation, diarrhea, or an alternating pattern of both) or consistency of stools, and the passage of mucus. Patients with IBS do not usually lose weight. Ask whether the patient has had any GI infections. Collect information on all drugs the patient is taking, because some of them can cause symptoms similar to those of IBS. Ask about the nutrition history, including the use of caffeinated drinks or beverages sweetened with sorbitol or fructose, which can cause bloating or diarrhea.

The course of the illness is specific to each patient. Most patients can identify factors that cause exacerbations, such as diet, stress, or anxiety. Food intolerance may be associated with IBS. Dairy products (e.g., lactose intolerance), raw fruits, and grains can contribute to bloating, **flatulence** (gas), and abdominal distention.

A flare-up of worsening cramps, abdominal pain, and diarrhea and/or constipation may bring the patient to the health care provider. One of the *most common concerns of patients with IBS is pain in the left lower quadrant of the abdomen*. Assess the location, intensity, and quality of the pain. Some patients have internal visceral (organ) hypersensitivity that can cause or contribute to the pain. Nausea may be associated with mealtime and defecation. The constipated stools are small and hard and are generally followed by several softer stools. The diarrheal stools are soft and watery, and mucus is often present in the stools. Patients with IBS often report belching, gas, anorexia, and bloating.

The patient generally appears well, with a stable weight, and nutritional and fluid status are within normal ranges. Inspect and auscultate the abdomen. Bowel sounds vary but are generally within normal range. With constipation, bowel sounds may be hypoactive; with severe diarrhea, they may be hyperactive.

Routine laboratory values (including a complete blood count [CBC], serum albumin, erythrocyte sedimentation rate [ESR], and stools for occult blood) are normal in IBS. Some health care providers request a *hydrogen breath test*

(Lindberg, 2009). When small-intestinal bacterial overgrowth or malabsorption of nutrients is present, excess hydrogen is produced. Some of this hydrogen is absorbed into the bloodstream and travels to the lungs where it is exhaled. Patients with IBS often have an increased amount of hydrogen during exhalation.

Teach the patient that he or she will need to be NPO (may have water) for at least 12 hours before the hydrogen breath test. At the beginning of the test, the patient blows into a hydrogen analyzer. Then, small amounts of test sugar are ingested, depending on the purpose of the test, and additional breath samples are taken every 15 minutes for 1 hour or longer. If lactose tolerance is evaluated, lactose is ingested. If bacterial overgrowth is tested, lactulose is given (Pagana & Pagana, 2010).

INTERVENTIONS

The patient with IBS is usually cared for in an ambulatory care setting and learns self-management strategies. Interventions include health teaching, drug therapy, and stress reduction. Some patients also use complementary and alternative therapies. A holistic approach to patient care is essential for positive outcomes (Bengtsson et al., 2010).

Keeping a symptom diary in which the patient records potential triggers and bowel habits for a period of time can assist in identifying triggers for disease symptoms. Assist patients to identify and avoid specific foods that they cannot tolerate. These foods may include caffeine, alcohol, egg, wheat products, beverages that contain sorbitol or fructose, and other gastric irritants. Milk and milk products should be avoided if lactose intolerance is suspected. In this case, teach patients to use lactose-free or soy products as substitutes. Patients who are lactose intolerant need to increase intake of calcium-rich, lactose-free foods or take a calcium supplement because they are at high risk for osteoporosis.

Dietary fiber and bulk help produce bulky, soft stools and establish regular bowel habits. The patient should ingest about 30 to 40 g of fiber each day. Eating regular meals, drinking 8 to 10 cups of liquid each day, and chewing food slowly help promote normal bowel function. If needed, collaborate with the dietitian to help the patient and family with meal planning.

Drug therapy depends on the predominant symptom of IBS. The health care provider may prescribe bulk-forming or antidiarrheal agents and/or newer drugs to control symptoms.

For the treatment of *constipation-predominant IBS (IBS-C)*, bulk-forming laxatives, such as *psyllium* hydrophilic mucilloid (Metamucil), are generally taken at mealtimes with a glass of water. The hydrophilic properties of these drugs help prevent dry, hard, or liquid stools. *Lubiprostone* (Amitiza) is a new oral drug available for women with IBS-C. The drug is not effective for men. Lubiprostone is classified as a locally acting chloride channel activator that increases intestinal chloride without affecting intestinal sodium and potassium concentrations. Teach the patient to take the drug with food and water.

Diarrhea-predominant IBS (IBS-D) may be treated with antidiarrheal agents, such as loperamide (Imodium), and psyllium (a bulk-forming agent). *Alosetron* (Lotronex), a selective serotonin (5-HT₃) receptor antagonist, may be used with caution in women with IBS-D as a last resort when they

have not responded to conventional therapy. Patients taking this drug must agree to report symptoms of colitis or constipation early because it is associated with potentially life-threatening bowel complications.

! NURSING SAFETY PRIORITY

Drug Alert

Before the patient begins alosetron, take a thorough drug (including herbs) history, both prescribed and over the counter, because it interacts with many drugs in a variety of classes. Teach patients to report constipation, fever, increasing abdominal pain, increasing fatigue, darkened urine, bloody diarrhea, or rectal bleeding as soon as it occurs and stop the drug immediately.

Many patients with IBS who have bloating and abdominal distention without constipation have success with *rifaximin* (Xifaxan), an antibiotic that works locally with little systemic absorption (Pimental et al., 2011). Although the drug has been approved for “traveler’s diarrhea” and other illnesses, the U.S. Food and Drug Administration (FDA) has not yet approved its use for patients with IBS.

A newer group of drugs called *muscarinic-receptor antagonists* also inhibit intestinal motility. Some of these agents have been approved for people with overactive bladders but have not yet received FDA approval for IBS. Examples in this group currently undergoing clinical trials are darifenacin (Enablex) and fesoterodine (Toviaz).

For IBS in which pain is the predominant symptom, tricyclic antidepressants such as amitriptyline (Elavil) have also been successfully used. It is unclear whether their effectiveness is due to the antidepressant or anticholinergic effects of the drugs. If patients have postprandial (after eating) discomfort, they should take these drugs 30 to 45 minutes before mealtime.

Complementary and Alternative Therapies

For patients with increased intestinal bacterial overgrowth, recommend daily probiotic supplements. *Probiotics* have been shown to be effective for reducing bacteria and successfully alleviating GI symptoms of IBS (Lyra et al., 2010). There is also evidence that peppermint oil capsules may be effective in reducing symptoms for patients with IBS (Pirodda, 2009).

Acupuncture and moxibustion (Acu-Moxa) treatment has helped some patients by reducing flatulence and bloating and improving stool consistency (Anastasi et al., 2009). Moxibustion is the use of herbs to facilitate healing. Encourage patients to try these therapies, especially if they can be reimbursed by insurance companies. Third-party payers are becoming more sensitive to the use of these proven therapies as adjuncts in holistic disease management.

Stress management is also an important part of holistic care. Suggest relaxation techniques, meditation, and/or yoga to help the patient decrease GI symptoms. If the patient is in a stressful work or family situation, personal counseling may be helpful. Based on patient preference, make appropriate referrals or assist in making appointments, if needed. The opportunity to discuss problems and attempt creative problem solving is often helpful. Teach the patient that regular exercise is important for managing stress and promoting regular bowel elimination.

FIG. 59-2 Types of abdominal hernias.

FIG. 59-3 A right direct inguinal hernia.

HERNIATION

Pathophysiology

A **hernia** is a weakness in the abdominal muscle wall through which a segment of the bowel or other abdominal structure protrudes. Hernias can also penetrate through any other defect in the abdominal wall, through the diaphragm, or through other structures in the abdominal cavity.

The most common types of abdominal hernias (Fig. 59-2) are indirect, direct, femoral, umbilical, and incisional.

- An **indirect inguinal hernia** is a sac formed from the peritoneum that contains a portion of the intestine or omentum. The hernia pushes downward at an angle into the inguinal canal. In males, indirect inguinal hernias can become large and often descend into the scrotum.
- **Direct inguinal hernias**, in contrast, pass through a weak point in the abdominal wall (Fig. 59-3).
- **Femoral hernias** protrude through the femoral ring. A plug of fat in the femoral canal enlarges and eventually pulls the peritoneum and often the urinary bladder into the sac.
- **Umbilical hernias** are congenital or acquired. Congenital umbilical hernias appear in infancy. Acquired umbilical hernias directly result from increased intra-abdominal pressure. They are most commonly seen in obese people.

- **Incisional, or ventral, hernias** occur at the site of a previous surgical incision. These hernias result from inadequate healing of the incision, which is usually caused by postoperative wound infections, inadequate nutrition, and obesity.

Hernias may also be classified as reducible, irreducible (incarcerated), or strangulated. A hernia is **reducible** when the contents of the hernial sac can be placed back into the abdominal cavity by gentle pressure. An **irreducible** (incarcerated) hernia cannot be reduced or placed back into the abdominal cavity. *Any hernia that is not reducible requires immediate surgical evaluation.*

A hernia is **strangulated** when the blood supply to the herniated segment of the bowel is cut off by pressure from the hernial ring (the band of muscle around the hernia). If a hernia is strangulated, there is ischemia and obstruction of the bowel loop. This can lead to necrosis of the bowel and possibly bowel perforation. *Signs of strangulation are abdominal distention, nausea, vomiting, pain, fever, and tachycardia.*

The most important elements in the development of a hernia are congenital or acquired muscle weakness and increased intra-abdominal pressure. The most significant factors contributing to increased intra-abdominal pressure are obesity, pregnancy, and lifting heavy objects.

Indirect inguinal hernias, the most common type, are most common in men because they follow the tract that develops when the testes descend into the scrotum before birth. Direct hernias occur more often in older adults. Femoral and adult umbilical hernias are most common in obese or pregnant women. Incisional hernias can occur in people who have undergone abdominal surgery.

Defects in the muscle wall result from weakened collagen or widened spaces at the inguinal ligament. These muscle weaknesses can be inherited or acquired as part of the aging process. Increases in intra-abdominal pressure as a result of pregnancy, obesity, abdominal distention, ascites, heavy lifting, or coughing can contribute to their occurrence.

Health Promotion and Maintenance

Even though the muscle weakness cannot be prevented, exercises can strengthen muscles. Obesity is considered a contributing factor because it causes increased intra-abdominal pressure. Weight control helps decrease the likelihood of hernias by decreasing pressure on the abdominal muscles.

Heavy lifting and straining also increase intra-abdominal pressure and should be avoided.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The patient with a hernia typically comes to the health care provider's office or the emergency department with a report of a "lump" or protrusion felt at the involved site. The development of the hernia may be associated with straining or lifting.

Perform an abdominal assessment inspecting the abdomen when the patient is lying and again when he or she is standing. If the hernia is reducible, it may disappear when the patient is lying flat. The advanced practice nurse or other health care provider asks the patient to strain or perform the Valsalva maneuver and observes for bulging. Auscultate for active bowel sounds. *Absent bowel sounds may indicate obstruction and strangulation, which is a medical emergency!*

To palpate an inguinal hernia, the health care provider gently examines the ring and its contents by inserting a finger in the ring and noting any changes when the patient coughs. *The hernia is never forcibly reduced; that maneuver could cause strangulated intestine to rupture.*

If a male patient suspects a hernia in his groin, the health care provider has him stand for the examination. Using the right hand for the patient's right side and the left hand for the patient's left side, the examiner pushes in the loose scrotal skin with the index finger, following the spermatic cord upward to the external inguinal cord. At this point, the patient is asked to cough, and any palpable herniation is noted.

INTERVENTIONS

The type of treatment selected depends on patient factors such as age, as well as the type and severity of the hernia.

Nonsurgical Management

If the patient is not a surgical candidate, often an older adult with multiple health problems, the health care provider may prescribe a truss for an inguinal hernia, most often for men. A **truss** is a pad made with firm material. It is held in place over the hernia with a belt to help keep the abdominal contents from protruding into the hernial sac. If a truss is used, it is applied only after the physician has reduced the hernia if it is not incarcerated. The patient usually applies the truss upon awakening. Teach him to assess the skin under the truss daily and to protect it with a light layer of powder.

Surgical Management

Most hernias are inguinal. Surgical repair of a hernia is the treatment of choice. Surgery is usually performed on an ambulatory care basis for patients who have no pre-existing health conditions that would complicate the operative course. In same-day surgery centers, anesthesia may be regional or general and the surgery is typically laparoscopic. More extensive surgery, such as a bowel resection or temporary colostomy, may be necessary if strangulation results in a gangrenous section of bowel. Patients undergoing extensive surgery are hospitalized for a longer period.

A **minimally invasive inguinal hernia repair (MIIHR)** through a laparoscope, also called **herniorrhaphy**, is the surgery of choice. A conventional open herniorrhaphy may be performed when laparoscopy is not appropriate. Patients having minimally invasive surgery (MIS) recover more quickly, have less pain, and develop fewer postoperative complications compared with those having the conventional surgery.

In addition to patient education about the procedure, the most important preoperative preparation is to teach the patient to remain NPO for the number of hours before surgery that the surgeon specifies. If same-day surgery is planned, remind the patient to arrange for someone to take him or her home and be available for the rest of the day at home. For patients having an open surgical approach, provide general preoperative care as described in [Chapter 16](#).

During an MIIHR, the surgeon makes several small incisions, identifies the defect, and places the intestinal contents back into the abdomen. During a traditional herniorrhaphy, the surgeon makes an abdominal incision to perform this procedure. When a **hernioplasty** is also performed, the surgeon reinforces the weakened outside abdominal muscle wall with a mesh patch.

The patient who has had MIIHR is discharged from the surgical center in 3 to 5 hours, depending on recovery from anesthesia. Teach him or her to rest for several days before returning to work and a normal routine. Caution patients who are taking oral opioids for pain management to not drive or operate heavy machinery. Teach them to observe incisions for redness, swelling, heat, drainage, and increased pain and promptly report their occurrence to the surgeon. Remind patients that soreness and discomfort rather than severe, acute pain are common after MIS. Be sure to make a follow-up telephone call on the day after surgery to check on the patient's status.

General postoperative care of patients having a hernia repair is the same as that described in [Chapter 18](#) *except that they should avoid coughing*. To promote lung expansion, encourage deep breathing and ambulation. With repair of an indirect inguinal hernia, the physician may suggest a scrotal support and ice bags applied to the scrotum to prevent swelling, which often contributes to pain. Elevation of the scrotum with a soft pillow helps prevent and control swelling.

In the immediate postoperative period, male patients who have had an inguinal hernia repair may experience difficulty voiding. Encourage them to stand to allow a more natural position for gravity to facilitate voiding and bladder emptying. Urine output of less than 30 mL per hour should be reported to the surgeon. Techniques to stimulate voiding such as allowing water to run may also be used. A fluid intake of at least 1500 to 2500 mL daily prevents dehydration and maintains urinary function. A "straight" or intermittent catheterization is required if the patient cannot void.

Most patients have uneventful recoveries after a hernia repair. Surgeons generally allow them to return to their usual activities after surgery, with avoidance of straining and lifting for several weeks while subcutaneous tissues heal and strengthen.

Provide oral instructions and a written list of symptoms to be reported, including fever, chills, wound drainage, redness or separation of the incision, and increasing incisional pain. Teach the patient to keep the wound dry and clean with antibacterial soap and water. Showering is usually permitted in a few days.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A nurse is caring for a client 1 day after an open hernia repair surgery. Which assessment finding will the nurse report to the surgeon immediately?

- A. Pain in the incisional area
- B. Blood pressure of 130/82 mm Hg
- C. Bronchovesicular breath sounds
- D. Rigid, board-like abdomen

COLORECTAL CANCER

Pathophysiology

Colorectal refers to the colon and rectum, which together make up the large intestine, also known as the *large bowel*. Colorectal cancer (CRC) is cancer of the colon or rectum and is a major health problem worldwide. In the United States, it is one of the most common malignancies.

Most CRCs are **adenocarcinomas**, which are tumors that arise from the glandular epithelial tissue of the colon. They develop as a multi-step process, resulting in a number of molecular changes, such as loss of key tumor suppressor genes and activation of certain oncogenes that alter colonic mucosa cell division. The increased proliferation of the colonic mucosa forms polyps that can transform into malignant tumors. Most CRCs are believed to arise from adenomatous polyps that present as a visible protrusion from the mucosal surface of the bowel (McCance et al., 2010).

Tumors occur in different areas of the colon, with about two thirds occurring within the rectosigmoid region. The percentages in Fig. 59-4 indicate an increased incidence of cancer in the proximal sections of the large intestine over the past 35 years.

Colorectal cancer (CRC) can metastasize by direct extension or by spreading through the blood or lymph. The tumor may spread locally into the four layers of the bowel wall and

into neighboring organs. It may enlarge into the lumen of the bowel or spread through the lymphatics or the circulatory system. The circulatory system is entered directly from the primary tumor through blood vessels in the bowel or via the lymphatics. The liver is the most frequent site of metastasis from circulatory spread. Metastasis to the lungs, brain, bones, and adrenal glands may also occur. Colon tumors can also spread by peritoneal seeding during surgical resection of the tumor. Seeding may occur when a tumor is excised and cancer cells break off from the tumor into the peritoneal cavity. For this reason, special techniques are used during surgery to decrease this possibility.

Complications related to the increasing growth of the tumor locally or through metastatic spread include bowel obstruction or perforation with resultant peritonitis, abscess formation, and fistula formation to the urinary bladder or the vagina. The tumor may invade neighboring blood vessels and cause frank bleeding. Tumors growing into the bowel lumen can gradually obstruct the intestine and eventually block it completely. Those extending beyond the bowel wall may place pressure on neighboring organs (uterus, urinary bladder, and ureters) and cause symptoms that mask those of the cancer. Chapter 23 discusses cancer pathophysiology in more detail.

Etiology and Genetic Risk

The major risk factors for the development of colorectal cancer (CRC) include being older than 50 years, genetic predisposition, personal or family history of cancer, and/or diseases that predispose the patient to cancer such as familial adenomatous polyposis (FAP), Crohn's disease, and ulcerative colitis (McCance et al., 2010). Only a small percentage of colorectal cancers are familial and transmitted genetically.

GENETIC/GENOMIC CONSIDERATIONS

People with a first-degree relative (sister, sibling, or child) diagnosed with colorectal cancer (CRC) have three to four times the risk for developing the disease. An autosomal dominant inherited genetic disorder known as *familial adenomatous polyposis (FAP)* accounts for 1% of CRCs. FAP is the result of one or more mutations in the adenomatous polyposis coli (APC) gene (McCance et al., 2010). In these very young patients, thousands of adenomatous polyps develop over the course of 10 to 15 years and have nearly a 100% chance of becoming malignant. By 20 years of age, most patients require surgical intervention, usually a colectomy with ileostomy or ileoanal pull-through, to prevent cancer. Chemotherapy may also be used for cancer prevention.

Hereditary nonpolyposis colorectal cancer (HNPCC) is another autosomal dominant disorder and accounts for a small percentage of all colorectal cancers. HNPCC is also caused by gene mutations, including *MLH1* and *MLH2*. People with these mutations have an 80% chance of developing CRC at an average of 45 years of age. They also tend to have a higher incidence of endometrial, ovarian, stomach, and ureteral cancers (Nussbaum et al., 2007). Genetic testing is available for both of these familial CRC syndromes. Refer patients for genetic counseling and possible testing if the patient prefers.

FIG. 59-4 The incidence of cancer in relation to colorectal anatomy.

The role of infectious agents in the development of colorectal and anal cancer continues to be investigated. Some lower GI cancers are related to *Helicobacter pylori*, *Streptococcus bovis*, JC virus, and human papilloma virus (HPV) infections.

There is also strong evidence that long-term smoking, increased body fat, physical inactivity, and heavy alcohol

consumption are risk factors for colorectal cancer ([American Cancer Society \[ACS\], 2010](#)). A high-fat diet, particularly animal fat from red meats, increases bile acid secretion and anaerobic bacteria, which are thought to be carcinogenic within the bowel. Diets with large amounts of refined carbohydrates that lack fiber decrease bowel transit time.

Incidence/Prevalence

Colorectal cancer (CRC) is the third most common cause of cancer death in the United States ([ACS, 2010](#)). It is not common before 40 years of age, but the incidence in younger adults is slowly increasing, most likely due to increases in HPV infections ([Stubenrauch, 2010](#)). The overall incidence of CRC has decreased over the past 10 years, most likely as a result of increased cancer screenings. The disease is most common in African Americans, and their survival rate is lower than that of Euro-Americans (Caucasians). The possible reasons for this difference include less use of diagnostic testing (especially colonoscopy), decreased access to health care, cultural beliefs, and lack of education about the need for early cancer detection (Good et al., 2010; [Hamlyn, 2008](#)).

Health Promotion and Maintenance

People at risk can take action to decrease their chance of getting CRC and/or increase their chance of surviving it. For example, those whose family members have had hereditary CRC should be genetically tested for FAP and HNPCC. If gene mutations are present, the person at risk can collaborate with the health care team to decide what prevention or treatment plan to implement.

Teach people about the need for diagnostic screening. When an adult turns 40 years of age, he or she should discuss with the health care provider about the need for colon cancer screening. The interval depends on level of risk. People of average risk who are 50 years of age and older, without a family history, should undergo regular CRC screening. The screening includes fecal occult blood testing (FOBT) and colonoscopy every 10 years or double-contrast barium enema every 5 years. People who have a personal or family history of the disease should begin screening earlier and more frequently ([National Comprehensive Cancer Network, 2008](#)). Teach all patients to follow the American Cancer Society recommendations for CRC screening listed in [Chart 59-1](#).

Teach patients, regardless of risk, to modify their diets as needed to decrease fat, refined carbohydrates, and low-fiber foods. Encourage baked or broiled foods, especially those high in fiber and low in animal fat. Teach people the hazards of smoking, excessive alcohol, and physical inactivity. Refer patients as needed for smoking- or alcohol-cessation programs, and recommend ways to increase regular physical exercise.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

When taking a history, ask the patient about major risk factors, such as a personal history of breast, ovarian, or endometrial cancer (which can spread to the colon); ulcerative colitis; Crohn's disease; familial polyposis or adenomas;

CHART 59-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Screening Recommendations for Men and Women Ages 50 Years and Older at Average Risk for Colorectal Cancer

PROCEDURE: CHOICE OF ONE OF THE FOLLOWING	INTERVAL AFTER SCREENING INITIATED AT AGE 50 YEARS	COMMENTS
FOBT and sigmoidoscopy	Every 5 years	FOBT procedure: two or three samples from three consecutive bowel movements obtained at home; tested by physician or nurse
OR Double-contrast barium enema	Every 5 years	
OR Colonoscopy	Every 10 years	

FOBT, Fecal occult blood testing.

polyps, or a family history of CRC. Also assess the patient's participation in age-specific cancer screening guidelines. Ask about whether the patient uses tobacco and/or alcohol. Assess the patient's usual physical activity level.

Ask whether vomiting and changes in bowel habits, such as constipation or change in shape of stool with or without blood, have been noted. The patient may also report fatigue (related to anemias), abdominal fullness, vague abdominal pain, or unintentional weight loss. These symptoms suggest advanced disease.

Physical Assessment/Clinical Manifestations

The clinical manifestations of CRC depend on the location of the tumor. *However, the most common signs are rectal bleeding, anemia, and a change in stool consistency or shape.* Stools may contain microscopic amounts of blood that are not noticeably visible, or the patient may have mahogany (dark)-colored or bright red stools ([Fig. 59-5](#)). Gross blood is not usually detected with tumors of the right side of the colon but is common (but not massive) with tumors of the left side of the colon and the rectum.

Tumors in the transverse and descending colon result in symptoms of obstruction as growth of the tumor blocks the passage of stool. The patient may report "gas pains," cramping, or incomplete evacuation. Tumors in the rectosigmoid colon are associated with [hematochezia](#) (the passage of red blood via the rectum), straining to pass stools, and narrowing of stools. Patients may report dull pain. Right-sided tumors can grow quite large without disrupting bowel patterns or appearance because the stool consistency is more liquid in this part of the colon. These tumors ulcerate and bleed intermittently, so stools can contain dark or mahogany-colored blood. A mass may be palpated in the lower right quadrant, and the patient often has anemia secondary to blood loss.

Examination of the abdomen begins with assessment for obvious distention or masses. Visible peristaltic waves accompanied by high-pitched or "tinkling" bowel sounds may indicate a partial bowel obstruction from the tumor. Total absence

FIG. 59-5 Common causes of lower gastrointestinal bleeding.

of bowel sounds indicates a complete bowel obstruction. Palpation and percussion are performed by the advanced practice nurse or other health care provider to determine whether the spleen or liver is enlarged or whether masses are present along the colon. The examiner may also perform a digital rectal examination to palpate the rectum and lower sigmoid colon for masses. Fecal occult blood screening should not be done with a specimen from a rectal examination because it is not reliable.

Psychosocial Assessment

The psychological consequences associated with a diagnosis of colorectal cancer (CRC) are many. Patients must cope with a diagnosis that instills fear and anxiety about treatment, feelings that life has been disrupted, a need to search for ways to deal with the diagnosis, and concern about family. They also have questions about why colon cancer affected them, as well as concerns about pain, possible disfigurement, and possible death. In addition, if the cancer is believed to have a genetic origin, there is anxiety concerning implications for immediate family members.

Laboratory Assessment

Hemoglobin and hematocrit values are often decreased as a result of the intermittent bleeding associated with the tumor. For some patients, that may be the first indication that a tumor is present. CRC that has metastasized to the liver causes liver function tests to be elevated.

A positive test result for occult blood in the stool (**fecal occult blood test [FOBT]**) indicates bleeding in the GI tract. These tests can yield false-positive results if certain vitamins or drugs are taken before the test. Remind the patient to avoid aspirin, vitamin C, and red meat for 48 hours before giving a stool specimen. Also assess whether the patient is taking anti-inflammatory drugs (e.g., ibuprofen, corticosteroids, or

salicylates). These drugs should be discontinued for a designated period before the test. Two or three separate stool samples should be tested on 3 consecutive days. Negative results do not completely rule out the possibility of CRC.

Carcinoembryonic antigen (CEA), an oncofetal antigen, is elevated in many people with CRC. The normal value is less than 5 ng/mL or 5 mcg/L (SI units) (Pagana & Pagana, 2010). This protein is not specifically associated with the colorectal cancer, and it may be elevated in the presence of other benign or malignant diseases and in smokers. CEA is often used to monitor the effectiveness of treatment and to identify disease recurrence.

Imaging Assessment

A double-contrast barium enema (air and barium are instilled into the colon) or colonoscopy provides better visualization of polyps and small lesions than a barium enema alone. These tests may show an occlusion in the bowel where the tumor is decreasing the size of the lumen.

Computed tomography (CT) or magnetic resonance imaging (MRI) of the chest, abdomen, pelvis, lungs, or liver helps confirm the existence of a mass, the extent of disease, and the location of distant metastases. CT-guided virtual colonoscopy is growing in popularity and may be more thorough than traditional colonoscopy. However, treatments or surgeries cannot be performed when a virtual colonoscopy is used.

Other Diagnostic Assessment

A sigmoidoscopy provides visualization of the lower colon using a fiberoptic scope. Polyps can be visualized, and tissue samples can be taken for biopsy. Polyps are usually removed during the procedure. A colonoscopy provides views of the entire large bowel from the rectum to the ileocecal valve. As with sigmoidoscopy, polyps can be seen and removed, and tissue samples can be taken for biopsy. *Colonoscopy is the definitive test for the diagnosis of colorectal cancer. These procedures and associated nursing care are discussed in Chapter 55.*

ANALYSIS

The priority problems for patients with colorectal cancer (CRC) include:

1. Potential for colorectal cancer metastasis
2. Grieving related to cancer diagnosis

PLANNING AND IMPLEMENTATION

The primary approach to treating CRC is to remove the entire tumor or as much of the tumor as possible to prevent or slow metastatic spread of the disease. A patient-centered collaborative care approach is essential to meet the desired outcomes.

Preventing or Controlling Metastasis

Planning: Expected Outcomes. The patient with colorectal cancer (CRC) is expected to not have the cancer spread to vital organs. Thus the patient's life expectancy will be increased and the quality of life will be improved. However, if metastasis is present, the desired outcome is to ensure that the patient is as comfortable as possible and pain is well-managed.

Interventions. Although surgical resection is the primary means used to control the disease, several adjuvant (additional) therapies are used. Adjuvant therapies are

administered before or after surgery to achieve a cure, if possible, and to prevent recurrence.

Nonsurgical Management. The type of therapy used is based on the pathologic staging of the disease. Several staging systems may be used. The American Joint Committee on Cancer (AJCC) system uses this broad staging classification and description:

- Stage I—Tumor invades up to muscle layer
- Stage II—Tumor invades up to other organs or perforates peritoneum
- Stage III—Any level of tumor invasion and up to 4 regional lymph nodes
- Stage IV—Any level of tumor invasion; many lymph nodes affected with distant metastases

Radiation Therapy. The administration of preoperative radiation therapy has not improved overall survival rates for colon cancer, but it has been effective in providing local or regional control of the disease. Postoperative radiation has not demonstrated any consistent improvement in survival or recurrence. However, as a palliative measure, radiation therapy may be used to control pain, hemorrhage, bowel obstruction, or metastasis to the lung in advanced disease. For rectal cancer, unlike colon cancer, radiation therapy is almost always a part of the treatment plan. Reinforce information about the radiation therapy procedure to the patient and family, and monitor for possible side effects (e.g., diarrhea, fatigue). **Chapter 24** describes the general care of patients undergoing radiation therapy.

Drug Therapy. Adjuvant *chemotherapy* after primary surgery is recommended for patients with stage II or stage III disease to interrupt the DNA production of cells and improve survival. The drugs of choice are IV 5-fluorouracil (5-FU) with leucovorin (LV) (folinic acid), capecitabine (Xeloda), or a combination of drugs referred to as *FOLFOX*. The most frequently used *FOLFOX* combination for metastatic CRC is 5-FU (fluorouracil), leucovorin, and oxaliplatin (Eloxatin), a platinum analog. These drugs cannot discriminate between cancer and healthy cells. Therefore common side effects are diarrhea, mucositis, leukopenia, mouth ulcers, and peripheral neuropathy.

Bevacizumab (Avastin) is the first antiangiogenesis drug to be approved for advanced CRC. This type of drug reduces blood flow to the growing tumor cells, thereby depriving them of necessary nutrients needed to grow. It is usually given in combination with other chemotherapeutic agents.

Cetuximab (Erbix), a monoclonal antibody, may also be given for advanced disease. This drug works by blocking factors that promote cancer cell growth. Cetuximab is usually given in combination with another drug.

Intrahepatic arterial chemotherapy, often with 5-FU, may be administered to patients with liver metastasis. Patients with CRC also receive drugs for relief of symptoms, such as opioid analgesics and antiemetics.

Surgical Management. Surgical removal of the tumor with margins free of disease is the best method of ensuring removal of CRC. The size of the tumor, its location, the extent of metastasis, the integrity of the bowel, and the condition of the patient determine which surgical procedure is performed for colorectal cancer (**Table 59-1**). Many regional lymph nodes are removed and examined for presence of cancer. The number of lymph nodes that contain cancer is a strong predictor of prognosis. The most common surgeries performed

TABLE 59-1 SURGICAL PROCEDURES FOR COLORECTAL CANCERS IN VARIOUS LOCATIONS

Right-Sided Colon Tumors

- Right hemicolectomy for smaller lesions
- Right ascending colostomy or ileostomy for large, widespread lesions
- Cecostomy (opening into the cecum with intubation to decompress the bowel)

Left-Sided Colon Tumors

- Left hemicolectomy for smaller lesions
- Left descending colostomy for larger lesions

Sigmoid Colon Tumors

- Sigmoid colectomy for smaller lesions
- Sigmoid colostomy for larger lesions
- Abdominoperineal resection for large, low sigmoid tumors (near the anus) with colostomy (the rectum and the anus are completely removed, leaving a perineal wound)

Rectal Tumors

- Resection with anastomosis or pull-through procedure (preserves anal sphincter and normal elimination pattern)
- Colon resection with permanent colostomy
- Abdominoperineal resection with colostomy

are **colon resection** (removal of the tumor and regional lymph nodes) with reanastomosis, **colectomy** (colon removal) with *colostomy* (temporary or permanent) or *ileostomy/ileoanal pull-through*, and **abdominoperineal (AP) resection**. A **colostomy** is the surgical creation of an opening of the colon onto the surface of the abdomen. An AP resection is performed when rectal tumors are present. The surgeon removes the sigmoid colon, rectum, and anus through combined abdominal and perineal incisions.

For patients having a colon resection, minimally invasive surgery (MIS) via laparoscopy is commonly performed today. This procedure results in shorter hospital stays, less pain, fewer complications, and quicker recovery compared with the conventional open surgical approach.

Preoperative Care. Reinforce the physician's explanation of the planned surgical procedure. The patient is told as accurately as possible what anatomic and physiologic changes will occur with surgery. The location and number of incision sites and drains are also discussed.

Before evaluating the tumor and colon during surgery, the surgeon may not be able to determine whether a colostomy (or less commonly, an ileostomy) will be necessary. The patient is told that a colostomy is a possibility. If a colostomy is planned, the surgeon consults a certified wound, ostomy, continence nurse (CWOCN) or an enterostomal therapist (ET) (ostomy nurse) to recommend optimal placement of the ostomy. He or she teaches the patient about the rationale and general principles of ostomy care. In many settings, the CWOCN marks the patient's abdomen to indicate a potential ostomy site that will decrease the risk for complications such as interference of the undergarments or a prosthesis with the ostomy appliance. **Table 59-2** describes the role of the CWOCN or ET.

The patient who requires low rectal surgery (e.g., AP resection) is faced with the risk for postoperative sexual

TABLE 59-2 PREOPERATIVE ASSESSMENT BY THE CWCN OR ET NURSE**Key Points of Psychosocial Assessment**

- Patient's and family's level of knowledge of disease and ostomy care
- Patient's educational level
- Patient's physical limitations (particularly sensory)
- Support available to patient
- Patient's type of employment
- Patient's involvement in activities such as hobbies
- Financial concerns regarding purchase of ostomy supplies

Key Points of Physical Assessment

- Before marking, the nurse specialist considers:
 - Contour of the abdomen in lying, sitting, and standing positions
 - Presence of skin folds, creases, bony prominences, and scars
 - Need to avoid a prosthesis
 - Location of belt line
 - Location that is easily visible to the patient
 - Possible location in the rectus muscle

Adapted from Pontieri-Lewis, V. (2006). Basics of ostomy care. *MEDSURG Nursing*, 15(4), 199-202.
 ET, Enterostomal therapist; CWCN, certified wound, ostomy, continence nurse.

dysfunction and urinary incontinence after surgery as a result of nerve damage during surgery. The surgeon discusses the risk for these problems with the patient before surgery and allows him or her to verbalize concerns and questions related to this risk. Reinforce teaching about abdominal surgery performed for the patient under general anesthesia, and review the routines for turning and deep breathing (see [Chapter 16](#)). Teach the patient about the method of pain management to be used after surgery such as IV patient-controlled analgesia (PCA), epidural analgesia, or other method.

If the bowel is not obstructed or perforated, elective surgery is planned. The patient may be instructed to thoroughly clean the bowel, or “bowel prep,” to minimize bacterial growth and prevent complications. Mechanical cleaning is accomplished with laxatives and enemas or with “whole-gut lavage.” For whole-gut lavage, the patient may drink large quantities of a sodium sulfate and polyethylene glycol solution (e.g., GoLYTELY). This solution overwhelms the absorptive capacity of the small bowel and clears feces from the colon. However, the use of bowel preps is controversial, and some surgeons do not recommend it because of patient discomfort. Older adults may become dehydrated from this process. Infection rates are not different with or without bowel preps.

To reduce the risk for infection, the surgeon may prescribe one dose of oral or IV antibiotics to be given before the surgical incision is made. Teach patients that a nasogastric tube (NGT) may be placed for decompression of the stomach after surgery. A peripheral IV or central venous catheter is also placed for fluid and electrolyte replacement while the patient is NPO after surgery. Patients having minimally invasive surgeries do not need an NGT.

The patient with colorectal cancer faces a serious illness with long-term consequences of the disease and treatment. A case manager or social worker can be very helpful in identifying patient and family needs, as well as ensuring continuity of care and support.

Operative Procedures. For the conventional open surgical approach, the surgeon makes a large incision in the abdomen and explores the abdominal cavity to determine whether the tumor can be removed. For a colon resection, the portion of the colon with the tumor is excised and the two open ends of the bowel are irrigated before **anastomosis** (reattachment) of the colon. If an anastomosis is not feasible because of the location of the tumor or the bowel is inflamed, a colostomy is created.

A colostomy may be created in the ascending, transverse, descending, or sigmoid colon ([Fig. 59-6](#)). One of several techniques is used to construct a colostomy. A loop **stoma** (surgical opening) is made by bringing a loop of colon to the skin surface, severing and everting the anterior wall, and suturing it to the abdominal wall. Loop colostomies are usually performed in the transverse colon and are usually temporary. An external rod may be used to support the loop until the intestinal tissue adheres to the abdominal wall. Care must be taken to avoid displacing the rod, especially during appliance changes.

An end stoma is often constructed, most often in the descending or sigmoid colon, when a colostomy is intended to be permanent. It may also be done when the surgeon oversees the distal stump of the colon and places it in the abdominal cavity, preserving it for future reattachment. An end stoma is constructed by severing the end of the proximal portion of the bowel and bringing it out through the abdominal wall.

The least common colostomy is the **double-barrel stoma**, which is created by dividing the bowel and bringing both the proximal and distal portions to the abdominal surface to create two stomas. The proximal stoma (closest to the patient's head) is the functioning stoma and eliminates stool. The distal stoma (farthest from the head) is considered nonfunctioning, although it may secrete some mucus. The distal stoma is sometimes referred to as a *mucous fistula*.

MIS colon resection or total colectomy allows complete tumor removal with an adequate surgical margin and removal of associated lymph nodes. Several small incisions are made, and a miniature video camera is placed within the abdomen to help see the area that is involved. This technique takes longer than the conventional procedure and requires specialized training. However, blood loss is less.

Postoperative Care. Patients who have an *open colon resection* without a colostomy receive care similar to that of those having any abdominal surgery (see [Chapter 18](#)). Other patients have surgeries that also require colostomy management. They typically have a nasogastric tube (NGT) after open surgery and receive IV PCA for the first 24 to 36 hours. After NGT removal, the diet is slowly progressed from liquids to solid foods as tolerated. The care of patients with an NGT is found on p. 1256 in the discussion of Interventions in the Intestinal Obstruction section.

By contrast, patients who have *laparoscopic (MIS) surgery* can progress from liquids to solids more quickly. Because they usually have less pain, they are able to ambulate earlier than those who have the conventional approach. The hospital stay is usually shorter for the patient with MIS—less than 23 hours or 1 to 2 days, depending on the patient's age and general condition.

Colostomy Management. The patient who has a colostomy may return from surgery with a clear ostomy pouch system

The **ascending colostomy** is done for right-sided tumors.

The **transverse (double-barrel) colostomy** is often used in such emergencies as intestinal obstruction or perforation because it can be created quickly. There are two stomas. The proximal one, closest to the small intestine, drains feces. The distal stoma drains mucus.

The **descending colostomy** is done for left-sided tumors.

The **sigmoid colostomy** is done for rectal tumors.

FIG. 59-6 Different locations of colostomies in the colon.

in place. A clear pouch allows the health care team to observe the stoma. If no pouch system is in place, a petrolatum gauze dressing is usually placed over the stoma to keep it moist. This is covered with a dry, sterile dressing. In collaboration with the ostomy nurse, place a pouch system as soon as possible. The colostomy pouch system, also called an *appliance*, allows more convenient and acceptable collection of stool than a dressing does.

Assess the color and integrity of the stoma frequently. A healthy stoma should be reddish pink and moist and protrude about $\frac{3}{4}$ inch (2 cm) from the abdominal wall (Fig. 59-7). During the initial postoperative period, the stoma may be slightly edematous. A small amount of bleeding at the stoma is common.

! NURSING SAFETY PRIORITY

Action Alert

Report any of these problems related to the colostomy to the surgeon:

- Signs of ischemia and necrosis (dark red, purplish, or black color; dry, firm, or flaccid)
- Unusual bleeding
- Mucocutaneous separation (breakdown of the suture line securing the stoma to the abdominal wall)

Also assess the condition of the peristomal skin (skin around the stoma), and frequently check the pouch system for proper fit and signs of leakage. The skin should be intact, smooth, and without redness or excoriation.

FIG. 59-7 A mature colostomy.

The colostomy should start functioning in 2 to 4 days postoperatively. When it begins to function, the pouch may need to be emptied frequently because of excess gas collection. It should be emptied when it is one-third to one-half full of stool. Stool is liquid immediately postoperatively but becomes more solid, depending on where in the colon the stoma was placed. For example, the stool from a colostomy in the ascending colon is liquid, the stool from a colostomy in the transverse colon is pasty, and the stool from a

colostomy in the descending colon is more solid (similar to usual stool expelled from the rectum).

Wound Management. For an AP resection, the perineal wound is generally surgically closed and two bulb suction drains such as Jackson-Pratt drains are placed in the wound or through stab wounds near the wound. The drains help prevent drainage from collecting within the wound and are usually left in place for several days, depending on the character and amount of drainage. These drains are described in more detail in [Chapter 18](#).

Monitoring drainage from the perineal wound and cavity is important because of the possibility of infection and abscess formation. Serosanguineous drainage from the perineal wound may be observed for 1 to 2 months after surgery. Complete healing of the perineal wound may take 6 to 8 months. This wound can be a greater source of discomfort than the abdominal incision and ostomy, and more care may be required. The patient may experience phantom rectal sensations because sympathetic innervation for rectal control has not been interrupted. Rectal pain and itching may occasionally occur after healing. However, there is no known physiologic explanation for these sensations. Interventions may include use of antipruritic drugs, such as benzocaine, and sitz baths. Continually assess for signs of infection, abscess, or other complications, and implement methods for promoting wound drainage and comfort ([Chart 59-2](#)).

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A nurse is assigned to care for a client who had a partial colectomy and ascending colostomy yesterday. What assessment findings are expected for the client? **Select all that apply.**

- A. The colostomy stoma is pinkish red and moist.
- B. The nasogastric tube is draining bright red blood.
- C. The client has pain that is controlled by analgesics.
- D. The colostomy is draining solid brown stool.
- E. The perineal incision is covered with a surgical dressing.

Assisting with the Grieving Process

Planning: Expected Outcomes. The expected outcomes are that the patient will verbalize feelings about the diagnosis and treatment and progress through the normal stages of grief.

Interventions. The patient and family are faced with a possible loss of or alteration in body functions. Medical and surgical interventions for the treatment of colorectal cancer may result in cure, disease control, or palliation. Interventions are designed to assist the patient in planning effective strategies for expressing feelings of grief and developing coping skills.

Observe and identify:

- The patient's and family's current methods of coping
- Effective sources of support used in past crises
- The patient's and family's present perceptions of the health problem
- Signs of anticipatory grief, such as crying, anger, and withdrawal from usual relationships

Encourage the patient to verbalize feelings about the diagnosis, treatment, and anticipated alteration in body functions if a colostomy is planned. (See discussion of Operative Procedures on p. 1248 in the Surgical Management section.)

CHART 59-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Perineal Wound Care

Wound Care

- Place an absorbent dressing (e.g., abdominal pad) over the wound.
- Instruct the patient that he or she may:
 - Use a feminine napkin as a dressing
 - Wear jockey-type shorts rather than boxers

Comfort Measures

- If prescribed, soak the wound area in a sitz bath for 10 to 20 minutes three or four times per day.
- Administer pain medication as prescribed, and assess its effectiveness.
- Instruct the patient about permissible activities. The patient should:
 - Assume a side-lying position in bed; avoid sitting for long periods
 - Use foam pads or a soft pillow to sit on whenever in a sitting position
 - Avoid the use of air rings or rubber donut devices

Prevention of Complications

- Maintain fluid and electrolyte balance by monitoring intake and output and by monitoring output from the perineal wound.
- Observe incision integrity, and monitor wound drains; watch for erythema, edema, bleeding, drainage, unusual odor, and excessive or constant pain.

Sadness, anger, feelings of loss, and depression are normal responses to this change in body function.

If a colostomy is planned, instruct the patient on what to expect about the appearance and care of the colostomy. Postoperatively, encourage him or her to look at and touch the stoma. When the patient is physically able, ask him or her to participate in colostomy care. Participation helps restore the patient's sense of control over his or her lifestyle and thus facilitates improved self-esteem.

Assist the patient in identifying the nature of and reaction to the loss. Encourage the patient to verbalize feelings and identify fears to help move him or her through the appropriate phases of the grief process. Establish a trusting, ongoing relationship with the patient, and provide support through the personal grieving stages.

In collaboration with the social worker or chaplain, and when appropriate, assist the patient in identifying personal coping strategies. Encourage him or her to implement cultural, religious, and social customs associated with the loss, and identify sources of community support. Modifications in lifestyle are needed for patients with CRC. Help the patient and family identify these changes and how best to make them.

NURSING SAFETY PRIORITY

Action Alert

Refer patients who are at risk for or have familial CRC for genetic counseling. Specially trained nurses can discuss the purposes and goals of genetic testing. Ensure privacy and confidentiality. A review of the family history may provide important information concerning the pattern of colorectal cancer inheritance. To make an informed decision, the patient and family need information about the advantages, risks, and costs of appropriate genetic tests. Monitor the patient's response regarding genetic risk factors.

The chaplain, social worker, or case manager assists in discussions and decisions with them concerning treatment, the prognosis, and end-of-life decisions, as appropriate.

Community-Based Care

Patients undergoing an uncomplicated colon resection by open approach are typically hospitalized for 3 days or longer, depending on the age of the patient and any complications or concurrent health problems. Collaborate with the case manager to assist patients and their families in coping with the immediate postoperative phase of recovery. After hospitalization for surgery, the patient is usually managed at home. Radiation therapy or chemotherapy is typically done on an ambulatory care basis. For the patient with advanced cancer, hospice care may be an option (see [Chapter 9](#)).

Home Care Management

Assess all patients for their ability for self-management within limitations. For those requiring assistance with care, home care visits by nurses or assistive nursing personnel can be provided.

For the patient who has undergone a colostomy, review the home situation to aid the patient in arranging for care. Ostomy products should be kept in an area (preferably the bathroom) where the temperature is neither hot nor cold (skin barriers may become stiff or melt in extreme temperatures) to ensure proper functioning. The home care nurse or CWCN or ET may serve as a consultant after the patient is discharged home to ensure continuity of care (per The Joint Commission's National Patient Safety Goals).

No changes are needed in sleeping accommodations. A moisture-proof covering may initially be placed over the bed mattress if patients feel insecure about the pouch system. They may consume their usual diet on discharge.

Teaching for Self-Management

Before discharge, teach the patient to avoid lifting heavy objects or straining on defecation to prevent tension on the anastomosis site. If he or she had the open surgical approach, the patient should avoid driving for 4 to 6 weeks while the incision heals. Patients who have had laparoscopy can usually return to all usual activities in 1 to 2 weeks.

! NURSING SAFETY PRIORITY

Action Alert

A stool softener may be prescribed to keep stools at a soft consistency for ease of passage. Teach patients to note the frequency, amount, and character of the stools. In addition to this information, teach those with colon resections to watch for and report clinical manifestations of intestinal obstruction and perforation (e.g., cramping, abdominal pain, nausea, vomiting). Advise the patient to avoid gas-producing foods and carbonated beverages. Four to six weeks may be required to establish the effects of certain foods on bowel patterns.

Colostomy Care. Rehabilitation after surgery requires that patients and family members learn how to perform colostomy care. Provide adequate opportunity before discharge for patients to learn the psychomotor skills involved in this care. Plan sufficient practice time for learning how to handle, assemble, and apply all ostomy equipment. Teach patients and families or other caregivers about:

- The normal appearance of the stoma
- Signs and symptoms of complications
- Measurement of the stoma
- The choice, use, care, and application of the appropriate appliance to cover the stoma
- Measures to protect the skin adjacent to the stoma
- Nutrition changes to control gas and odor
- Resumption of normal activities, including work, travel, and sexual intercourse

The appropriate pouch system must be selected and fitted to the stoma. Patients with flat, firm abdomens may use either flexible (bordered with paper tape) or nonflexible (full skin barrier wafer) pouch systems. A firm abdomen with lateral creases or folds requires a flexible system. Patients with deep creases, flabby abdomens, a retracted stoma, or a stoma that is flush or concave to the abdominal surface benefit from a convex appliance with a stoma belt. This type of system presses into the skin around the stoma, causing the stoma to protrude. This protrusion helps tighten the skin and prevents leaks around the stoma opening onto the peristomal skin.

Measurement of the stoma is necessary to determine the correct size of the stomal opening on the appliance. The opening should be large enough not only to cover the peristomal skin but also to avoid stomal trauma. The stoma will shrink within 6 to 8 weeks after surgery. Therefore it needs to be measured at least once weekly during this time and as needed if the patient gains or loses weight. Teach the patient and family caregiver to trace the pattern of the stomal area on the wafer portion of the appliance and to cut an opening about $\frac{1}{8}$ - to $\frac{1}{16}$ -inch larger than the stomal pattern to ensure that stomal tissue will not be constricted.

Skin preparation may include clipping peristomal hair or shaving the area (moving from the stoma outward) to achieve a smooth surface, prevent unnecessary discomfort when the wafer is removed, and minimize the risk for infected hair follicles. Advise the patient to clean around the stoma with mild soap and water before putting on an appliance. He or she should avoid using moisturizing soaps to clean the area because the lubricants can interfere with adhesion of the appliance.

! NURSING SAFETY PRIORITY

Action Alert

Teach the patient and family to apply a skin sealant (preferably without alcohol) and allow it to dry before application of the appliance (colostomy bag) to facilitate less painful removal of the tape or adhesive. If peristomal skin becomes raw, stoma powder or paste or a combination may also be applied. The paste or other filler cream is also used to fill in crevices and creases to create a flat surface for the faceplate of the colostomy bag. If the patient develops a fungal rash, an antifungal cream or powder should be used.

Control of gas and odor from the colostomy is often an important outcome for patients with new ostomies. Although a leaking or inadequately closed pouch is the usual cause of odor, flatus can also contribute to the odor. Remind the patient that although generally no foods for ostomates are forbidden, certain foods and habits can cause flatus or contribute to odor when the pouch is open. Broccoli, beans, spicy foods, onions, brussels sprouts, cabbage, cauliflower, cucumbers, mushrooms, and peas often cause flatus, as does chewing gum, smoking, drinking beer, and skipping meals. Crackers,

CHART 59-3 HOME CARE ASSESSMENT

The Patient with a Colostomy

Assess gastrointestinal status, including:

- Dietary and fluid intake and habits
- Presence or absence of nausea and vomiting
- Weight gain or loss
- Bowel elimination pattern and characteristics and amount of effluent (stool)
- Bowel sounds

Assess condition of stoma, including:

- Location, size, protrusion, color, and integrity
- Signs of ischemia, such as dull coloring or dark or purplish bruising

Assess peristomal skin for:

- Presence or absence of excoriated skin, leakage underneath drainage system
- Fit of appliance and effectiveness of skin barrier and appliance

Assess patient's and family's coping skills, including:

- Self-care abilities in the home
- Acknowledgment of changes in body image and function
- Sense of loss

toast, and yogurt can help prevent gas. Asparagus, broccoli, cabbage, turnips, eggs, fish, and garlic contribute to odor when the pouch is open. Buttermilk, cranberry juice, parsley, and yogurt will help prevent odor. Charcoal filters, pouch deodorizers, or placement of a breath mint in the pouch will help eliminate odors. The patient should be cautioned to not put aspirin tablets in the pouch because they may cause ulceration of the stoma. Vents that allow release of gas from the ostomy bag through a deodorizing filter are available and may decrease the patient's level of self-consciousness about odor.

The patient with a sigmoid colostomy may benefit from colostomy irrigation to regulate elimination. However, most patients with a sigmoid colostomy can become regulated through diet. An irrigation is similar to an enema but is administered through the stoma rather than the rectum.

In addition to teaching the patient about the clinical manifestations of obstruction and perforation, ask the patient to report any fever or sudden onset of pain or swelling around the stoma. Other home care assessment is listed in [Chart 59-3](#).

Psychosocial Concerns. The diagnosis of cancer can be emotionally immobilizing for the patient and family or significant others, but treatment may be welcomed because it may provide hope for control of the disease. Explore reactions to the illness and perceptions of planned interventions.

The patient's reaction to ostomy surgery may include:

- Fear of not being accepted by others
- Feelings of grief related to disturbance in body image
- Concerns about sexuality

Symms et al. (2008) found in their study of male veterans with intestinal ostomies that problems related to sexual activity and intimacy were their greatest challenge. (See the Evidence-Based Practice box above.)

Allow the patient to verbalize his or her feelings. By teaching how to physically manage the ostomy, help him or her begin to restore self-esteem and improve body image. Inclusion of family and significant others in the rehabilitation process may help maintain relationships and raise self-esteem. Anticipatory instruction includes information on leakage accidents, odor control measures, and adjustments to resuming sexual relationships.

EVIDENCE-BASED PRACTICE

What Are the Sexuality Challenges That Men with Intestinal Ostomies Have?

Symms, M.R., Rawl, S.M., Grant, M., Wendel, C.S., Coons, S.J., Hickey, S., et al. (2008). Sexual health and quality of life among male veterans with intestinal ostomies. *Clinical Nurse Specialist*, 22(1), 30-40.

The researchers conducted this study of 481 male veterans in three Veterans Administration sites to determine the effect of intestinal ostomies on their sexual health. The design was case-controlled, and both quantitative and qualitative data were collected. The study group was compared with another group who had other surgeries. Quality of life was determined by responses on the modified City of Hope Quality of Life-Ostomy questionnaire.

Compared with sexual activity before surgery, the study group reported more problems with intimacy and sexuality than the control group. They had less sexual activity and more erectile dysfunction than men in the control group. For study group subjects, those who had successful sexual relationships felt less isolation and less trouble adjusting to their ostomies.

Level of Evidence: 2

The study used a large sample and a control group for comparison.

Commentary—Implications for Practice and Research

Although the researchers used a convenience sample of one group of men, they had a large sample and obtained both quantitative and qualitative data. Nurses need to include a sexual health assessment in their care of patients with ostomies. They need to be open to discussion about sexual issues and refer patients to other resources, such as intimacy or sexual counselors, as needed. Additional studies should be conducted with non-veterans and include women of various ethnicities.

Health Care Resources

Several resources are available to maintain continuity of care in the home environment and provide for patient needs that the nurse is not able to meet. Make referrals to community-based case managers or social workers, who can provide further emotional counseling, aid in managing financial concerns, or arrange for services in the home or long-term care as needed.

Provide information about the United Ostomy Associations of America, Inc. (www.uoaa.org), a self-help group of people who have ostomies. This group has literature such as the organization's publication (*Ostomy Quarterly*) and information about local chapters. The organization conducts a visitor program that sends specially trained visitors (who have an ostomy [ostomate]) to talk with patients. After obtaining consent, make a referral to the visitor program so that the volunteer ostomate can see the patient both preoperatively and postoperatively. A physician's consent for visitation may be necessary.

The local division or unit of the American Cancer Society (ACS) (www.cancer.org) can help provide necessary medical equipment and supplies, home care services, travel accommodations, and other resources for the patient who is having cancer treatment or surgery. Inform the patient and family of the programs available through the local division or unit.

Because of short hospital stays, patients with new ostomies receive much health teaching from nurses working for home care agencies. This resource also helps provide physical care needs, medication management, and emotional support. If

the patient has advanced colorectal cancer, a referral for hospice services in the home, nursing home, or other long-term care setting may be appropriate. The home care nurse informs the patient and family about what ostomy supplies are needed and where they can be purchased. Price and location are considered before recommendations are made.

EVALUATION: OUTCOMES

Evaluate the care of the patient with colorectal cancer based on the identified priority patient problems. The expected outcomes are that the patient:

- Adjusts to actual or impending loss
- Is free of complications or metastasis associated with CRC
- States he or she has well-controlled pain and is as comfortable as possible (if metastasis is present)

INTESTINAL OBSTRUCTION

Pathophysiology

Intestinal obstructions can be partial or complete and are classified as mechanical or nonmechanical. In **mechanical obstruction**, the bowel is physically blocked by problems outside the intestine (e.g., adhesions), in the bowel wall (e.g., Crohn's disease), or in the intestinal lumen (e.g., tumors). **Nonmechanical obstruction** (also known as **paralytic ileus** or *adynamic ileus*) does not involve a physical obstruction in or outside the intestine. Instead, peristalsis is decreased or absent as a result of neuromuscular disturbance, resulting in a slowing of the movement or a backup of intestinal contents.

Intestinal contents are composed of ingested fluid, food, and saliva; gastric, pancreatic, and biliary secretions; and swallowed air. In both mechanical and nonmechanical obstructions, the intestinal contents accumulate at and above the area of obstruction. Distention results from the intestine's inability to absorb the contents and move them down the intestinal tract. To compensate for the lag, peristalsis increases in an effort to move the intestinal contents forward. This increase stimulates more secretions, which then leads to additional distention. The bowel then becomes edematous, and increased capillary permeability results. Plasma leaking into the peritoneal cavity and fluid trapped in the intestinal lumen decrease the absorption of fluid and electrolytes into the vascular space. Reduced circulatory blood volume (hypovolemia) and electrolyte imbalances typically occur. Hypovolemia ranges from mild to extreme (hypovolemic shock).

Specific fluid and electrolyte problems result, depending on the part of the intestine that is blocked. An obstruction high in the small intestine causes a loss of gastric hydrochloride, which can lead to *metabolic alkalosis*. Obstruction below the duodenum but above the large bowel results in loss of both acids and bases, so that acid-base imbalance is usually not compromised. Obstruction at the end of the small intestine and lower in the intestinal tract causes loss of alkaline fluids, which can lead to *metabolic acidosis*.

If hypovolemia is severe, renal insufficiency or even death can occur. Bacterial peritonitis with or without actual perforation can also result. Bacteria in the intestinal contents lie stagnant in the obstructed intestine. This is not a problem unless the blood flow to the intestine is compromised.

However, with so-called *closed-loop obstruction* (blockage in two different areas) or a **strangulated obstruction** (obstruction with compromised blood flow), the risk for peritonitis is greatly increased. Bacteria without blood supply can form and release an endotoxin into the peritoneal or systemic circulation and cause septic shock. With a strangulated obstruction, major blood loss into the intestine and the peritoneum can result.

Etiology

Intestinal obstruction is a common and serious disorder caused by a variety of conditions and is associated with significant morbidity. It can occur anywhere in the intestinal tract, although the ileum in the small intestine (the narrowest part of the intestinal tract) is the most common site.

Mechanical obstruction can result from:

- Adhesions (scar tissue from surgeries or pathology)
- Benign or malignant tumor
- Complications of appendicitis
- Hernias
- Fecal impactions (especially in older adults)
- Strictures due to Crohn's disease or previous radiation therapy
- **Intussusception** (telescoping of a segment of the intestine within itself) (Fig. 59-8)
- **Volvulus** (twisting of the intestine) (see Fig. 59-8)
- Fibrosis due to disorders such as endometriosis
- Vascular disorders (e.g., emboli and arteriosclerotic narrowing of mesenteric vessels)

In people ages 65 years or older, diverticulitis, tumors, and fecal impaction are the most common causes of obstruction.

Paralytic ileus, or nonmechanical obstruction, is most commonly caused by handling of the intestines during abdominal surgery; intestinal function is lost for a few hours

FIG. 59-8 Two types of mechanical obstruction.

to several days. Electrolyte disturbances, especially hypokalemia, predispose the patient to this problem. The ileus can also be a consequence of peritonitis, because leakage of colonic contents causes severe irritation and triggers an inflammatory response. Vascular insufficiency to the bowel, also referred to as *intestinal ischemia*, is another potential cause of an ileus. It results when arterial or venous thrombosis or an embolus decreases blood flow to the mesenteric blood vessels surrounding the intestines, as in heart failure or severe shock. Severe insufficiency of blood supply can result in infarction of surrounding organs (e.g., bowel infarction).

Incidence/Prevalence

Obstruction of the intestines is the most common reason for surgery of the small intestine. Because bowel obstruction is a result of other disorders, statistics on the incidence of bowel obstruction are not readily available.

Obstruction of the intestines occurs in all age-groups, but the incidence differs with age. In adults, most obstructions occur in the small intestine.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Collect information about a history of:

- Abdominal surgery
- Radiation therapy
- Inflammatory bowel disease
- Gallstones
- Hernias
- Trauma
- Peritonitis
- Tumors

Question the patient about recent nausea and vomiting and the color of emesis. Perform a thorough pain assessment with particular attention to the onset, aggravating factors, alleviating factors, and patterns or rhythms of the pain. Severe pain that then stops and changes to tenderness on palpation may indicate perforation and should be reported promptly to the physician. Ask about the passage of flatus and the time, character, and consistency of the last bowel movement. Singultus (hiccups) is common with all types of intestinal obstruction. When an obstruction is suspected, keep the patient NPO and contact the physician promptly for further guidance.

Assess for a family history of colorectal cancer (CRC), and ask about blood in the stool or a change in bowel pattern. Body temperature with uncomplicated obstruction is rarely higher than 100° F (37.8° C). A temperature higher than this, with or without guarding and tenderness, and a sustained elevation in pulse could indicate a strangulated obstruction or peritonitis. A fever, tachycardia, hypotension, increasing abdominal pain, abdominal rigidity, or change in color of skin overlying the abdomen should be reported to the attending physician immediately.

Physical Assessment/Clinical Manifestations

The patient with *mechanical* obstruction in the *small intestine* often has mid-abdominal pain or cramping. The pain can be sporadic, and the patient may feel comfortable between

episodes. If strangulation is present, the pain becomes more localized and steady. Vomiting often accompanies obstruction and is more profuse with obstructions in the proximal small intestine. The vomitus may contain bile and mucus or be orange-brown and foul smelling as a result of bacterial overgrowth with low ileal obstruction. **Obstipation** (no passage of stool) and failure to pass flatus accompany complete obstruction. Diarrhea may be present in partial obstruction.

Mechanical colonic obstruction causes a milder, more intermittent colicky abdominal pain than is seen with small-bowel obstruction. Lower abdominal distention and obstipation may be present, or the patient may have ribbon-like stools if obstruction is partial. Alterations in bowel patterns and blood in the stools accompany the obstruction if colorectal cancer or diverticulitis is the cause.

On examination of the abdomen, observe for abdominal distention, which is common in all forms of intestinal obstruction. Peristaltic waves may also be visible. Auscultate for proximal high-pitched bowel sounds (**borborygmi**), which are associated with cramping early in the obstructive process as the intestine tries to push the mechanical obstruction forward. In later stages of mechanical obstruction, bowel sounds are absent, especially distal to the obstruction. Abdominal tenderness and rigidity are usually minimal. The presence of a tense, fluid-filled bowel loop mimicking a palpable abdominal mass may signal a closed-loop, strangulating small-bowel obstruction.

In most types of *nonmechanical* obstruction, the pain is described as a constant, diffuse discomfort. Colicky cramping is not characteristic of this type of obstruction. Pain associated with obstruction caused by vascular insufficiency or infarction is usually severe and constant. On inspection, abdominal distention is typically present. On auscultation of the abdomen, note and document decreased bowel sounds in early obstruction and absent bowel sounds in later stages. Vomiting of gastric contents and bile is frequent, but the vomitus rarely has a foul odor and is rarely profuse. Obstipation may or may not be present. **Chart 59-4** compares small-bowel and large-bowel obstructions.

CHART 59-4 KEY FEATURES

Small-Bowel and Large-Bowel Obstructions

SMALL-BOWEL OBSTRUCTIONS	LARGE-BOWEL OBSTRUCTIONS
Abdominal discomfort or pain possibly accompanied by visible peristaltic waves in upper and middle abdomen	Intermittent lower abdominal cramping
Upper or epigastric abdominal distention	Lower abdominal distention
Nausea and early, profuse vomiting (may contain fecal material)	Minimal or no vomiting
Obstipation	Obstipation or ribbon-like stools
Severe fluid and electrolyte imbalances	No major fluid and electrolyte imbalances
Metabolic alkalosis	Metabolic acidosis (not always present)

Laboratory Assessment

There is no definitive laboratory test to confirm a diagnosis of mechanical or nonmechanical obstruction. White blood cell (WBC) counts are normal unless there is a strangulated obstruction, in which case there may be leukocytosis (increased WBCs). Hemoglobin, hematocrit, creatinine, and blood urea nitrogen (BUN) values are often elevated, indicating dehydration. Serum sodium, chloride, and potassium concentrations are reduced because of loss of fluid and electrolytes. Elevations in serum amylase levels may be found with strangulating obstructions, which can damage the pancreas.

Patients with high obstruction in the small intestine have arterial blood gas (ABG) values indicative of metabolic alkalosis. Obstruction in the large intestine may show values suggestive of metabolic acidosis. [Chapter 14](#) describes ABGs and these acid-base imbalances in detail.

Imaging Assessment

The health care provider obtains supine and upright abdominal x-rays and a CT scan as soon as an obstruction is suspected. Distention with fluid and gas in the small intestine with the absence of gas in the colon indicates an obstruction in the small intestine. X-ray findings are often normal when a strangulated obstruction actually exists in the small intestine.

Other Diagnostic Assessment

The diagnostic examination chosen depends on the suspected location of the obstruction. As an initial assessment, the physician may choose to do an abdominal ultrasound to evaluate the potential cause of the obstruction. The physician may perform endoscopy (sigmoidoscopy or colonoscopy) to determine the cause of the obstruction, except when perforation or complete obstruction is suspected.

INTERVENTIONS

Interventions are aimed at uncovering the cause and relieving the obstruction. Intestinal obstructions can be relieved by nonsurgical or surgical means. If the obstruction is partial and there is no evidence of strangulation, nonsurgical management is the treatment of choice.

Nonsurgical Management

Paralytic ileus responds well to nonsurgical methods of relieving obstruction. Nonsurgical approaches are also preferred in the treatment of patients with terminal disease associated with bowel obstruction. In addition to being NPO, patients typically have a nasogastric tube (NGT) inserted to decompress the bowel by draining fluid and air. The tube is attached to suction.

Nasogastric Tubes. Most patients with an obstruction have an NGT unless the obstruction is mild.

A Salem sump tube is inserted through the nose and placed into the stomach. It is attached to low continuous suction. This tube has a vent ("pigtail") that prevents the stomach mucosa from being pulled away during suctioning. Levin tubes do not have a vent and therefore should be connected to low intermittent suction. They are used less often than the Salem sump tubes. [Chart 58-5](#) in [Chapter 58](#) describes how to insert an NGT.

Question the patient about the passage of flatus, and record flatus and the character of bowel movements daily. Flatus or stool means that peristalsis has returned. Assess for nausea, and ask the patient to report this manifestation.

! NURSING SAFETY PRIORITY

Action Alert

At least every 4 hours, assess the patient with an NGT for proper placement of the tube, tube patency, and output (quality and quantity). Monitor the nasal skin around the tube for irritation. Use a device that secures the tube to the nose to prevent accidental removal. Clean the nose with the same type of skin protectant used for ostomy skin care before applying the NGT securing device. Assess for peristalsis by auscultating for bowel sounds with the suction disconnected (suction masks peristaltic sounds).

Monitor any NGT for proper functioning. Occasionally, NGTs move out of optimal drainage position or become plugged. In this case, note a decrease in gastric output or stasis of the tube's contents. Assess the patient for nausea, vomiting, increased abdominal distention, and placement of the tube. If the NGT is repositioned or replaced, confirmation of proper placement is obtained by x-ray examination before use. After appropriate placement is established, aspirate the contents and irrigate the tube with 30 mL of normal saline every 4 hours or as requested by the health care provider.

Other Nonsurgical Interventions. Most types of nonmechanical obstruction respond to nasogastric decompression in conjunction with medical treatment of the primary disorder. Incomplete mechanical obstruction can sometimes be successfully treated without surgery. Obstruction caused by lower fecal impaction usually resolves after disimpaction and enema administration. Intussusception may respond to hydrostatic pressure changes during a barium enema.

IV fluid replacement and maintenance are indicated for all patients with intestinal obstruction because the patient is NPO and fluids and electrolytes are lost (particularly potassium) through vomiting and nasogastric suction. On the basis of serum electrolytes and blood urea nitrogen (BUN) levels, the health care provider prescribes aggressive fluid replacement with 2 to 4 L of normal saline or lactated Ringer's solution with potassium added. Use care with patients who are susceptible to fluid overload (e.g., older adults with a history of heart or kidney failure). Monitor lung sounds, weight, and intake and output daily. Blood replacement may be indicated in strangulated obstruction because of blood loss into the bowel or peritoneal cavity.

Monitor vital signs and other measures of fluid status (e.g., urine output, skin turgor, mucous membranes) every 2 to 4 hours depending on the severity of the patient's symptoms. In collaboration with the dietitian, the physician may prescribe total parenteral nutrition (TPN), especially if the patient has had chronic nutritional problems and has been NPO for an extended period. [Chapter 63](#) discusses the nursing care of patients receiving TPN.

The patient with intestinal obstruction is usually thirsty, although older adults have a decreased thirst response as they age. Delegate frequent mouth care to unlicensed assistive personnel (UAP) to help maintain moist mucous membranes. Be sure to supervise this activity. A few ice chips may be allowed if the patient is not having surgery. Follow agency protocol or the physician's request regarding ice chips.

Abdominal distention can cause a great deal of discomfort, especially when it is severe. The colicky, crampy pain that comes and goes with mechanical obstruction and the nausea, vomiting, dry mucous membranes, and thirst contribute to

the patient's discomfort. Continually assess the character and location of the pain, and immediately report any pain that significantly increases or changes from a colicky, intermittent type to a constant discomfort. These changes can indicate perforation of the intestine or peritonitis.

Opioid analgesics may be temporarily withheld in the diagnostic workup period so that clinical manifestations of perforation or peritonitis are not masked. Explain to the patient and family the rationale for not giving analgesics. In addition, if analgesics such as morphine are given, they may slow intestinal motility and can cause vomiting. Be alert to this side effect because nausea and vomiting are also signs of NG tube obstruction or worsening bowel obstruction.

Help the patient obtain a position of comfort with frequent position changes to promote increased peristalsis. A semi-Fowler's position helps alleviate the pressure of abdominal distention on the chest. This position is for comfort and promotion of thoracic excursion to facilitate breathing.

Discomfort is generally less with nonmechanical obstruction than with mechanical obstruction. With both types of obstruction, discomfort is aggravated by taking in food or fluids.

If strangulation is thought to be likely, the health care provider prescribes IV broad-spectrum antibiotics. In addition, in cases of partial obstruction or paralytic ileus, drugs that enhance gastric motility such as octreotide acetate (Sandostatin) may be used.

Surgical Management

In patients with complete mechanical obstruction and in some cases of incomplete mechanical obstruction, surgical intervention is necessary to relieve the obstruction. A strangulated obstruction is complete, and surgical intervention is always required. An **exploratory laparotomy** (a surgical opening of the abdominal cavity to investigate the cause of the obstruction) is initially performed for many patients with obstruction. More specific surgical procedures depend on the cause of the obstruction.

Preoperative Care. Provide general preoperative teaching for both the patient and family as discussed in [Chapter 16](#). In cases of complete obstruction, the patient may feel too ill to want the information. Reinforce the information with the family or other caregiver. Depending on the cause and severity of the obstruction, as well as the expertise of the surgeon, patients have either minimally invasive surgery (MIS) via laparoscopy or a conventional open approach.

Operative Procedures. In the *conventional open surgical approach*, the surgeon makes a large incision, enters the abdominal cavity, and explores for obstruction and its cause, if possible (**exploratory laparotomy**). If adhesions are found, they are lysed (cut and released). Obstruction caused by a tumor or diverticulitis requires a colon resection with primary anastomosis or a temporary or permanent colostomy. If obstruction is caused by intestinal infarction, an embolectomy, thrombectomy, or resection of the gangrenous small or large bowel may be necessary. In severe cases, a colectomy (removal of the entire colon) may be needed.

For the *MIS approach*, the specially trained surgeon makes several small incisions in the abdomen and places a video camera to view the abdominal contents to determine the extent of the obstruction. A laparoscope (type of endoscope) with a lighted end is inserted along with various surgical

instruments to remove the problem. This procedure takes longer than the open approach, but blood loss is less.

Postoperative Care. General postoperative care for the patient undergoing an *exploratory laparotomy* with lysis of adhesions, colon resection, thrombectomy, or embolectomy is similar to that described in [Chapter 18](#). In addition, patients have an NGT in place until peristalsis resumes. A clear liquid diet may be prescribed to encourage peristalsis return. As liquids are started, the NGT can be disconnected from suction and capped for 1 to 2 hours after the patient has taken clear liquids to determine if he or she is able to tolerate them. If the patient vomits after liquids, the suction is resumed. When the patient has return of peristalsis, the NGT is removed slowly by first discontinuing suction and then clamping the tube for a scheduled amount of time. Residual drainage is checked at each stage to assess peristalsis without decompression before removing the tube entirely.

Most patients today have laparoscopic surgery (MIS) for mechanical intestinal obstructions. They usually do *not* have an NGT and can recover more quickly than those with the open surgical approach. The hospital stay for those having MIS to remove tumors, adhesions, and other obstructions may be as short as 1 to 2 days compared with 3 days or longer for the conventional surgical patients. Recovery is much quicker because there is less pain and fewer postoperative complications among those who had laparoscopic surgery.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

A 91-year-old woman is admitted from an independent living facility with a diagnosis of complete intestinal obstruction due to a severe fecal impaction. She has been vomiting for 2 days and is extremely dehydrated. Her serum electrolytes are abnormal, and she is very weak. Her daughter and granddaughter are in the emergency department and tell you that they are very concerned about her health. They ask you what is wrong with her and what her prognosis is.

1. What is your best response to the family members at this time?
2. What evidence-based collaborative interventions are appropriate for this patient immediately?
3. What information do you need to better care for the patient?
4. What electrolyte imbalances would you expect? What clinical manifestations of dehydration do you expect this patient to have? How might her presentation be somewhat different from that of a younger adult and why?
5. What safety concerns do you have for this patient? What interventions are needed to ensure her safety?

Community-Based Care

All patients with intestinal obstruction are hospitalized for monitoring and treatment. The length of stay varies according to the type of obstruction, the treatment, and the presence of complications. Patients who have complicated obstruction, such as strangulation or incarceration, are at greater risk for peritonitis, sepsis, and shock.

Patients with nonmechanical (adynamic) intestinal obstruction are less likely to require a lengthy hospitalization because of the obstruction alone. Adynamic obstruction generally responds to NG intubation and suction within a few days. However, if the ileus occurs as a complication of an abdominal surgery, the hospital stay could be lengthy.

CHART 59-5 NURSING FOCUS ON THE OLDER ADULT

Preventing Fecal Impaction

- Teach the patient to eat high-fiber foods, including plenty of raw fruits and vegetables and whole-grain products.
- Encourage the patient to drink adequate amounts of fluids, especially water.
- Do not routinely administer a laxative; teach the patient that laxative abuse decreases abdominal muscle tone and contributes to an atonic colon.
- Encourage the patient to exercise regularly, if possible. Walking every day is an excellent exercise for promoting intestinal motility.
- Use natural foods to stimulate peristalsis, such as warm beverages and prune juice.
- Take bulk-forming products, such as Metamucil, to provide fiber.
- Check the patient's stool for amount and frequency; oozing of soft or diarrheal stool often indicates a fecal impaction.
- Have the patient sit on a toilet or bedside commode, rather than on a bedpan, for elimination.

Home Care Management

For the patient who has had an intestinal obstruction, preparation for home care depends on the cause of the obstruction and the treatment required. Those who have resolution of obstruction without surgical intervention are assessed for their knowledge of strategies to avoid recurrent obstruction. For example, if fecal impaction was the cause of the obstruction, assess the patient's ability to carry out a bowel regimen independently (Chart 59-5). For those who have had surgery, evaluate their ability to function at home with the added tasks of incision care and possibly colostomy care.

Teaching for Self-Management

Instruct the patient to report any abdominal pain or distention, nausea, or vomiting, with or without constipation, because these symptoms might indicate recurrent obstruction. The patient should be reassured, however, that recurrent paralytic ileus is not common.

Teach the patient who has had surgery about incision care, drug therapy, and activity limitations. Drug therapy consists of an oral opioid analgesic, such as oxycodone hydrochloride with acetaminophen (Tylox, Percocet, Endocet ) , to be taken as needed for incisional discomfort. As with any opioid therapy, scheduled doses of a laxative with a softener (e.g., Docusate with Senna) may be added to prevent constipation and possible recurrent obstruction.

The patient who had curative treatment of the underlying cause most likely requires less support than one who had treatment of obstruction related to a serious disease that will require further management. Encourage the patient to express fears and concerns about the future. Assess the patient's understanding and needs with regard to treatment plans.

Health Care Resources

The need for follow-up appointments depends on the cause of the obstruction and the treatment required. In collaboration with the case manager, make arrangements for a home care nurse if the patient needs help with incision or colostomy care.

ABDOMINAL TRAUMA**Pathophysiology**

Abdominal trauma is defined as injury to the structures located between the diaphragm and the pelvis, which occurs when the abdomen is subjected to blunt or penetrating forces. Organs injured may include the large or small bowel, liver, spleen, duodenum, pancreas, kidneys, and urinary bladder.

At least one half of all *blunt abdominal traumas* occur from motor vehicle crashes. Other causes of blunt trauma include falls, aggravated assaults, and contact sports. The spleen is the most commonly injured organ from *blunt* abdominal trauma. *Penetrating abdominal trauma* is caused by gunshot wounds, stabbing, or impalement with an object. The liver is the most commonly injured organ from penetrating abdominal trauma. Most penetrating injuries are caused by gunshot wounds (GSWs). *Trauma is the leading cause of death in young adults (younger than 40 years) in the United States.*

PATIENT-CENTERED COLLABORATIVE CARE**ASSESSMENT**

First, assess any patient experiencing trauma for airway, breathing, and circulation (ABCs).

! NURSING SAFETY PRIORITY**Critical Rescue**

Once the patient with abdominal trauma has been assessed for airway, breathing, and circulation, focus on the risks for hemorrhage, shock, and peritonitis. Mental status, vital signs, and skin perfusion are *priority* nursing assessments, with skin perfusion being the most reliable clinical guide in assessing hypovolemic shock:

- In a person with mild shock, the skin is pale, cool, and moist.
- With moderate shock, diaphoresis is more marked and urine output ceases.
- With severe shock, changes in mental status are manifested by agitation, disorientation, and recent memory loss.

Assess for abdominal trauma by asking the patient about the presence, location, and quality of pain. Inspect the abdomen, flanks, back, genitalia, and rectum for contusions, abrasions, lacerations, ecchymosis, penetrating injuries, and symmetry. All of the patient's clothes must be removed for this examination.

Inspection of the abdomen may reveal distention. To perform an adequate inspection, turn the patient while maintaining spinal immobilization. *Ecchymosis (bruising) may indicate internal bleeding. Ecchymosis present in the distribution of a lap seat belt should be reported to the health care provider immediately because the bowel or other major organ may be injured.*

Auscultate the abdomen for bowel sounds. Absent or diminished bowel sounds may be caused by the presence of blood, bacteria, or a chemical irritant in the abdominal cavity. Also auscultate for bruits in the abdomen, which could indicate renal artery injury.

Injury to the spleen is present in many people with left lower rib fractures. Liver injury may be present in those with right lower rib fractures. Dullness over hollow organs that normally contain gas, such as the stomach and the large and small intestines, may indicate the presence of blood or fluid. Light abdominal palpation identifies areas of tenderness,

rebound tenderness, guarding, rigidity, and spasm. A palpated mass may be blood or a fluid collection.

The patient without obvious significant bleeding or definite signs of peritoneal irritation undergoes abdominal ultrasound, **diagnostic peritoneal lavage (DPL)**, and CT. For DPL, the physician inserts a large-bore catheter into the abdomen and allows fluid to enter the abdominal cavity. If the return drainage from the abdomen is pink or grossly bloody, the health care team prepares for surgery. Abdominal ultrasound or focused abdominal sonography for trauma (FAST) is used to diagnose blunt abdominal trauma and may replace CT and DPL for diagnosis. Patients with hemodynamic instability or peritonitis are candidates for immediate laparotomy.

INTERVENTIONS

Nonsurgical and surgical interventions are aimed at preserving or restoring hemodynamic stability, preventing or decreasing blood loss, and preventing complications. Patients with abdominal trauma from a vehicle crash often have other injuries such as multiple fractures. *The priority for care is to establish and maintain the ABCs.*

Emergency Care: Abdominal Trauma

Nursing interventions include placement of at least two large-bore IV catheters in the upper extremities. IV catheters are not used in the lower extremities; if the vasculature has been injured, fluid can pool in the abdomen. The health care provider may insert a central venous catheter to assist with rapid fluid volume infusion. IV fluids include saline, crystalloids, and possibly blood. Be sure to type and cross-match the patient for as many as 4 to 8 units of packed red blood cells.

These laboratory values are monitored:

- Arterial blood gases
- Complete blood count (CBC)
- Serum electrolyte, glucose and amylase, and blood urea nitrogen (BUN) determinations
- Liver function tests
- Coagulation studies

Measuring arterial blood gases may help determine the severity of shock. Hemoglobin and hematocrit values do not initially reflect true blood loss; values can be skewed because of hemoconcentration from volume loss or the dilutional effects of IV fluids. Serial hemoglobin and hematocrit measurements may be more accurate in determining true blood loss. An elevated white blood cell (WBC) count may indicate a ruptured spleen or intestinal injury. Elevated levels of serum transaminases may indicate liver injury. Elevation of serum amylase activity may signal injury to the pancreas or the bowel. All laboratory work is compiled so that values can be compared and subtle changes noted.

Continuous hemodynamic monitoring is begun in the emergency department. Insert an indwelling urinary (Foley) catheter unless there is blood at the urinary meatus. Initially and hourly thereafter, evaluate urine output for bleeding and specific gravity. Laboratory tests indicate the amount of blood and protein in the urine. If there is an open abdominal wound or evisceration, cover it with a sterile dry dressing unless the physician requests otherwise. Unless it is contraindicated, as in the case of a skull fracture, the physician or nurse inserts a nasogastric tube (NGT) to identify bleeding

and minimize the risk for vomiting and aspiration. Antibiotics are administered as prescribed to reduce the risk for peritonitis.

If the patient with known abdominal trauma has no definite clinical manifestations of active bleeding or organ injury, he or she is admitted to the hospital for observation. Many patients are admitted to the critical care unit. Blunt trauma can cause active, but often not obvious, damage.

! NURSING SAFETY PRIORITY

Critical Rescue

For the patient who has sustained abdominal trauma, assess for abdominal or referred pain and nausea. Every 15 to 30 minutes in the early postinjury period and then hourly, evaluate:

- Mental status
- Vital signs
- Clinical findings, such as vomiting, guarding, rigidity, or rebound tenderness
- Bowel sounds
- Urine output

Report any change immediately to the health care provider! It is more important to recognize the high risk for an active abdominal injury and assess for general signs of organ injury (e.g., hemorrhage and peritonitis) than to identify the exact nature of the abdominal injury. Opioid analgesics are given for pain after the physician's initial assessment is complete. Explain to the patient and family the rationale for delaying analgesics.

Intra-abdominal Pressure Monitoring

Some patients are monitored for intra-abdominal pressure (IAP) using a continuous monitoring system. As the name implies, **intra-abdominal pressure** is pressure within the abdominal cavity. The normal IAP in healthy adults is 0 to 5 mm Hg, but obese patients often have a higher normal value. In patients with abdominal injury (especially blunt trauma), IAP may increase to the point that major body organs are damaged.

When IAP becomes higher than the central venous pressure, the inferior vena cava and other abdominal vessels are compressed. This leads to impaired venous return, increased afterload, and decreased preload. The patient is then at risk for deep vein thrombosis and pulmonary embolism (PE). The patient has tachycardia and hypotension. As the IAP increases further (over 20 mm Hg), acidosis and ischemia occur. *If elevated IAP is left untreated, damage to the intestine increases the risk for sepsis, multiple organ dysfunction syndrome (MODS), and death.* Renal, cardiac, and respiratory damage are the most likely to occur, although the central nervous system can be affected.

The health care provider may request continuous or intermittent IAP monitoring in the critical care unit. It is usually done by inserting a urinary catheter and using a stopcock, pressure transducer system, clamp, IV tubing, and bag of saline. *Report any increase in IAP immediately to the physician. A sustained or repeated IAP of 12 mm Hg or higher is considered **intra-abdominal hypertension (IAH)** or **acute compartment syndrome (ACS)**.* Acute IAH has a rapid onset after abdominal trauma (especially blunt trauma) and must be treated immediately using either a nonsurgical (vasopressor drugs and fluids) or surgical approach (fasciotomy). Surgery is risky because it increases the chance of embolic stroke and PE.

Surgical Management

For the patient with severe abdominal trauma, the surgeon performs an *exploratory laparotomy* and repairs abdominal injuries immediately if there are definite signs of peritoneal irritation. These signs include rebound tenderness, significant blood loss, evisceration, or a gunshot wound (GSW) with possible peritoneal involvement. After surgery, many of these patients are admitted to a critical care unit and mechanically ventilated.

Most stab wounds and GSWs require exploratory laparotomy. Using local anesthesia, the surgeon explores and cleans superficial penetrating wounds. The patient does not require an exploratory laparotomy for superficial wounds.

Patients with multiple trauma stay in the hospital for a prolonged period. Before discharge from the hospital, teach the patient and family the signs and symptoms of abdominal bleeding whether or not surgery has been performed. Instruct them to report abdominal pain, nausea, vomiting, bloody or black stools, fever, weakness, and dizziness.

Hemorrhage can occasionally occur weeks after blunt abdominal trauma, despite medical evaluation or treatment. For the patient who has surgery or exploration of wounds, provide instructions on wound care before discharge from the hospital. Provide additional health teaching as the patient's overall condition requires.

POLYPS

Pathophysiology

Polyyps in the intestinal tract are small growths covered with mucosa and attached to the surface of the intestine. Although most are benign, they are significant because some have the potential to become malignant.

Polyyps are identified by their tissue type. Although only a very small number of adenomas progress to cancer, almost all colorectal cancers develop from an adenoma. Adenomas are further classified as villous or tubular. Of these, villous adenomas pose a greater cancer risk.

Familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC) are inherited syndromes characterized by progressive development of colorectal adenomas. Unless these syndromes are treated, colorectal cancer (CRC) inevitably occurs by the fourth to fifth decade of life. These conditions were discussed on p. 1245 in the Genetic/Genomic Considerations feature in the Colorectal Cancer section.

In addition to being classified by their tissue type, polyyps are described according to their appearance (Fig. 59-9).

FIG. 59-9 Pedunculated and sessile polyyps. Pedunculated polyyps, such as tubular adenomas, are stalk-like. Sessile polyyps, such as villous adenomas, are broad based.

Pedunculated polyyps are stalk-like; a thin stem attaches them to the intestinal wall. They become elongated as peristalsis pulls them into the lumen of the intestine. Polyyps attached to the intestinal walls by a broad base are described as sessile. A malignant polyp may be pedunculated or sessile.

PATIENT-CENTERED COLLABORATIVE CARE

Polyyps are usually asymptomatic and are discovered during routine colonoscopy screening. However, they can cause gross rectal bleeding, intestinal obstruction, or intussusception (telescoping of the bowel). Biopsy specimens of polyyps can be obtained and the entire polyp can be removed (polypectomy) with the use of a snare that fits through the sigmoidoscope or colonoscope. This often eliminates the need for abdominal surgery to remove a suspicious or definitely malignant polyp. The patient with FAP often requires a total colectomy (colon removal) to prevent the development of cancer.

Nursing care focuses on patient education. Instruct the patient about:

- The nature of the polyp
- Clinical manifestations to report to the health care provider
- The need for regular, routine monitoring or screening

If the patient has had a polypectomy, follow-up sigmoidoscopic or colonoscopic examinations are needed because there is an increased risk for developing multiple polyyps.

Nursing care of the patient after a polypectomy of the colorectal area includes monitoring for abdominal distention and pain, rectal bleeding, mucopurulent drainage from the rectum, and fever. A small amount of blood might appear in the stool after a polypectomy, but this should be temporary.

HEMORRHOIDS

Pathophysiology

Hemorrhoids are unnaturally swollen or distended veins in the anorectal region. The veins involved in the development of hemorrhoids are part of the normal structure in the anal region. With limited distention, the veins function as a valve overlying the anal sphincter that assists in continence. Increased intra-abdominal pressure causes elevated systemic and portal venous pressure, which is transmitted to the anorectal veins. Arterioles in the anorectal region shunt blood directly to the distended anorectal veins, which increases the pressure. With repeated elevations in pressure from increased intra-abdominal pressure and engorgement from arteriolar shunting of blood, the distended veins eventually separate from the smooth muscle surrounding them. The result is prolapse of the hemorrhoidal vessels.

Hemorrhoids can be internal or external (Fig. 59-10). **Internal hemorrhoids**, which cannot be seen on inspection of the perineal area, lie above the anal sphincter. **External hemorrhoids** lie below the anal sphincter and can be seen on inspection of the anal region. Prolapsed hemorrhoids can become thrombosed or inflamed, or they can bleed.

Hemorrhoids are common and not significant unless they cause pain or bleeding. Caused by increased abdominal pressure, the condition worsens during pregnancy, constipation

FIG. 59-10 Internal, external, and prolapsed hemorrhoids. *Internal hemorrhoids* lie above the anal sphincter and cannot be seen on inspection of the anal area. *External hemorrhoids* lie below the anal sphincter and can be seen on inspection of the anal region. Hemorrhoids that enlarge, fall down, and protrude through the anus are called *prolapsed hemorrhoids*.

with straining, obesity, heart failure, prolonged sitting or standing, and strenuous exercise and weight lifting. Decreased fluid intake can also cause hemorrhoids because of the development of hard stool and subsequent constipation. Straining while evacuating stool causes them to enlarge.

Health Promotion and Maintenance

Prevention of constipation is the most important preventive measure. It can be prevented by increasing fiber in the diet, such as eating more whole grains and raw vegetables and fruits. Encourage patients to drink plenty of water unless otherwise contraindicated (e.g., kidney disease, heart disease). Remind the patient to avoid straining at stool. Remind him or her to exercise regularly with a gradual buildup in intensity. Maintaining a healthy weight also helps prevent hemorrhoids.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The most common symptoms of hemorrhoids are bleeding, swelling, and prolapse (bulging). Blood is characteristically bright red and is present on toilet tissue or streaked in the stool. Pain is a common symptom and is often associated with thrombosis, especially if thrombosis occurs suddenly. Other symptoms include itching and a mucous discharge. Diagnosis is usually made by inspection and digital examination, although anoscopy, proctoscopy, or proctoscopic ultrasonography can be performed.

INTERVENTIONS

Interventions are typically conservative and are aimed at reducing symptoms with a minimum of discomfort, cost, and time lost from usual activities. Local treatment and nutrition therapy are used when symptoms begin. Cold packs applied

to the anorectal region for a few minutes at a time beginning with the onset of pain and tepid sitz baths three or four times per day are often enough to relieve discomfort, even if the hemorrhoids are thrombosed.

Topical anesthetics, such as lidocaine (Xylocaine), are useful for severe pain. Dibucaine (Nupercainal) ointment and similar products are available over the counter and may be applied for mild to moderate pain and itching. This ointment should be used only temporarily, however, because it can mask worsening symptoms and delay diagnosis of a severe disorder. If itching or inflammation is present, the health care provider prescribes a steroid preparation, such as hydrocortisone. Cleansing the anal area with moistened cleansing tissues rather than standard toilet tissue helps avoid irritation. The anal area should be cleansed gently by dabbing, rather than by wiping.

Diets high in fiber and fluids are recommended to promote regular bowel movements without straining. Stool softeners, such as docusate sodium (Colace), can be used temporarily. Irritating laxatives are avoided, as are foods and beverages that can make hemorrhoids worse. Spicy foods, nuts, coffee, and alcohol can be irritating. Remind patients to avoid sitting for long periods. The health care provider may prescribe mild oral analgesics for pain if the hemorrhoids are thrombosed.

Conservative treatment should alleviate symptoms in 3 to 5 days. If symptoms continue or recur frequently, the patient may require surgical intervention.

The surgeon can perform several procedures for symptomatic internal hemorrhoids on an ambulatory care basis. Current recommended therapies include ultrasound coagulation, rubber band ligation, circular stapling, and laser-assisted or simple resection of the hemorrhoids. The type of surgery depends on the degree of prolapse, whether there is thrombosis, and the overall condition of the patient.

The harmonic scalpel is an ultrasonically activated instrument that vibrates to coagulate small and medium-size vessels. In rubber band ligation, a rubber ring is placed around the internal hemorrhoid that constricts blood flow to the hemorrhoid, resulting in shrinking of the hemorrhoid. The rubber band usually causes a feeling of tightness in the area until the rubber band falls off in 2 to 4 days. Complications of these procedures include pain, thrombosis of other hemorrhoids, infection, and abscess formation. Bleeding may occur after the band falls off. If the hemorrhoid is prolapsed, a circular stapling device is used to excise a band of mucosa above the prolapse and restore the hemorrhoidal tissue back into the anal canal.

Hemorrhoidectomy, or resection of the hemorrhoid, tends to cause more pain than the other procedures. Urinary retention can also occur because of rectal spasms and anorectal tenderness. Hemorrhage, which may be internal and not visible or external, is a rare but potential complication.

Teach patients with hemorrhoids about the need to eat high-fiber, high-fluid diets to promote regular bowel patterns before and after surgery. Advise them to avoid stimulant laxatives, which can be habit forming.

For patients who undergo any type of surgical intervention, monitor for bleeding and pain postoperatively and teach them to report these problems to their health care provider. Using moist heat (e.g., sitz baths) three or four times per day can help promote comfort.

! NURSING SAFETY PRIORITY**Action Alert**

Tell the patient who has had surgical intervention for hemorrhoids that the first postoperative bowel movement may be very painful. Be sure that someone is with or near the patient when this happens. Some patients become light-headed and diaphoretic and may have syncope ("blackout").

The physician usually prescribes stool softeners such as docusate sodium (Colace) to begin preoperatively and continue after surgery. Analgesics and anti-inflammatory drugs are prescribed. A mild laxative should be administered if the patient has not had a bowel movement by the third postoperative day.

MALABSORPTION SYNDROME**Pathophysiology**

Malabsorption is a syndrome associated with a variety of disorders and intestinal surgical procedures. It interferes with the ability to absorb nutrients and is a result of a generalized flattening of the mucosa of the small intestine. With various disorders, physiologic mechanisms limit absorption of nutrients because of one or more of these abnormalities:

- Bile salt deficiencies
- Enzyme deficiencies
- Presence of bacteria
- Disruption of the mucosal lining of the small intestine
- Altered lymphatic and vascular circulation
- Decrease in the gastric or intestinal surface area

The nutrient involved in malabsorption depends on the type and location of the abnormality in the intestinal tract.

Deficiencies of bile salts can lead to malabsorption of fats and fat-soluble vitamins. Bile salt deficiencies can result from decreased synthesis of bile in the liver, bile obstruction, or alteration of bile salt absorption in the small intestine.

Enzymes normally found in the intestine split disaccharides (complex sugars) to monosaccharides (simple sugars). Examples of these enzymes are lactase, sucrase, maltase, and isomaltase. Lactase deficiency is the most common disaccharide enzyme deficiency. Without sufficient amounts of this enzyme, the body is not able to break down lactose. Lactase deficiency can be due to genetic inheritance, injury to intestinal mucosa from viral hepatitis, bacterial proliferation in the intestine, or sprue. Deficiencies of the other disaccharide enzymes are rare.

Pancreatic enzymes are also necessary for absorption of vitamin B₁₂. With destruction or obstruction of the pancreas or insufficient pancreatic stimulation, this nutrient is not well absorbed. Chronic pancreatitis, pancreatic carcinoma, resection of the pancreas, and cystic fibrosis can cause these malabsorption problems.

Loops of bowel can accumulate intestinal contents, resulting in bacterial overgrowth, when peristalsis is decreased. Bacteria at these sites break down bile salts, and fewer salts are available for fat absorption. They can also ingest vitamin B₁₂, which contributes to vitamin B₁₂ deficiency. This process can occur after a gastrectomy.

Disruption of the mucosal lining of the intestine is responsible for the malabsorption that occurs with celiac

(nontropical) sprue, tropical sprue, Crohn's disease, and ulcerative colitis. In celiac (nontropical) sprue, the absorptive surface area in the small intestine is lost; there is malabsorption of most nutrients. Celiac sprue is thought to be due to a genetic immune hypersensitivity response to gluten or its breakdown products or to result from the accumulation of gluten in the diet with peptidase deficiency.

Tropical sprue is caused by an infectious agent that has not been identified but is thought to be bacterial. Mucosal changes occur in a more widespread manner than in celiac sprue. However, the changes are not as severe as in celiac sprue. Tropical sprue results in malabsorption of fat, folic acid, and vitamin B₁₂ in later stages of the disease.

The inflammation in Crohn's disease interferes with the surface of cells absorbing bile salts and therefore leads to fat malabsorption. In ulcerative colitis, protein loss may occur.

Obstruction to lymphatic flow in the intestine can lead to loss of plasma proteins along with loss of minerals (e.g., iron, copper, calcium), vitamin B₁₂, folic acid, and lipids. Lymphatic obstruction can be caused by many conditions. Certain cancers such as lymphoma, inflammatory states, radiation enteritis, Crohn's disease, heart failure, and constrictive pericarditis are causes of lymphatic obstruction.

Interference with blood flow to the intestinal mucosa results in malabsorption. With intestinal surgery, there is loss of the surface area needed to facilitate absorption. Resection of the ileum results in vitamin B₁₂, bile salt, and other nutrient deficiencies. Gastric surgery is one of the most common causes of malabsorption and maldigestion. Other conditions associated with poor digestion and malabsorption include small-bowel ischemia and radiation enteritis.

PATIENT-CENTERED COLLABORATIVE CARE**ASSESSMENT**

Chronic diarrhea is a classic symptom of malabsorption. It occurs as a result of unabsorbed nutrients, which add to the bulk of the stool, and unabsorbed fat. **Steatorrhea** (greater than normal amounts of fat in the feces) is a common sign. It is a result of bile salt deconjugation, nonabsorbed fats, or bacteria in the intestine. Not all patients with malabsorption have diarrhea. Instead, some have an increased stool mass. Other clinical manifestations include:

- Unintentional weight loss
- Bloating and flatus (carbohydrate malabsorption)
- Decreased libido
- Easy bruising (purpura)
- Anemia (with iron and folic acid or vitamin B₁₂ deficiencies)
- Bone pain (with calcium and vitamin D deficiencies)
- Edema (caused by hypoproteinemia)

Laboratory studies reveal a decrease in mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). These decreases indicate hypochromic microcytic anemia resulting from iron deficiency. Increased MCV and variable MCH and MCHC values indicate macrocytic anemia resulting from vitamin B₁₂ and folic acid deficiencies. Serum iron levels are low in protein malabsorption because of

insufficient gastric acid for use of iron. Serum cholesterol levels may be low from decreased absorption and digestion of fat. Low serum calcium levels may indicate malabsorption of vitamin D and amino acids. Low levels of serum vitamin A (retinol) and carotene, its precursor, indicate a bile salt deficiency and malabsorption of fat. Serum albumin and total protein levels are low if protein is lost. A quantitative fecal fat analysis is elevated in either malabsorption or maldigestion.

A *lactose tolerance test* result that shows less than a 20% rise in the blood glucose level over the fasting blood glucose level indicates lactose intolerance. A hydrogen breath test can also be performed to detect this problem. The xylose absorption test can reveal low urine and serum D-xylose levels if malabsorption in the small intestine is present, a common finding in celiac sprue. An abnormal D-xylose test can indicate bacterial overgrowth in the small intestine.

The *Schilling test* measures urinary excretion of vitamin B₁₂ for diagnosis of pernicious anemia and a variety of other malabsorption syndromes. The *bile acid breath test* assesses the absorption of bile salt. If the patient has bacterial overgrowth, the bile salts will become deconjugated and the carbon dioxide level in the breath will peak earlier than expected.

Biopsy of the small intestine is performed for diagnosis of tropical sprue or celiac sprue. Ultrasonography is used to diagnose pancreatic tumors and tumors in the small intestine that are causing malabsorption. X-rays of the GI tract reveal pancreatic calcifications, tumors, or other abnormalities that cause malabsorption. A CT scan may also be done.

INTERVENTIONS

Interventions for most malabsorption syndromes focus on (1) avoidance of substances that aggravate malabsorption and (2) supplementation of nutrients. Surgical management of the primary disease may be indicated. Drug therapy may also improve or resolve malabsorption.

Nutrition management includes a low-fat diet for patients who have gallbladder disease, severe steatorrhea, or cystic fibrosis. A low-fat diet may or may not be indicated for pancreatic insufficiency because this disorder improves with enzyme replacement. Some clinicians believe that limitation of fat intake is not necessary with enzyme replacement. Dietary intake of fat is actually beneficial to the patient because it has a high number of calories. After a total gastrectomy, a high-protein, high-calorie diet and small, frequent meals are recommended. Lactose-free or lactose-restricted diets are available for patients with lactase deficiency, and gluten-free diets are available for those with celiac sprue.

The health care provider prescribes nutritional supplements according to the specific deficiency. Common supplements include:

CHART 59-6 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Special Skin Care for Patients with Chronic Diarrhea

- Use medicated wipes or premoistened disposable wipes rather than toilet tissue to clean the perineal area.
- Clean the perineal area well with mild soap and warm water after each stool; rinse soap from the area well.
- If the physician allows, provide a sitz bath several times per day.
- Apply a thin coat of A+D Ointment or other medicated protective barrier, such as aloe products, after each stool.
- Keep the patient off the affected buttock area.
- For open areas, cover with thin DuoDerm or Tegaderm occlusive dressing to promote rapid healing.
- Observe for fungal or yeast infections, which appear as dark red rashes with "satellite" lesions. Obtain prescription for medication if this problem occurs.

- Water-soluble vitamins, such as folic acid and vitamin B complex
- Fat-soluble vitamins, such as vitamin A, vitamin D, and vitamin K
- Minerals, such as calcium, iron, and magnesium
- Pancreatic enzymes, such as pancrelipase (Pancrease, Viokase)

Antibiotics are used to treat tropical sprue, Whipple's disease, and other disorders involving bacterial overgrowth. Tropical sprue is treated with trimethoprim/sulfamethoxazole (Bactrim, Septra). Bacterial overgrowth can be caused by a variety of disorders but is often treated with tetracycline and metronidazole (Flagyl, Novonidazol ). Steroids are sometimes given in celiac disease to decrease inflammation.

Drug therapy is used to control the clinical manifestations of malabsorption. Antidiarrheal agents, such as diphenoxylate hydrochloride and atropine sulfate (Lomotil), are often used to control diarrhea and steatorrhea. Anticholinergics, such as dicyclomine hydrochloride (Bentyl, Bentylol ) , may be given before meals to inhibit gastric motility. IV fluids may be necessary to replenish fluid losses associated with diarrhea.

Provide special measures to protect the skin when chronic diarrhea occurs (Chart 59-6). Conduct an ongoing assessment for clinical manifestations of malabsorption, and relate these to activities and dietary intake. For example, patients with steatorrhea are monitored for fluid and electrolyte imbalances and are encouraged to drink electrolyte-rich liquids liberally. Teach them the rationale for dietary, drug, and surgical management of nutritional deficiencies, and evaluate interventions on the basis of changes in or resolution of clinical manifestations.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient has impaired absorption and inadequate nutrition as a result of non-inflammatory intestinal disorders?

- Rectal bleeding
- Report of change in bowel habits
- Diarrhea or report of constipation
- Fatigue
- Vomiting
- Abdominal pain
- Change in bowel sounds (decreased or increased)
- Weight loss

NURSING CONCEPT REVIEW—cont'd

What should you INTERPRET and how should you RESPOND to a patient with impaired absorption and inadequate nutrition as a result of noninflammatory intestinal disorders?

Perform and interpret focused physical assessment findings, including:

- Vital signs
- Complete pain assessment
- Abdominal assessment
- Current weight compared with previous weight

Respond:

- Decrease abdominal pain by placing patient in sitting position.
- Start IV (large-bore) to replace fluids and electrolytes, and give blood transfusion as prescribed.
- Provide rest.
- Provide privacy and dignity.

- Assist with hygiene as needed.
- Insert nasogastric tube and connect to low suction as needed.
- Check laboratory values of hemoglobin and hematocrit.
- Check stool for occult or frank blood.
- Give antidiarrheal drugs if prescribed.
- Record intake and output.
- Assist with ADLs and ambulation as needed.

On what should you REFLECT?

- Continue to monitor for vomiting and diarrhea and for changes in pain.
- Think about what you need to document. Decide when you might need to call the health care provider or Rapid Response Team.
- Determine what health teaching and community resources may be needed for the patient and family.
- Think about what you can do to help prevent complications of the health problem.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Refer patients with familial CRC syndromes for genetic counseling and testing.
- Refer ostomy patients to the United Ostomy Associations of America, Inc. and the American Cancer Society for additional information and support groups.
- Consult with the certified wound, ostomy, continence nurse (CWOCN) or enterostomal therapist (ET) when a patient is scheduled for or has a new colostomy.
- Prioritize care for patients experiencing abdominal trauma: first assess airway, breathing, and circulation (ABCs), and then monitor mental status, vital signs, and skin perfusion to assess for hypovolemic shock.

Health Promotion and Maintenance

- Teach patients with irritable bowel syndrome (IBS) to avoid GI stimulants, such as caffeine, alcohol, and milk and milk products, and to manage stress.
- Instruct patients on dietary modifications to decrease the occurrence of colorectal cancer (CRC).
- Teach adults 50 years and older to have routine screening for CRC as listed in [Chart 59-1](#); people with genetic predispositions should have earlier and more frequent screening.
- Teach patients and caregivers how to provide colostomy care, including dietary measures, skin care, and ostomy products.

- Teach people measures for preventing constipation to minimize hemorrhoid occurrence.

Psychosocial Integrity

- Assess effects of IBS on patient lifestyle; recommend stress management techniques.
- Assist the patient with CRC with the anticipatory grieving process.
- Be aware that having a colostomy is a life-altering event that can severely impact one's body image; issues related to sexuality and fear of acceptance should be discussed.

Physiological Integrity

- Assess patients with IBS for elimination pattern, abdominal pain, and nausea.
- Be aware that minimally invasive inguinal hernia repair is an ambulatory procedure done via laparoscopy; postoperative management requires health teaching regarding rest for a few days and inspection of incisions for signs of infection.
- Be aware that a strangulated hernia can cause ischemia and bowel obstruction, requiring immediate intervention.
- Monitor patients who have conventional open herniorrhaphy for ability to void.
- Recognize that surgical procedures for CRC vary depending on tumor location as specified in [Table 59-1](#).
- Keep the peristomal skin clean and dry; observe for leakage around the pouch seal.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Provide meticulous perineal wound care for patients having an abdominoperineal (AP) resection, as described in [Chart 59-2](#).
- Assess the characteristics of the colostomy stoma, which should be reddish pink and moist; report abnormalities such as ischemia and necrosis (purplish or black) or unusual bleeding to the surgeon.
- Recall that bowel sounds are altered in patients with obstruction; absent bowel sounds imply total obstruction.
- Assess the patient's nasogastric tube for proper placement, patency, and output at least every 4 hours.
- Monitor patients with bowel obstruction for signs and symptoms of fluid, electrolyte, and acid-base imbalances.
- Teach patients having hemorrhoid surgery to take stool softeners before and after surgery to decrease discomfort during defecation.
- Be aware that intestinal polyps are usually benign but can become malignant if not removed.

CHAPTER

60

Care of Patients with Inflammatory Intestinal Disorders

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges
Audio Glossary

Concept Map Creator

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Describe the importance of collaborating with health care team members to provide care for patients with chronic inflammatory bowel disease (IBD).

Health Promotion and Maintenance

2. Differentiate care for older adults with acute and chronic inflammatory bowel disorders.
3. Develop a health teaching plan for patients to promote self-management when caring for ileostomy or other surgical diversion.
4. Identify community resources for patients and families regarding chronic IBD.
5. Discuss ways that food poisoning can be prevented.

Psychosocial Integrity

6. Identify expected body image changes associated with having an ileostomy or other surgical diversion.
7. Describe patient and family response to chronic IBD.

Physiological Integrity

8. Differentiate common types of acute inflammatory bowel disease.
9. Develop a collaborative plan of care for the patient who has appendicitis and peritonitis.
10. Discuss the common causes of gastroenteritis.
11. Compare and contrast the pathophysiology and clinical manifestations of ulcerative colitis and Crohn's disease.
12. Identify priority problems for patients with ulcerative colitis.
13. Explain the purpose of and nursing implications related to drug therapy for patients with IBD.
14. Plan priority postoperative care for a patient undergoing surgery for IBD.
15. Develop a hospital discharge teaching plan for patients having surgery for IBD.
16. Explain the role of nutrition therapy in managing the patient with diverticular disease.
17. Describe the comfort measures that the nurse can use for the patient with anal disorders.

Inflammatory bowel health problems affect the small intestine, large intestine (colon), or both. Together, these organs are called the *intestinal tract*. Continued digestion of food and absorption of nutrients occur primarily in the small intestine (bowel) to meet the body's needs for energy. Water is reabsorbed in the large intestine to help maintain a fluid balance and promote the passage of waste products. When the intestinal tract and its nearby structures become inflamed,

digestion and nutrition may be inadequate to meet a patient's needs.

ACUTE INFLAMMATORY BOWEL DISORDERS

Appendicitis, gastroenteritis, and peritonitis are the most common acute inflammatory bowel problems. These

disorders are potentially life threatening and can have major systemic complications if not treated promptly.

APPENDICITIS

Pathophysiology

Appendicitis is an acute inflammation of the vermiform appendix that occurs most often among young adults. It is the most common cause of right lower quadrant (RLQ) pain. The appendix usually extends off the proximal cecum of the colon just below the ileocecal valve. Inflammation occurs when the lumen (opening) of the appendix is obstructed (blocked), leading to infection as bacteria invade the wall of the appendix. The initial obstruction is usually a result of fecaliths (very hard pieces of feces) composed of calcium phosphate-rich mucus and inorganic salts. Less common causes are malignant tumors, helminthes (worms), or other infections.

When the lumen is blocked, the mucosa secretes fluid, increasing the internal pressure and restricting blood flow, resulting in pain. If the process occurs slowly, an abscess may develop, but a rapid process may result in peritonitis (inflammation of the peritoneum). *All complications of peritonitis are serious. Gangrene can occur within 24 to 36 hours, is life threatening, and is one of the most common indications for emergency surgery. Perforation may develop within 24 hours, but the risk rises rapidly after 48 hours.* Perforation of the appendix also results in peritonitis with a temperature of greater than 101° F (38.3° C) and a rise in pulse rate.

CONSIDERATIONS FOR OLDER ADULTS

Appendicitis is relatively rare at extremes in age. However, perforation is more common in older people, causing a higher mortality rate. The diagnosis of appendicitis is difficult to establish in older adults because symptoms of pain and tenderness may not be as pronounced in this age-group. This difference results in treatment delay and an increased risk for perforation, peritonitis, and death.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History taking and tracking the sequence of symptoms are important because nausea or vomiting before abdominal pain can indicate gastroenteritis. Abdominal pain followed by nausea and vomiting can indicate appendicitis. Ask about risk factors such as age, familial tendency, and intra-abdominal tumors. Classically, patients with appendicitis have cramplike pain in the epigastric or periumbilical area. Anorexia is a frequent symptom with nausea and vomiting occurring in many cases.

Perform a complete pain assessment. Initially, pain can present anywhere in the abdomen or flank area. As the inflammation and infection progress, the pain becomes more severe and steady and shifts to the RLQ between the anterior iliac crest and the umbilicus. This area is referred to as **McBurney's point** (Fig. 60-1). *Abdominal pain that increases with cough or movement and is relieved by bending the right hip or the knees suggests perforation and peritonitis.* An advanced practice nurse or other health care provider assesses for muscle rigidity and guarding on palpation of the abdomen. The patient

FIG. 60-1 McBurney's point is located midway between the anterior iliac crest and the umbilicus in the right lower quadrant. This is the classic area for localized tenderness during the later stages of appendicitis.

may report pain after release of pressure. This is referred to as "rebound" tenderness.

Laboratory findings do not establish the diagnosis, but often there is a moderate elevation of the white blood cell (WBC) count (leukocytosis) to 10,000 to 18,000/mm³ with a "shift to the left" (an increased number of immature WBCs). A WBC elevation to greater than 20,000/mm³ may indicate a perforated appendix. An ultrasound study may show the presence of an enlarged appendix. If symptoms are recurrent or prolonged, a computed tomography (CT) scan can be used for diagnosis and may reveal the presence of a fecalith.

INTERVENTIONS

All patients with suspected or confirmed appendicitis are hospitalized and examined by a surgeon. When the diagnosis is not clear, the health care team observes the patient before surgical exploration.

Nonsurgical Management

Keep the patient with suspected or known appendicitis on NPO to prepare for the possibility of emergency surgery and to avoid making the inflammation worse.

! NURSING SAFETY PRIORITY

Action Alert

For the patient with suspected appendicitis, administer IV fluids as prescribed to prevent fluid and electrolyte imbalance and to replace fluid volume. If tolerated, advise the patient to maintain a semi-Fowler's position so that abdominal drainage, if any, can be contained in the lower abdomen. Once the diagnosis of appendicitis is confirmed and surgery is scheduled, administer opioid analgesics and antibiotics as prescribed. *The patient with suspected or confirmed appendicitis should not receive laxatives or enemas, which can cause perforation of the appendix. Heat should never be applied to the abdomen because this may increase circulation to the appendix and result in increased inflammation and perforation!*

Surgical Management

Surgery is required as soon as possible. An **appendectomy** is the removal of the inflamed appendix by one of several surgical approaches. Uncomplicated appendectomy procedures are usually done via laparoscopy. A **laparoscopy** is a

minimally invasive surgical (MIS) procedure with one or more small incisions near the umbilicus through which a small endoscope is placed. Patients having this type of surgery for appendix removal have few postoperative complications. A newer procedure known as *natural orifice transluminal endoscopic surgery* (NOTES) (e.g., transvaginal endoscopic appendectomy) does not require an external skin incision. In this procedure, the surgeon places the endoscope into the vagina or other orifice and makes a small incision to enter the peritoneal space. Patients having any type of laparoscopic procedures are typically discharged the same day of surgery with less pain and few complications after discharge. Most patients can return to usual activities in 1 to 2 weeks.

If the diagnosis is not definitive but the patient is at high risk for complications from suspected appendicitis, the surgeon may perform an exploratory laparotomy to rule out appendicitis. A **laparotomy** is an open surgical approach with a larger abdominal incision for complicated or atypical appendicitis or peritonitis.

Preoperative teaching is often limited because the patient is in pain or may be transferred quickly to the operating suite for emergency surgery. The patient is prepared for general anesthesia and surgery, as described in [Chapter 16](#). After surgery, care of the patient who has undergone an appendectomy is the same as that required for anyone who has received general anesthesia (see [Chapter 18](#)).

If peritonitis or abscesses are found, wound drains are inserted and a nasogastric tube may be placed to decompress the stomach and prevent abdominal distention. Administer IV antibiotics and opioid analgesics as prescribed. Help the patient out of bed on the evening of surgery to help prevent respiratory complications, such as atelectasis. He or she may be hospitalized for as long as 3 to 5 days and return to normal activity in 4 to 6 weeks.

PERITONITIS

Peritonitis is a life-threatening, acute inflammation of the visceral/parietal peritoneum and endothelial lining of the abdominal cavity. Primary peritonitis is rare and indicates the peritoneum is infected via the bloodstream. This problem is not discussed here.

Pathophysiology

Normally the peritoneal cavity contains about 50 mL of sterile fluid (transudate), which prevents friction in the abdominal cavity during peristalsis. When the peritoneal cavity is contaminated by bacteria, the body first begins an inflammatory reaction walling off a localized area to fight the infection. This local reaction involves vascular dilation and increased capillary permeability, allowing transport of leukocytes and subsequent phagocytosis of the offending organisms. If this walling off process fails, the inflammation spreads and contamination becomes massive, resulting in diffuse (widespread) peritonitis.

Peritonitis is most often caused by contamination of the peritoneal cavity by bacteria or chemicals. Bacteria gain entry into the peritoneum by perforation (from appendicitis, diverticulitis, peptic ulcer disease) or from an external penetrating wound, a gangrenous gallbladder, bowel obstruction, or ascending infection through the genital tract. Less common causes include perforating tumors, leakage or contamination

during surgery, and infection by skin pathogens in patients undergoing continuous ambulatory peritoneal dialysis (CAPD). Common bacteria responsible for peritonitis include *Escherichia coli*, *Streptococcus*, *Staphylococcus*, *Pneumococcus*, and *Gonococcus*. Chemical peritonitis results from leakage of bile, pancreatic enzymes, and gastric acid.

When diagnosis and treatment of peritonitis are delayed, blood vessel dilation continues. The body responds to the continuing infectious process by shunting extra blood to the area of inflammation (hyperemia). Fluid is shifted from the extracellular fluid compartment into the peritoneal cavity, connective tissues, and GI tract (“*third spacing*”). This shift of fluid can result in a significant decrease in circulatory volume and *hypovolemic shock*. Severely decreased circulatory volume can result in insufficient perfusion of the kidneys, leading to kidney failure with electrolyte imbalance. Assess for clinical manifestations of these life-threatening problems.

Peristalsis slows or stops in response to severe peritoneal inflammation, and the lumen of the bowel becomes distended with gas and fluid. Fluid that normally flows to the small bowel and the colon for reabsorption accumulates in the intestine in volumes of 7 to 8 L daily. The toxins or bacteria responsible for the peritonitis can also enter the bloodstream from the peritoneal area and lead to bacteremia or **septicemia** (bacterial invasion of the blood).

Respiratory problems can occur as a result of increased abdominal pressure against the diaphragm from intestinal distention and fluid shifts to the peritoneal cavity. Pain can interfere with respirations at a time when the patient has an increased oxygen demand because of the infectious process.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Ask the patient about abdominal pain, and determine the character of the pain (e.g., cramping, sharp, aching), location of the pain, and whether the pain is localized or generalized. Ask about a history of a low-grade fever or recent spikes in temperature.

Physical findings of peritonitis ([Chart 60-1](#)) depend on several factors: the stage of the disease, the ability of the body to localize the process by walling off the infection, and whether the inflammation has progressed to generalized

CHART 60-1 KEY FEATURES

Peritonitis

- Rigid, boardlike abdomen (classic)
- Abdominal pain (localized, poorly localized, or referred to the shoulder or chest)
- Distended abdomen
- Nausea, anorexia, vomiting
- Diminishing bowel sounds
- Inability to pass flatus or feces
- Rebound tenderness in the abdomen
- High fever
- Tachycardia
- Dehydration from high fever (poor skin turgor)
- Decreased urine output
- Hiccups
- Possible compromise in respiratory status

peritonitis. The patient most often appears acutely ill, lying still, possibly with the knees flexed. Movement is guarded, and he or she may report and show signs of pain (e.g., facial grimacing) with coughing or movement of any type. During inspection, observe for progressive abdominal distention, often seen when the inflammation markedly reduces intestinal motility. Auscultate for bowel sounds, which usually disappear with progression of the inflammation.

The cardinal signs of peritonitis are abdominal pain and tenderness. In the patient with localized peritonitis, the abdomen is tender on palpation in a well-defined area with rebound tenderness in this area. With generalized peritonitis, tenderness is widespread.

! NURSING SAFETY PRIORITY

Action Alert

For patients with peritonitis, assess for abdominal wall rigidity, which is a classic finding that is sometimes referred to as a “boardlike” abdomen. Monitor the patient for a high fever because of the infectious process. Assess for tachycardia occurring in response to the fever and decreased circulating blood volume. Observe whether he or she has dry mucous membranes and a low urine output seen with third spacing. Nausea and vomiting may also be present. Hiccups may occur as a result of diaphragmatic irritation. Be sure to document all assessment findings.

White blood cell (WBC) counts are often elevated to 20,000/mm³ with a high neutrophil count. Blood culture studies may be done to determine whether septicemia has occurred and to identify the causative organism to enable appropriate therapy. The health care provider requests laboratory tests to assess fluid and electrolyte balance and renal status, including electrolytes, blood urea nitrogen (BUN), creatinine, hemoglobin, and hematocrit. Oxygen saturation and end-carbon dioxide monitoring may be obtained to assess respiratory function and acid-base balance.

Abdominal x-rays can assess for free air or fluid in the abdominal cavity, indicating perforation. The x-rays may also show dilation, edema, and inflammation of the small and large intestines. An abdominal sonogram may be useful in locating the problem.

INTERVENTIONS

Patients with peritonitis are hospitalized because of the severe nature of the illness. If complications are extensive, the patients are often admitted to a critical care unit. Nursing interventions focus on the early identification of complications.

Nonsurgical Management

The physician prescribes IV fluids and broad-spectrum antibiotics immediately after establishing the diagnosis of peritonitis. IV fluids are used to replace fluids collected in the peritoneum and bowel. Monitor daily weight and intake and output carefully. A nasogastric tube (NGT) decompresses the stomach and the intestine, and the patient is NPO. Apply oxygen as prescribed and according to the patient's respiratory status and oxygen saturation via pulse oximetry. Administer analgesics, and monitor for pain control. Document pain assessments thoroughly. A surgical consultation is requested in case surgery should become necessary.

Surgical Management

Abdominal surgery is the usual treatment for identifying and repairing the cause of the peritonitis. If the patient is so critically ill that surgery would be life threatening, it may be delayed. Surgery focuses on controlling the contamination, removing foreign material from the peritoneal cavity, and draining collected fluid.

Exploratory **laparotomy** (surgical opening into the abdomen) or laparoscopy is used to remove or repair the inflamed or perforated organ (e.g., appendectomy for an inflamed appendix; a colon resection, with or without a colostomy, for a perforated diverticulum). Before the incision(s) is closed, the surgeon irrigates the peritoneum with antibiotic solutions. Several catheters may be inserted to drain the cavity and provide a route for irrigation after surgery.

The preoperative care is similar to that described in Chapter 16 for patients having general anesthesia. Chapter 18 describes general postoperative care for exploratory laparotomy. Multi-system complications can occur with peritonitis. Loss of fluids from the extracellular space to the peritoneal cavity, NGT suctioning, and NPO status require that the patient receives IV fluid replacement. Be sure that unlicensed assistive personnel (UAP) carefully measure intake and output. Fluid rates may be changed frequently based on laboratory values and patient condition.

! NURSING SAFETY PRIORITY

Action Alert

Monitor the patient's level of consciousness, vital signs, respiratory status (respiratory rate and breath sounds), and intake and output at least hourly immediately after abdominal surgery. Maintain the patient in a semi-Fowler's position to promote drainage of peritoneal contents into the lower region of the abdominal cavity. This position helps increase lung expansion.

The patient has one or more incisions and drains. If an open surgical procedure is needed, the infection may slow healing of an incision or the incision may be partially open to heal by second or third intention. These wounds require special care involving manual irrigation or packing as prescribed by the surgeon. If the surgeon requests peritoneal irrigation through a drain, *maintain sterile technique during manual irrigation*. Assess whether the patient retains the fluid used for irrigation by comparing the amount of fluid returned with the amount of fluid instilled. Fluid retention could cause abdominal distention or pain.

Community-Based Care

The length of hospitalization depends on the extent and severity of the infectious process. Patients who have a localized abscess drained and who respond to antibiotics and IV fluids without multi-system complications are discharged in several days. Others may require mechanical ventilation or hemodialysis with longer hospital stays. Some patients may be transferred to a transitional care unit to complete their antibiotic therapy and recovery. Convalescence is often longer than for other surgeries because of multi-system involvement.

When discharged home, assess the patient's ability for self-management at home with the added task of incision care and a reduced activity tolerance. Provide the patient and

family with written and oral instructions to report these problems to the health care provider immediately:

- Unusual or foul-smelling drainage
- Swelling, redness, or warmth or bleeding from the incision site
- A temperature higher than 101° F (38° C)
- Abdominal pain
- Signs of wound dehiscence or ileus

Patients with an incision healing by second or third intention may require dressings, solution, and catheter-tipped syringes to irrigate the wound. A home care nurse may be needed to assess, irrigate, or pack the wound and change the dressing as needed until the patient and family feel comfortable with the procedure. If the patient needs assistance with ADLs, a home care aide or temporary placement in a skilled care facility may be indicated. Collaborate with the case manager (CM) to determine the most appropriate setting for seamless continuing care in the community.

Review information about antibiotics and analgesics. For patients taking oral opioid analgesics such as oxycodone with acetaminophen (Tylox, Percocet, Endocet ) for any length of time, a stool softener such as docusate sodium (Colace, Regulax ) may be prescribed. Older adults are especially at risk for constipation from codeine-based drugs.

Teach patients to refrain from any lifting for *at least* 6 weeks. Other activity limitations are made on an individual basis with the physician's recommendation.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

An older adult has a perforated appendix and is scheduled for emergent surgery. What assessment findings will the nurse expect the client to have before surgery? **Select all that apply.**

- A. Bradycardia
- B. Dizziness
- C. Distended abdomen
- D. Fever
- E. Diarrhea
- F. Fistulas
- G. Incontinence

GASTROENTERITIS

Pathophysiology

Gastroenteritis is an increase in the frequency and water content of stools and/or vomiting as a result of inflammation of the mucous membranes of the stomach and intestinal tract. It affects mainly the small bowel and can be caused by either viral or bacterial infections, which have similar manifestations. They are considered self-limiting in their course unless complications occur. All organisms implicated in gastroenteritis can cause diarrhea. However, the organisms discussed in this section have distinguishing characteristics.

Some clinicians include shigellosis when discussing gastroenteritis. Others consider shigellosis separately as a dysentery type of illness. Dysenteries affect the *large* bowel. Gastroenteritis affects the *small* bowel. Other clinicians classify infectious disease of the intestine as bacterial, viral, or parasitic, without using the term *gastroenteritis*.

Food poisoning is sometimes described in conjunction with gastroenteritis with specific reference to the organism causing the food poisoning. Gastroenteritis, however, differs

from food poisoning with regard to transmission in the body, incubation time, and effect on immunity.

The following discussion of gastroenteritis includes the epidemic viral form and the bacterial forms (*Campylobacter*, *Escherichia coli*, and shigellosis) (Table 60-1). Organisms associated with food poisoning are discussed later in this chapter.

Infection with viral and bacterial organisms can produce GI illnesses that cause watery diarrhea. These disorders may be caused by noninflammatory, inflammatory, or penetrating mechanisms. Organisms such as enterotoxigenic *E. coli* can release enterotoxin (a noninflammatory toxic substance specific to the intestinal mucosa), which results in diarrhea. *Shigella* or *Campylobacter* can attach itself to mucosal epithelium without penetrating it, resulting in destruction of the intestinal villi and malabsorption. Infections that are caused by bacterial toxins reduce the absorptive capacity of the distal small bowel and proximal colon, resulting in diarrhea. Finally, the organism can penetrate the intestine, causing cellular destruction, necrosis, and a potential for ulceration. Diarrhea occurs often with white blood cells (WBCs) or red blood cells (RBCs) present in the stool.

All of these organisms are transmitted via the oral-fecal route and result in *increased* GI motility, with fluids and electrolytes being secreted into the intestine at rapid rates. Invading organisms more easily attach to the intestinal mucosa if the normal intestinal flora is altered. This can occur in patients who are receiving antibiotics, are malnourished, or are debilitated. Two groups of viruses, the rotaviruses (which usually affect young children) and Norwalk virus, as well as bacterial pathogens, are the most common causes of

TABLE 60-1 COMMON TYPES OF GASTROENTERITIS AND THEIR CHARACTERISTICS

TYPE	CHARACTERISTICS
Viral Gastroenteritis	
Epidemic viral	Caused by many parvovirus-type organisms Transmitted by the fecal-oral route in food and water Incubation period 10-51 hrs Communicable during acute illness
Rotavirus and Norwalk virus	Transmitted by the fecal-oral route and possibly the respiratory route Incubation in 48 hrs Rotavirus is most common in infants and young children Norwalk virus affects young children and adults
Bacterial Gastroenteritis	
<i>Campylobacter</i> enteritis	Transmitted by the fecal-oral route or by contact with infected animals or infants Incubation period 1-10 days Communicable for 2-7 weeks
<i>Escherichia coli</i> diarrhea	Transmitted by fecal contamination of food, water, or fomites
Shigellosis	Transmitted by direct and indirect fecal-oral routes Incubation period 1-7 days Communicable during the acute illness to 4 wk after the illness Humans possibly carriers for months

gastroenteritis. Rotaviruses can also affect older adults in group settings, such as long-term care facilities.

The three most common types of *bacterial* gastroenteritis are *E. coli* diarrhea (“traveler’s diarrhea”), *Campylobacter* enteritis (another “traveler’s diarrhea”), and *Shigellosis* (bacillary dysentery). The reservoirs of *E. coli* are humans, who are often asymptomatic.

Diarrhea caused by *E. coli* and *Campylobacter* occurs worldwide, commonly in epidemic outbreaks. *E. coli* epidemics are highest in areas of poor sanitation during warm months. *Campylobacter* incidence is highest during warm months. *Shigellosis* occurs in every age-group but most frequently in children (younger than 10 years) and older adults because of their depressed immune systems. Outbreaks of *shigellosis* are common in areas with crowded living conditions, such as in correctional facilities.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The patient history can provide information related to the potential cause of the illness. Ask about recent travel, especially to tropical regions of Asia, Africa, or Central or South America. Some areas of Mexico may also be the source of gastroenteritis. Newcomers (immigrants) from these countries often have gastroenteritis. Traveler’s diarrhea can begin 3 days to 2 weeks after the patient’s arrival.

The patient who has gastroenteritis usually looks ill. Nausea and vomiting can occur with all types of gastroenteritis but are usually limited to the first 1 or 2 days. Patients have diarrhea, which varies in consistency and amount with the causative organism.

In patients with epidemic viral gastroenteritis, myalgia (muscle aches), headache, and malaise are often reported. Weakness and cardiac dysrhythmias may be the result of loss of potassium (hypokalemia) from diarrhea. Monitor for and document manifestations of hypokalemia.

NURSING SAFETY PRIORITY

Action Alert

For patients with gastroenteritis, note any abdominal distention and listen for hyperactive bowel sounds. Depending on the amount of fluids lost through diarrhea and vomiting, patients may have varying degrees of dehydration manifested by:

- Poor skin turgor
- Fever
- Dry mucous membranes
- Orthostatic blood pressure changes (which can cause falls, especially for older adults)
- Hypotension
- Oliguria

In some cases, dehydration may be severe, and shock may occur if diarrhea is prolonged. *Dehydration occurs rapidly in older adults and may require hospitalization. Monitor mental status changes, such as acute confusion, that result from hypoxia in the older adult. These changes may be the only clinical manifestation of dehydration in older adults.*

Diarrhea associated with epidemic viral gastroenteritis is commonly limited to 24 to 48 hours. Infection with the Norwalk virus has a rapid onset of nausea, abdominal

cramps, vomiting, and diarrhea. This enteritis is usually mild. *Campylobacter* enteritis is a more severe disease with foul-smelling stools containing blood, which can number 20 to 30 per day for up to 7 days. *E. coli* gastroenteritis may or may not have blood or mucus in the stool. Diarrhea can last for up to 10 days. *Shigella* causes stools to have blood and mucus, which can continue for up to 5 days. Monitor for and document the number of stools daily for the patient who is hospitalized.

As part of the laboratory assessment, Gram stain of stool is usually done before culture. Cultures positive for the organism are diagnostic (Pagana & Pagana, 2010). Many WBCs on Gram stain suggest shigellosis. The presence of WBCs and RBCs in the stool may indicate *Campylobacter* gastroenteritis.

INTERVENTIONS

For any type of gastroenteritis, encourage fluid replacement. The amount and route of fluid administration are determined by the patient’s hydration status and overall health condition.

Fluid Replacement

Teach patients to drink extra fluids to replace fluid lost through vomiting and diarrhea. Depending on the patient’s age and severity of dehydration, he or she may be admitted to the hospital for gastroenteritis or may stay in the emergency department or urgent care center until adequate hydration is restored.

Obtain a weight, orthostatic blood pressure, and other vital sign measurements at admission. IV fluids such as half-strength normal saline (0.45% sodium chloride) to replace sodium lost in vomitus, with or without potassium supplements, are infused as prescribed. *Potassium is usually needed for patients with excessive diarrhea.* Continue to monitor the patient’s vital signs, intake and output, and weight. A rapid gain or loss of 1 kg (2.2 lbs) of body weight is equivalent to the gain or loss of 1 L of fluid. Advise the patient to alternate periods of rest and activity.

Depending on the type of gastroenteritis, especially if the geographic area is experiencing epidemic infections, the local health department may need to be notified. For example, it is mandatory that every case of shigellosis be reported. In some endemic areas, *Campylobacter* enteritis must be reported.

Drug Therapy

Drugs that suppress intestinal motility may not be given for bacterial or viral gastroenteritis. *Use of these drugs can prevent the infecting organisms from being eliminated from the body.* If the health care provider determines that antiperistaltic agents are necessary, an initial dose of loperamide (Imodium) 4 mg can be administered orally, followed by 2 mg after each loose stool, up to 16 mg daily.

NURSING SAFETY PRIORITY

Drug Alert

Diphenoxylate hydrochloride with atropine sulfate (Lomotil, Lomanate) reduces GI motility but is used sparingly because of its habit-forming ability. *The drug should not be used for older adults because it also causes drowsiness and could contribute to falls.*

Treatment with antibiotics may be needed if the gastroenteritis is due to bacterial infection with fever and severe diarrhea. Depending on the type and severity of the illness, examples of drugs that may be prescribed include ciprofloxacin (Cipro), levofloxacin (Levaquin), or azithromycin (Zithromax). If the gastroenteritis is due to shigellosis, anti-infective agents such as trimethoprim/sulfamethoxazole (Septra DS, Bactrim DS, Roubac ) or ciprofloxacin are prescribed.

For relatively short-term diarrhea of 24 to 48 hours' duration, the diagnosis is based primarily on the patient's history and clinical manifestations, not by a stool examination. When diarrhea is severe or persists for long periods, the stool is examined to determine the causative organism and to begin specific treatment. It should be determined whether the diarrhea is caused by *Salmonella* or by parasites because these organisms respond to specific medications (see p. 1289 in the Parasitic Infection section). Diarrhea that continues longer than 10 days, especially if associated with nocturnal diarrhea, is probably *not* due to gastroenteritis.

Skin Care

Frequent stools that are rich in electrolytes and enzymes, as well as frequent wiping and washing of the anal region, can irritate the skin. Teach the patient to avoid toilet paper and harsh soaps. Ideally, he or she can gently clean the area with warm water or an absorbent material, followed by thorough but gentle drying. Cream, oil, or gel can be applied to a damp, warm washcloth to remove stool that sticks to open skin. Special prepared skin wipes can also be used. Protective barrier cream can be applied to the skin between stools. Sitz baths for 10 minutes two or three times daily can also relieve discomfort.

If leakage of stool is a problem, the patient can use absorbent cotton or panty liner and keep it in place with snug underwear. For patients who are incontinent, remind unlicensed assistive personnel (UAP) to keep the perineal and buttock areas clean and dry. The use of incontinent pads at night instead of briefs allows air to circulate to the skin and prevents irritation.

Teaching for Self-Management

During the acute phase of the illness, teach the patient and family about the importance of fluid replacement. Teaching the patient and family about reducing the risk for transmission of gastroenteritis is also important (Chart 60-2). Adhere to these precautions for up to 7 weeks after the illness or up to several months if *Shigella* was the offending organism.

CHRONIC INFLAMMATORY BOWEL DISEASE

Ulcerative colitis and Crohn's disease are the two most common inflammatory bowel diseases (IBDs) that affect adults. Comparisons and differences are listed in Table 60-2. Viral and bacterial dysenteries can cause symptoms similar to those of IBD, and other problems must be ruled out before a definitive diagnosis is made.

The approach to each patient is individualized. Encourage patients to self-manage their disease by learning about the illness, treatment, drugs, and complications.

CHART 60-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Preventing Transmission of Gastroenteritis

Advise the patient to:

- Wash hands well for at least 30 seconds with an antibacterial soap, especially after a bowel movement, and maintain good personal hygiene.
- Restrict the use of glasses, dishes, eating utensils, and tubes of toothpaste for their own use. In severe cases, disposable utensils may be wise.
- Maintain clean bathroom facilities to avoid exposure to stool.
- Inform the health care provider if symptoms persist beyond 3 days.
- Do not prepare or handle food that will be consumed by others. If the patient is employed as a food handler, the public health department should be consulted for recommendations about the return to work.

TABLE 60-2 DIFFERENTIAL FEATURES OF ULCERATIVE COLITIS AND CROHN'S DISEASE

FEATURE	ULCERATIVE COLITIS	CROHN'S DISEASE
Location	Begins in the rectum and proceeds in a continuous manner toward the cecum	Most often in the terminal ileum, with patchy involvement through all layers of the bowel
Etiology	Unknown	Unknown
Peak incidence at age	15-25 yr and 55-65 yr	15-40 yr
Number of stools	10-20 liquid, bloody stools per day	5-6 soft, loose stools per day, non-bloody
Complications	Hemorrhage Nutritional deficiencies	Fistulas (common) Nutritional deficiencies
Need for surgery	Infrequent	Frequent

ULCERATIVE COLITIS

Pathophysiology

Ulcerative colitis (UC) creates widespread inflammation of mainly the rectum and rectosigmoid colon but can extend to the entire colon when the disease is extensive. Distribution of the disease can remain constant for years. UC is a disease that is associated with periodic remissions and exacerbations (flare-ups) (McCance et al., 2010). Many factors can cause exacerbations, including intestinal infections.

The intestinal mucosa becomes hyperemic (has increased blood flow), edematous, and reddened. In more severe inflammation, the lining can bleed and small erosions, or ulcers, occur. Abscesses can form in these ulcerative areas and result in tissue necrosis (cell death). Continued edema and mucosal thickening can lead to a narrowed colon and possibly a partial bowel obstruction. Table 60-3 lists the categories of the severity of UC.

The patient's stool typically contains blood and mucus. Patients report **tenesmus** (an unpleasant and urgent sensation to defecate) and lower abdominal colicky pain relieved with defecation. Malaise, anorexia, anemia, dehydration,

TABLE 60-3 AMERICAN COLLEGE OF GASTROENTEROLOGISTS CLASSIFICATION OF UC SEVERITY

SEVERITY	STOOL FREQUENCY	SIGNS/SYMPTOMS
Mild	<4 stools/day with/without blood	Asymptomatic Laboratory values usually normal
Moderate	>4 stools/day with/without blood	Minimal symptoms Mild abdominal pain Mild intermittent nausea Possible increased C-reactive protein* or ESR†
Severe	>6 bloody stools/day	Fever Tachycardia Anemia Abdominal pain Elevated C-reactive protein* and/or ESR†
Fulminant	>10 bloody stools/day	Increasing symptoms Anemia may require transfusion Colonic distention on x-ray

Adapted from Present, D.H. (2006). *Current and investigational approaches in the management of ulcerative colitis*. Secaucus, NJ: Thomson Professional Postgraduate Services/Shire Pharmaceuticals, Inc.

UC, Ulcerative colitis.

*C-reactive protein is a sensitive acute-phase serum marker that is evident in the first 6 hours of an inflammatory process.

†ESR (erythrocyte sedimentation rate) may be helpful but is less sensitive than C-reactive protein.

fever, and weight loss are common. Extraintestinal manifestations such as migratory polyarthritis, ankylosing spondylitis, and erythema nodosum are present in a large number of patients. The common complications of UC, including extraintestinal manifestations, are listed in Table 60-4.

Etiology and Genetic Risk

The exact cause of UC is unknown, but genetic and immunologic factors have been suspected. A genetic basis of the disease has been supported because it is often found in families and twins. Immunologic causes, including autoimmune dysfunction, are likely the etiology of extraintestinal manifestations of the disease. Epithelial antibodies in the IgG class have been identified in the blood of some patients with UC (McCance et al., 2010).

With long-term disease, cellular changes can occur that increase the risk for colon cancer. Damage from proinflammatory cytokines, such as specific interleukins (e.g., IL-1, IL-6, IL-8) and tumor necrosis factor (TNF)-alpha, have cytotoxic effects on the colonic mucosa (McCance et al., 2010).

Incidence/Prevalence

Chronic inflammatory bowel disease (IBD) affects about 1.4 million people in the United States and is split about equally between ulcerative colitis (UC) and Crohn's disease

TABLE 60-4 COMPLICATIONS OF ULCERATIVE COLITIS AND CROHN'S DISEASE

COMPLICATION	DESCRIPTION
Hemorrhage/perforation	Lower gastrointestinal bleeding results from erosion of the bowel wall.
Abscess formation	Localized pockets of infection develop in the ulcerated bowel lining.
Toxic megacolon	Paralysis of the colon causes dilation and subsequent colonic ileus, possibly perforation.
Malabsorption	Essential nutrients cannot be absorbed through the diseased intestinal wall, causing anemia and malnutrition (most common in Crohn's disease).
Nonmechanical bowel obstruction	Obstruction results from toxic megacolon or cancer.
Fistulas	In Crohn's disease in which the inflammation is transmural, fistulas can occur anywhere but usually track between the bowel and bladder resulting in pyuria and fecaluria.
Colorectal cancer	Patients with ulcerative colitis with a history longer than 10 years have a high risk for colorectal cancer. This complication accounts for about one third of all deaths related to ulcerative colitis.
Extraintestinal complications	Complications include arthritis, hepatic and biliary disease (especially cholelithiasis), oral and skin lesions, and ocular disorders, such as iritis. The cause is unknown.
Osteoporosis	Osteoporosis occurs especially in patients with Crohn's disease.

(discussed later). Peak age for being diagnosed with UC is between 30 and 40 years and again at 55 to 65 years. Women are more often affected than men in their younger years, but men have the disease more often as middle-aged and older adults (Crohn's and Colitis Foundation of America, 2008).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Collect data on family history of IBD, previous and current therapy for the illness, and dates and types of surgery. Obtain a nutrition history, including intolerance of milk and milk products and fried, spicy, or hot foods. Ask about usual bowel elimination pattern (color, number, consistency, and character of stools), abdominal pain, tenesmus, anorexia, and fatigue. Note any relationship between diarrhea, timing of meals, emotional distress, and activity. Inquire about recent (past 2 to 3 month) exposure to antibiotics suggesting *Clostridium difficile* infection. Has the patient traveled to or emigrated from tropical areas? Ask about recent use of NSAIDs that can either present with the initial diagnosis or cause a flare-up of the disease. Ask about any extraintestinal symptoms such as arthritis, mouth sores, vision problems, and skin disorders.

CULTURAL AWARENESS

Ulcerative colitis is more common among Jewish persons than among those who are not Jewish, and among whites more than non-whites (Crohn's and Colitis Foundation of America, 2008). The reasons for these cultural differences are not known.

Physical Assessment/Clinical Manifestations

Symptoms vary with an acuteness of onset. Vital signs are usually within normal limits in mild disease. In more severe cases, the patient may have a low-grade fever (99° to 100° F [37.2° to 37.8° C]). The physical assessment findings are usually nonspecific, and in milder cases the physical examination may be normal. Viral and bacterial infections cause symptoms similar to those of UC.

Note any abdominal distention along the colon. Patients with fever associated with tachycardia may indicate peritonitis, dehydration, and bowel perforation. Assess for clinical manifestations associated with extraintestinal complications, such as inflamed joints and lesions inside the mouth.

Psychosocial Assessment

Many patients are very concerned about the frequency of stools and the presence of blood. *The inability to control the disease symptoms, particularly diarrhea, can be disruptive and stress producing.* Severe illness may limit the patient's activities outside the home with fear of fecal incontinence resulting in feeling "tied to the toilet." Severe anxiety and depression may result. Eating may be associated with pain and cramping and an increased frequency of stools. Mealtimes may become unpleasant experiences. Frequent visits to health care providers and close monitoring of the colon mucosa for abnormal cell changes can be anxiety provoking.

Assess the patient's understanding of the illness and its impact on his or her lifestyle. Encourage and support the patient while exploring:

- The relationship of life events to disease exacerbations
- Stress factors that produce symptoms
- Family and social support systems
- Concerns regarding the possible genetic basis and associated cancer risks of the disease
- Internet access for reliable education information

Laboratory Assessment

As a result of chronic blood loss, hematocrit and hemoglobin levels may be low, which indicates anemia and a chronic disease state. *An increased WBC count, C-reactive protein, or erythrocyte sedimentation rate (ESR) is consistent with inflammatory disease.* Blood levels of sodium, potassium, and chloride may be low as a result of frequent diarrheal stools and malabsorption through the diseased bowel (Pagana & Pagana, 2010). Hypoalbuminemia (decreased serum albumin) is found in patients with extensive disease from losing protein in the stool.

Other Diagnostic Assessment

A colonoscopy is the most definitive test for diagnosing UC. Annual colonoscopies are recommended when the patient has longer than a 10-year history of UC involving the entire colon. In some cases, a *computed tomography (CT) scan* may be done to confirm the disease or its complications. *Barium enemas* with air contrast can show differences between UC and Crohn's disease and identify complications, mucosal patterns, and the distribution and depth of disease involvement. In early disease, the barium enema may show incomplete filling as a result of inflammation and fine ulcerations along the bowel contour, which appear deeper in more advanced disease.

ANALYSIS

The priority problems for patients with ulcerative colitis are:

1. Diarrhea and incontinence related to inflammation of the bowel mucosa
2. Pain related to inflammation and ulceration of the bowel mucosa and skin irritation
3. Potential for lower GI bleeding and resulting anemia

PLANNING AND IMPLEMENTATION

Decreasing Diarrhea and Bowel Incontinence

Planning: Expected Outcomes. The major concern for a patient with ulcerative colitis is the occurrence of frequent, bloody diarrhea and fecal incontinence from tenesmus. Therefore, with treatment, the patient is expected to have decreased diarrhea, formed stools, and control of bowel movements.

Interventions. Many measures are used to relieve symptoms and to reduce intestinal motility, decrease inflammation, and promote intestinal healing. Nonsurgical and/or surgical management may be needed.

Nonsurgical Management. Nonsurgical management includes drug and nutrition therapy. The use of physical and emotional rest is also an important consideration. Teach the patient to record color, volume, frequency, and consistency of stools to determine severity of the problem.

Monitor the skin in the perianal area for irritation and ulceration resulting from loose, frequent stools. Stool cultures may be sent for analysis if diarrhea continues. Have the patient weigh himself or herself one or two times per week. If the patient is hospitalized, remind unlicensed assistive personnel to weigh him or her on admission and daily and document all weights.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse is caring for a client with an exacerbation of ulcerative colitis. Which laboratory finding for the client will the nurse expect?

- A. Decreased erythrocyte sedimentation rate
- B. Decreased serum potassium
- C. Decreased C-reactive protein
- D. Decreased platelet count

Drug Therapy. Common drug therapy for UC includes aminosaliclates, glucocorticoids, antidiarrheal drugs, and immunomodulators. Teach patients about side effects and adverse drug events (ADEs) and when to call their health care provider.

The *aminosalicylates* are drugs commonly used to treat mild to moderate UC and/or maintain remission. Several aminosaliclic acid compounds are available. These drugs, also called 5-ASAs, are thought to have an anti-inflammatory effect by inhibiting prostaglandins and are usually effective in 2 to 4 weeks.

Sulfasalazine (Azulfidine, Azulfidine EN-tabs), the first aminosaliclate approved for UC, is metabolized by the intestinal bacteria into 5-ASA, which delivers the beneficial effects of the drug, and sulfapyridine, which is responsible for unwanted side effects.

Mesalamine (Asacol, Pentasa, Rowasa, Apriso, Canasa) is better tolerated than sulfasalazine because none of its

TABLE 60-5 RECOMMENDED DOSES FOR 5-ASA MEDICATIONS

GENERIC NAME	TRADE NAME	DOSAGE AVAILABLE	RECOMMENDED DOSE
Sulfasalazine	Azulfidine	500 mg tablets	3-4 g daily in divided doses
	Azulfidine En-tabs		Children >2 yr: 30 mg/kg/day not to exceed 2 g/day
	Azulfidine oral suspension (50 mg/mL)	250 mg/5 mL liquid	
Mesalamine	Asacol	400 mg tablets	800 mg three times daily
	Pentasa	500 mg tablets	1 g four times daily
	Rowasa enemas	4 g/60 mL	At bedtime
	Rowasa suppository	1000 mg/supp	Twice daily or at bedtime
Olsalazine (rarely used)	Dipentum	250 mg tablets	1 g daily in two divided doses
Balsalazide	Colazal	750 mg tablets	3 tablets three times daily

5-ASA, 5-aminosalicylic acid.

! NURSING SAFETY PRIORITY

Drug Alert

Teach patients taking sulfasalazine to report nausea, vomiting, anorexia, rash, and headache to the health care provider. With higher doses, hemolytic anemia, hepatitis, male infertility, or agranulocytosis can occur. This drug is in the same family as sulfonamide antibiotics. Therefore assess the patient for an allergy to sulfonamide or other drugs that contain sulfur *before* the patient takes the drug. The use of a thiazide diuretic is also a contraindication for sulfasalazine.

preparations contain sulfapyridine. Asacol is an enteric-coated drug and is released in the terminal ileum and right side of the colon. Pentasa and Apriso are delayed- and extended-release drugs that work throughout the colon and rectum. Rowasa can be given as an enema, and Canasa can be given as a suppository. These preparations have minimal systemic absorption and therefore have fewer side effects. Table 60-5 lists commonly used 5-ASA drugs.

Glucocorticoids, such as prednisone and prednisolone, are corticosteroid therapies prescribed during exacerbations of the disease. Prednisone (Deltasone, Winpred) 40 to 65 mg daily is typically prescribed, but the dose may be increased as acute flare-ups occur. Once clinical improvement occurs, the corticosteroids are tapered because of the adverse effects that commonly occur with long-term steroid therapy (e.g., hyperglycemia, osteoporosis, peptic ulcer disease, increased risk for infection). For patients with rectal symptoms, topical steroids in the form of small retention enemas may be prescribed.

To provide symptomatic management of diarrhea, **antidiarrheal drugs** may be prescribed. These drugs are given very cautiously, however, because they can cause colon dilation and toxic megacolon. Common antidiarrheal drugs include diphenoxylate hydrochloride and atropine sulfate (Lomotil) and loperamide (Imodium).

Immunomodulators are drugs that alter a person's immune response. Alone, they are often not effective in the treatment of ulcerative colitis. However, in combination with steroids, they may offer a synergistic effect to a quicker response, thereby decreasing the amount of steroids needed. Immunosuppressants used with UC (and Crohn's disease, discussed later in this chapter) include infliximab (Remicade) and adalimumab (Humira).

Although not approved as a first-line therapy for ulcerative colitis, **infliximab** (Remicade) may be used for refractory disease or for severe complications, such as **toxic megacolon** (massive dilation of the colon that can lead to gangrene and

peritonitis) and extraintestinal manifestations. Remicade is an immunoglobulin G (IgG) monoclonal antibody that reduces the activity of tumor necrosis factor (TNF) to decrease inflammation. Adalimumab (Humira) is another monoclonal antibody approved for refractory (not responsive to other therapies) cases. They are used more commonly in management of Crohn's disease. These drugs cause immunosuppression and should be used with caution. Teach the patient to report any signs of a beginning infection, including a cold, and to avoid large crowds or others who are sick.

Nutrition Therapy and Rest. Patients with severe symptoms are kept NPO to ensure bowel rest. The physician may prescribe total parenteral nutrition (TPN) for severely ill and malnourished patients during severe exacerbations. Chapter 63 describes this therapy in detail. Patients with less severe symptoms may drink elemental formulas such as Vivonex PLUS or Vivonex T.E.N, which are absorbed in the small bowel and reduce bowel stimulation.

Diet is not a major factor in the inflammatory process, but some patients with ulcerative colitis (UC) find that caffeine and alcohol increase diarrhea and cramping. For some patients, raw vegetables and other high-fiber foods can cause GI symptoms. Lactose-containing foods may be poorly tolerated and should be reduced or eliminated. Teach patients that carbonated beverages, pepper, nuts and corn, dried fruits, and smoking are common GI stimulants that could cause discomfort. Each patient differs in their food and fluid tolerances.

During an exacerbation of the disease, activity is generally restricted because rest can reduce intestinal activity, provide comfort, and promote healing. Ensure that the patient has easy access to a bedpan, bedside commode, or bathroom in case of urgency or tenesmus.

Complementary and Alternative Therapies. In addition to dietary changes, complementary and alternative therapies may be used to supplement traditional management of ulcerative colitis. Examples include herbs (e.g., flaxseed), selenium, and vitamin C. Biofeedback, hypnosis, yoga, acupuncture, and ayurveda (a combination of diet, yoga, herbs, and breathing exercises) may also be helpful. These therapies need further study to validate their effectiveness, but some patients find them helpful.

Surgical Management. Some patients with ulcerative colitis require surgery to help manage their disease when medical therapies alone are not effective. In some cases, surgery is performed for complications of UC such as toxic megacolon, hemorrhage, dysplastic biopsy results, and colon cancer.

**Stage 1.**

After removal of the colon, a temporary loop ileostomy is created and an ileo-anal reservoir is formed. The reservoir is created in an S-shaped reservoir (using three loops of ileum) or a J-shaped reservoir (suturing a portion of ileum to the rectal cuff, with an upward loop).

Stage 2.

After the reservoir has had time to heal—usually several months—the temporary loop ileostomy is reversed and stool is allowed to drain into the reservoir.

FIG. 60-2 The creation of an ileo-anal reservoir.

Preoperative Care. General preoperative teaching related to abdominal surgery is described in [Chapter 16](#). If a temporary or permanent ileostomy is planned, provide an in-depth explanation to the patient and family. An **ileostomy** is a procedure in which a loop of the ileum is placed through the abdominal wall (**stoma**) for drainage of fecal material into a pouching system worn on the abdomen. The external pouching system consists of a solid skin barrier (wafer) to protect the skin and a fecal collection device (pouch), similar to the system used for patients with colostomies (discussed in [Chapter 61](#)).

If an ileostomy is planned, the surgeon consults with a certified wound, ostomy, continence nurse (CWCN) or enterostomal therapist (ET) (sometimes called an *ostomy nurse*) before surgery for recommendations on the best location of the stoma. A visit from an **ostomate** (a patient with an ostomy) may be helpful before surgery. Parenteral antibiotics are given within 1 hour of surgical opening based on current best evidence and per The Joint Commission's National Patient Safety Goals.

In the past, patients have been required to follow a bowel preparation process before surgery using laxatives, enemas, and/or oral antibiotics to cleanse the bowel of normal flora to help reduce the risk for infection. Current research indicates that mechanical (enemas) and antibiotic bowel preparation does not affect the incidence of surgical site infections and is therefore not typically required (Howard et al., 2009).

Operative Procedures. Any one of several surgical approaches may be used for the patient with UC. Minimally invasive procedures, such as laparoscopic, laparoscopic-assisted, hand-assisted, and robotic-assisted surgery, are

becoming common for patients with ulcerative colitis in large tertiary care centers (Kessler et al., 2011). Laparoscopic surgery usually involves one or several small incisions but often takes longer to perform than the open surgical approach. A newer procedure, natural orifice transluminal endoscopic surgery (NOTES), can be performed via the anus or vagina for select patients. Patients may have moderate sedation or general anesthesia for minimally invasive surgical procedures and are often *not* admitted to critical care units for continuing postoperative care.

Patients who are obese, have had previous abdominal surgeries, or have dense scar tissue (adhesions) may not be candidates for laparoscopic procedures. The conventional open surgical approach involves an abdominal incision and is done under general anesthesia. Patients with open procedures are typically admitted to critical care units for stabilization.

Restorative Proctocolectomy with Ileo Pouch–Anal Anastomosis (RPC-IPAA). This procedure has become the gold standard for patients with UC. In some centers, the surgery is performed via laparoscopy (laparoscopic RPC-IPAA). It is usually a two-stage procedure that *first* includes the removal of the colon and most of the rectum ([Fig. 60-2](#)). The anus and anal sphincter remain intact. The surgeon surgically creates an internal pouch (reservoir) using the last 1½ feet of the small intestine. The pouch, sometimes called a *J-pouch*, *S-pouch*, or *pelvic pouch*, is then connected to the anus. A temporary ileostomy through the abdominal skin is created to allow healing of the internal pouch and all anastomosis sites. It also allows for an increase in the capacity of the internal pouch. In the *second* surgical stage, the loop ileostomy is closed. The time interval between the first and second stage varies, but

FIG. 60-3 A, Total proctocolectomy with a permanent ileostomy. This involved removal of the colon, the rectum, and the anus with closure of the anus. Note the missing colon, rectum, and anus with the resultant stoma (**B**) in the right lower quadrant.

many patients have the second surgical stage to close the ileostomy within 1 to 2 months of the first surgery.

Usually bowel continence is excellent after this procedure, but some patients have leakage of stool during sleep. They may take antidiarrheal drugs to help control this problem.

Total Proctocolectomy with a Permanent Ileostomy. Total proctocolectomy with a permanent ileostomy is done for patients who are not candidates or do not want the ileo-anal pouch. The procedure involves the removal of the colon, rectum, and anus with surgical closure of the anus (Fig. 60-3, A). The surgeon brings the end of the ileum out through the abdominal wall and forms a stoma, or **ostomy**.

With an ileostomy, initially after surgery the output is a loose, dark green liquid that may contain some blood. Over time, a process called “ileostomy adaptation” occurs. The small intestine begins to perform some of the functions that had previously been done by the colon, including the

! NURSING SAFETY PRIORITY

Critical Rescue

The ileostomy stoma (Fig. 60-3, B) is usually placed in the right lower quadrant of the abdomen below the belt line. It should not be prolapsed or retract into the abdominal wall. Assess the stoma frequently. It should be pinkish to cherry red to ensure an adequate blood supply. If the stoma looks pale, bluish, or dark, report these findings to the health care provider immediately!

absorption of increased amounts of sodium and water. Stool volume decreases, becomes thicker (pastelike), and turns yellow-green or yellow-brown. The effluent (fluid material) usually has little odor or a sweet odor. Any foul or unpleasant odor may be a symptom of a problem such as blockage or infection.

The ostomy drains frequently, and the stool is irritating. *The patient must wear a pouch system at all times.* The stool from the small intestine contains many enzymes and bile salts, which can quickly irritate and excoriate the skin. *Skin care around the stoma is a priority!* A pouch system with a skin barrier (gelatin or pectin) provides sufficient protection for most patients. Other products are also available.

Postoperative Care. Provide general postoperative care after surgery, as described in Chapter 18. All patients requiring open approach surgery for ulcerative colitis have a large abdominal incision. At first, most patients are NPO and a nasogastric tube (NGT) is used for suction. The tube is removed in 1 to 2 days as the drainage decreases, and fluids and food are slowly introduced. The patient having minimally invasive surgery (MIS) usually does not have an NGT.

In collaboration with the ostomy nurse, help the patient adjust and learn the required care. The ileostomy begins to drain within 24 hours after surgery at more than 1 L per day. Be sure that fluids are replaced by adding an additional 500 mL or more each day to prevent dehydration. After about a week of high-volume output, the drainage slows and becomes thicker. During this period, some patients need antidiarrheal drugs.

The hospital stay is usually from 2 to 5 days, depending on whether the patient has laparoscopic or conventional open surgery. Patients having MIS have less pain from surgery and faster restoration of bowel function when compared with other surgical patients, but the incidence of complications is about the same (Fajardo et al., 2010).

For those who have the RPC-IPAA procedure, remind them that the internal pouch can become inflamed. This problem is usually effectively treated with metronidazole (Flagyl) for 7 to 10 days. Teach patients that after the second stage of surgery, they might have burning during bowel elimination because gastric acid cannot be well absorbed by the ileum. Also instruct them to omit foods that can cause odors or gas, such as cabbage, asparagus, and beans. Teach patients to eliminate foods that cannot be well digested, such as nuts and corn. Each patient differs in which foods he or she can tolerate.

Surgery for UC may result in altered body image. However, it may be viewed as positive because the patient will have fewer symptoms and feel more comfortable than before the procedure. Patients have to adjust to having an ostomy before they can resume their presurgery activities.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The health care provider prescribes sulfasalazine (Azulfidine) for a client with ulcerative colitis. What nursing action is most important before the client begins the medication?

- Determine if the client's insurance pays for the drug.
- Ask the client if he smokes or drinks alcohol.
- Ask the client if he has any allergies to sulfa-type drugs.
- Teach the client the importance of avoiding crowds.

Minimizing Pain

Planning: Expected Outcomes. The desired outcome for the patient is that he or she will verbalize decreased pain as a result of evidence-based pain management collaborative interventions.

Interventions. Pain control requires pharmacologic and nonpharmacologic measures. Physical discomfort can contribute to emotional distress. A variety of symptom-reducing interventions and supportive measures are used. Surgery also reduces pain for many patients.

The purpose of pain management is alleviation of pain or a reduction in pain to a level of comfort that is acceptable to the patient. Increases in pain may indicate the development of complications such as peritonitis (see earlier discussion in this chapter). Assist the patient in reducing or eliminating factors that can cause or increase the pain experience. For example, he or she may benefit from nutrition changes to decrease abdominal discomfort such as cramping and bloating.

Antidiarrheal drugs may be needed to control diarrhea, thus reducing the discomfort. However, they must be used with caution and for a short time because toxic megacolon can develop.

Perineal skin can be irritated by contact with loose stools and frequent cleaning. Explain special measures for skin care. Use of medicated wipes is soothing if the rectal area is tender or sensitive from the use of toilet tissue (Chart 60-3). Various manufacturers of ostomies (Hollister, ConvaTec) produce a system for skin care that may help prevent and heal perineal skin irritation. These systems usually include a skin-cleaning solution, a moisturizing and healing cream, and a petroleum jelly-like barrier that prevents contact of moisture and stool with the skin.

Monitoring for Lower GI Bleeding

Planning: Expected Outcomes. For patients who experience GI bleeding, the patient with UC is expected to have a reduction in or cessation of bleeding with prompt collaborative care. If possible, patients are expected to remain free of complications of the disease that can cause bleeding, such as perforation.

Interventions. The primary nursing priority is to monitor the patient closely for signs and symptoms of GI bleeding resulting from the disease or its complications.

If the patient has lower GI bleeding of more than 0.5 mL per minute, a GI bleeding scan may be useful to localize the site of the bleeding (Pagana & Pagana, 2010). This test cannot indicate the cause of the bleeding, however, and may take several hours to administer. Patients in the critical care unit are not candidates for the test because they must leave the unit for the test.

CHART 60-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Pain Control and Skin Care for Patients with Inflammatory Bowel Disease

PATIENT PROBLEM	INTERVENTIONS
Abdominal pain (particularly with exacerbations of the disease)	Administer analgesics. Assist with frequent positioning. Identify foods that increase pain. Perform a comprehensive pain assessment. Observe for signs and symptoms of peritonitis. Evaluate effectiveness of pain management. Teach music therapy, guided imagery.
Skin excoriation and/or irritation from frequent bowel movements	Encourage good skin care with a mild soap and water after each bowel movement. Gently pat the area dry. Identify foods that increase diarrhea. Sitz baths may be of benefit. Apply a thin coat of A+D Ointment or aloe cream. Use medicated wipes instead of tissue. Ensure appropriate ostomy supplies that fit well. Antidiarrheal medications may help, but use with caution. Observe for symptoms related to megacolon (fever, leukocytosis, tachycardia, distended abdomen with 3-view abdominal x-ray noting an enlarged colon).

! NURSING SAFETY PRIORITY

Critical Rescue

For the patient with ulcerative colitis, monitor stools for blood loss. The blood may be bright red (frank bleeding) or black and tarry (**melena**). Monitor hematocrit, hemoglobin, and electrolyte values, and assess vital signs. Prolonged slow bleeding can lead to anemia. Observe for fever, tachycardia, and signs of fluid volume depletion. Changes in mental status may occur, especially among older adults, and may be the first indication of dehydration or anemia.

If symptoms of GI bleeding begin, notify the health care provider immediately. Blood products are often prescribed for patients with severe anemia. Prepare for the blood transfusion by inserting a large-bore IV catheter if it is not already in place. Chapter 42 outlines nursing actions during blood transfusion.

Community-Based Care

Home Care Management

The patient with ulcerative colitis provides self-management at home but usually requires hospitalization during severe exacerbations and surgery. In addition, those who have extraintestinal problems often need ongoing collaborative care for joint and/or skin problems.

Home care management focuses on controlling clinical manifestations and monitoring for complications. For patients returning home or transferring to nursing home or transitional care after surgery, ongoing respiratory care, incision care (if applicable), ostomy care, and pain management should be continued.

Teaching for Self-Management

Teach the patient about the nature of ulcerative colitis, including its acute episodes, remissions, and symptom management. Also stress that even though the cause is unknown, relapses

can be resolved with proper health care. Teach patients taking immunosuppressive drugs, such as corticosteroids and monoclonal antibodies, to report signs of possible infection, such as sore throat, to the health care provider. Remind them to avoid crowds and anyone who has an infection. Review the purpose of drug therapy, when drugs should be taken, side effects, and adverse drug events. Any signs and symptoms of an infection need to be reported to the health care provider.

Instruct the patient about measures to reduce or control abdominal pain, cramping, and diarrhea. Also teach the patient and family about symptoms associated with disease exacerbation that should be reported to the health care provider, such as fever higher than 101° F (38° C), tachycardia, palpitations, and an increase in diarrhea, abdominal pain, or nausea/vomiting. Provide written information and contact numbers for the health care provider.

There is no special diet for a patient with an ileostomy. However, teach the patient to avoid any foods that cause gas or make the stool thicker. Examples include high-fiber foods like nuts, raw cabbage, corn, celery, apples with peels, and popcorn. The patient needs to learn what foods he or she tolerates best and adjust the diet accordingly.

If he or she has undergone a temporary or permanent surgical diversion, collaborate with the ostomy nurse to explain and demonstrate required care so that the patient can self-manage. Also teach the importance of including adequate amounts of salt and water in the diet because the ileostomy increases the loss of these substances. Urge the patient to be cautious in situations that lead to heavy sweating or fluid loss, such as strenuous physical activity, high environmental heat, and episodes of diarrhea and vomiting.

Finding the best ostomy pouching system is a major issue for many patients. An effective system is one that:

- Protects the skin
- Contains the effluent (drainage) and reduces odor, if any
- Remains securely attached to the skin for a dependable period of time

Most patients desire an adhesive barrier that will last for 3 to 7 days. The barrier must create a solid seal to prevent the enzymes in the drainage from irritating the skin. Solid barriers are classified as “regular wear” or “extended wear.” A person with a high output may want an extended-wear barrier. A special cream can be used to help fill any uneven skin surfaces and provide a consistent seal. Pouches are also individualized by the patient. Large pouches can hold more but are heavy when full. Patients also have to consider the costs of the various systems and how much their insurance (if they have it) will pay for them. [Chart 60-4](#) describes the main aspects of ileostomy care, including skin care.

A patient with an ileostomy may have many concerns about management at home and about sexual and social adjustments. Considering possible sexual issues helps the patient identify and discuss these concerns with the sex partner. For example, a change in positioning during intercourse may alleviate apprehension. Social situations may cause anxiety related to decreased self-esteem and a disturbance in body image. Encourage the patient to discuss possible concerns in addressing and resolving these potentially stressful events. Clinical depression is common among patients with ulcerative colitis. Refer patients to appropriate mental health resources if depression is suspected.

CHART 60-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Ileostomy Care

Skin Protection

- Use a skin barrier to protect your skin from contact with contents from the ostomy.
- Use skin care products, such as skin sealants and ostomy skin creams. If your skin continues to come into contact with ostomy contents, select a product to fill in problem areas and provide an even skin surface.
- Watch your skin for any irritation or redness.

Pouch Care

- Empty your pouch when it is one-third to one-half full.
- Change the pouch during inactive times, such as before meals, before retiring at night, on waking in the morning, and 2 to 4 hours after eating.
- Change the entire pouch system every 3 to 7 days.

Nutrition

- Chew food thoroughly.
- Be cautious of high-fiber and high-cellulose foods. You may need to eliminate these from the diet if they cause severe problems (diarrhea, constipation, or blockage). Examples include corn, peanuts, coconut, Chinese vegetables, string beans, tough-fiber meats, shrimp and lobster, rice, bran, and vegetables with skins (tomatoes, corn, and peas).

Drug Therapy

- Avoid taking enteric-coated and capsule medications.
- Inform any health care provider who is prescribing medications for you that you have an ostomy. Before having prescriptions filled, inform your pharmacist that you have an ostomy.
- Do not take any laxative or enemas. You should usually have loose stool and should contact a physician if no stool has passed in 6 to 12 hours.

Symptoms to Watch for

- Report any drastic increase or decrease in drainage to your health care provider.
- If stomal swelling, abdominal cramping, or distention occurs or if ileostomy contents stop draining:
 - Remove the pouch with faceplate.
 - Lie down, assuming a knee-chest position.
 - Begin abdominal massage.
 - Apply moist towels to the abdomen.
 - Drink hot tea.
- If none of these maneuvers is effective in resuming ileostomy flow or if abdominal pain is severe, call your health care provider right away.

Health Care Resources

If the patient needs assistance with self-management at home, collaborate with the case manager or social worker to arrange the services of a home care aide or nurse. A home care nurse can provide assessment and guidance in integrating ostomy care into the patient's lifestyle. The nurse may also teach about wound care, including the monitoring of wound healing, if needed ([Chart 60-5](#)). The patient and family need to know where to purchase ostomy supplies, along with the name, size, and manufacturer's order number.

For patients with a permanent ileostomy, locate a community ostomy support group by contacting the United Ostomy Associations of America (www.uoaa.org). The United

Ostomy Association of Canada serves the needs of Canadian patients (www.ostomycanada.ca). A local support group or the Crohn's and Colitis Foundation of America (www.cdfa.org) may be helpful in obtaining supplies and providing education for ostomates. Inform the patient and family of available ostomy ambulatory care clinics and ostomy specialists. If the patient agrees, a visit from an ostomate can be continued after discharge to home.

EVALUATION: OUTCOMES

Evaluate the care of the patient with ulcerative colitis based on the identified priority patient problems. Expected outcomes may include that the patient will:

- Verbalize decreased pain
- Gain control over bowel elimination

CHART 60-5 HOME CARE ASSESSMENT

The Patient with Inflammatory Bowel Disease

Assess gastrointestinal function and nutritional status, including:

- Abdominal cramping or pain
- Bowel elimination pattern, specifically frequency, characteristics, and amount of stools and presence or absence of blood in stools
- Food and fluid intake (include relationship of specific foods to cramping and stools)
- Weight gain or loss
- Signs and symptoms of dehydration
- Presence or absence of fever, rectal tenesmus, or urgency
- Bowel sounds
- Condition of perianal skin, including presence or absence of perianal fistula or abscess

Assess patient's and family's coping skills, including:

- Current and ongoing stress level and coping style
- Availability of support system

Assess home environment, including:

- Adequacy and availability of bathroom facilities
- Opportunity for rest and relaxation

Assess ability to self-manage therapeutic regimen, including:

- Drug therapy
- Signs and symptoms to report
- Nutrition therapy
- Availability of community resources
- Importance of follow-up care

- Not experience lower GI bleeding
- Self-manage the ileostomy (temporary or permanent)
- Maintain peristomal skin integrity
- Demonstrate behaviors that integrate ostomy care into his or her lifestyle if a permanent ileostomy is performed

CROHN'S DISEASE

Pathophysiology

Crohn's disease (CD) is an inflammatory disease of the small intestine (most often), the colon, or both. It can affect the GI tract from the mouth to the anus but most commonly affects the terminal ileum. CD is a slowly progressive and unpredictable disease with involvement of multiple regions of the intestine with normal sections in between (called "skip lesions" on x-rays). Like ulcerative colitis (UC), this disease is recurrent with remissions and exacerbations.

Unlike UC, Crohn's disease presents as transmural inflammation that causes a thickened bowel wall. Strictures and deep ulcerations (cobblestone appearance) also occur, which put the patient at risk for developing bowel fistulas. The result is severe diarrhea and malabsorption of vital nutrients. Anemia is common, usually from iron deficiency or malabsorption issues.

The complications associated with Crohn's disease are similar to those of ulcerative colitis (see Table 60-4). Hemorrhage is more common in ulcerative colitis, but it can occur in CD as well. Severe malabsorption by the small intestine is more common in patients with CD because UC does not involve the small bowel to any significant extent. *Therefore patients with CD can become very malnourished and debilitated.*

Rarely, cancer of the small bowel and colon develop but can occur after the disease has been present for 15 to 20 years. Fistula formation is a common complication of CD but is rare in UC. Fistulas can occur between segments of the intestine or manifest as cutaneous fistulas (opening to the skin) or perirectal abscesses. They can also extend from the bowel to other organs and body cavities, such as the bladder or vagina (Fig. 60-4). Some patients develop intestinal obstruction, which, at first, is secondary to inflammation and edema.

External enterocutaneous
(between skin and intestine)

Enteroenteric
(between intestine and intestine)

FIG. 60-4 The types of fistulas that are complications of Crohn's disease.

Over time, fibrosis and scar tissue develop and obstruction results from a narrowing of the bowel. Most patients with CD require surgery at some time.

The exact cause of CD is not known, but it seems to include a combination of genetic, immune, and environmental factors. About 10% to 20% of patients have a positive family history for the disease, but no predominant inheritance pattern is present (Nussbaum et al., 2007). The discovery of a mutation in the *NOD2/CARD15* gene on chromosome 16 seems to be associated with some patients who have CD. This gene is found in monocytes that normally recognize and destroy bacteria. Other gene mutations that may contribute to the pathogenesis of CD are *IBD3*, *IBD5*, and *IBD10*.

Proinflammatory cytokines, such as tumor necrosis factor- α (TNF- α) and interleukins (e.g., IL-6 and IL-8), are immunologic factors that contribute to the etiology of CD. Many of the drugs used for the disease inhibit or block one or more of these factors.

Other risk factors include tobacco use, Jewish ethnicity, and living in urban areas (McCance et al., 2010). The reasons for these factors have not been established. It was once thought that stress and nutrition play a role in the *development* of CD, but these factors have not been proven. However, inadequate nutrition can worsen the patient's symptoms.

Almost a million people in the United States have Crohn's disease. Most have symptoms and are diagnosed as adolescents or young adults. It is more common in people of Ashkenazi Jewish background than in any other group (Nussbaum et al., 2007).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Crohn's disease is made worse by bacterial infection and inflammation. A detailed history is needed to identify manifestations specific to the disease. Ask about recent unintentional weight loss, the frequency and consistency of stools, the presence of blood in the stool, fever, and abdominal pain.

Perform a thorough abdominal examination, assess for manifestations of the disease, and evaluate the patient's nutritional and hydration status.

When inspecting the abdomen, assess for distention, masses, or visible peristalsis. Inspection of the perianal area may reveal ulcerations, fissures, or fistulas. During auscultation, bowel sounds may be decreased or absent with severe inflammation or obstruction. An increase in high-pitched or rushing sounds may be present over areas of narrowed bowel loops. Muscle guarding, masses, rigidity, or tenderness may be noted on palpation by the advanced practice nurse or other health care provider.

The clinical presentation of Crohn's disease varies greatly from person to person. Most patients report diarrhea, abdominal pain, and low-grade fever. Fever is common with fistulas, abscesses, and severe inflammation. If the disease occurs in only the ileum, diarrhea occurs five or six times per day, often with a soft, loose stool. **Steatorrhea** (fatty diarrheal stools) is common. Rarely, stools may contain bright red blood.

Abdominal pain from the inflammatory process is usually constant and often located in the right lower quadrant. The

patient also may have pain around the umbilicus before and after bowel movements. If the lower colon is diseased, pain is common in both lower abdominal quadrants.

Most patients with Crohn's disease have *weight loss*. Nutritional problems are the result of increased catabolism from chronic inflammation, anorexia, malabsorption, or self-imposed dietary restrictions. These problems result in fluid and electrolyte imbalances and vital nutrient deficiencies.

The inflammatory bowel changes decrease the small bowel's ability to absorb nutrients, which may be made worse by surgery and fistulas.

! NURSING SAFETY PRIORITY

Action Alert

For the patient with Crohn's disease, be especially alert for manifestations of peritonitis (discussed earlier in this chapter), small-bowel obstruction, and nutritional and fluid imbalances. Early detection of a change in the patient's status helps reduce these life-threatening complications.

The patient who has Crohn's disease (CD) needs a complete psychosocial assessment. The chronic nature of the problem and the associated complications can greatly affect patients and their families. Lifestyle changes are necessary to cope with such a disruptive and painful chronic illness. Assess the patient's coping skill, and help identify support systems. Clinical depression and severe anxiety disorders are common among patients with CD.

The health care provider requests many laboratory studies for patients with Crohn's disease. The results of laboratory tests often indicate the extent and severity of inflammation or complications that occur with the disease.

Anemia is common as a result of slow bleeding and poor nutrition. Serum levels of folic acid and vitamin B₁₂ are generally low because of malabsorption, further contributing to anemia. Amino acid malabsorption and protein-losing enteropathy may result in *decreased albumin* levels. C-reactive protein and ESR may be elevated to indicate inflammation. White blood cells (WBCs) in the urine may show infection (pyuria), which is caused by ureteral obstruction or an enterovesical (bowel to bladder) fistula. If severe diarrhea or fistula is present, the patient may have electrolyte losses, particularly potassium and magnesium. Assess the patient for clinical manifestations that can occur as a result of electrolyte losses (see [Chapter 13](#)).

X-rays show the narrowing, ulcerations, strictures, and fistulas common with Crohn's disease. An abdominal ultrasound or CT scan may also be performed. In acute illness, these tests may be deferred until the risk for perforation lessens. If the patient has lower GI bleeding of more than 0.5 mL per minute, a gastrointestinal bleeding scan may be useful to localize the site of the bleeding ([Pagana & Pagana, 2010](#)).

INTERVENTIONS

Collaborative care for patients with Crohn's disease is similar to that described on p. 1274 in the Nonsurgical Management discussion in the Ulcerative Colitis section. Specific interventions vary with the severity of disease and the complications that are present.

Drug Therapy

Drugs used to manage Crohn's disease (CD) are similar to those used in the treatment of ulcerative colitis (UC). For mild to moderate disease, 5-ASA drugs may be very effective (see p. 1274 in the Drug Therapy discussion in the Ulcerative Colitis section).

Most patients have moderate to severe disease and need stronger drug therapy to control their symptoms. Two agents that may be prescribed for CD are azathioprine (Imuran) and mercaptopurine (Purinethol). These drugs suppress the immune system but can lead to serious infections. Methotrexate (MTX) may also be given to suppress immune activity of the disease.

More recently, a group of monoclonal antibody drugs has been approved for use in Crohn's disease when other drugs have been ineffective. These drugs inhibit tumor necrosis factor (TNF)-alpha, which decreases the inflammatory response. Examples of commonly used drugs for patients with CD include infliximab (Remicade), adalimumab (Humira), natalizumab (Tysabri), and certolizumab pegol (Cimzia). These agents are not given to patients with a history of cancer, heart disease, or multiple sclerosis.

! NURSING SAFETY PRIORITY

Drug Alert

Both infliximab and certolizumab pegol must be given in a health care setting, such as a physician's office via parenteral routes. Adalimumab (Humira) is self-administered by subcutaneous injection every other week. If needed, instruct patients on how to give themselves a subcutaneous injection. Teach patients to report injection site reactions, including redness and swelling. Remind them that headache, abdominal pain, and nausea and vomiting are common side effects. Teach them to avoid crowds, such as malls and large shopping centers, and people with infection. Reinforce the need to report any infection, including a cold or sore throat, to the health care provider immediately.

Natalizumab is given IV under medical supervision every 4 weeks for moderate to severe CD and is given when other drugs are not effective. Although the use of this drug has decreased the length of hospital stays (Dudley-Brown et al., 2009), natalizumab can cause progressive multifocal leukoencephalopathy (PML), a deadly infection that affects the brain. Before giving the drug, be sure that patient is free of all infections. Teach patients the importance of reporting any cognitive, motor, or sensory changes immediately to the health care provider.

Although glucocorticoids can be effective for patients with Crohn's disease, sepsis can result from abscesses or fistulas that may be present. These drugs mask the symptoms of infection. Therefore they must be used with caution. Monitor the patient closely for signs of infection. Metronidazole (Flagyl, Novonidazole 🍁) has also been helpful in patients with fistulas.

Nutrition Therapy

Long-standing nutritional deficits can have severe consequences for the patient with Crohn's disease. Malnutrition can lead to poor fistula and wound healing, loss of lean muscle mass, decreased immune responses, and increased morbidity and mortality. During severe exacerbations of the disease, the patient may be hospitalized to provide bowel rest and nutritional support with total parenteral nutrition (TPN). For less severe exacerbations, an elemental or

semi-elemental product such as Vivonex PLUS may be prescribed to induce remission. These products are absorbed in the jejunum and therefore permit the distal small intestine and colon to rest. Nutritional supplements, such as Ensure or Sustacal, can be added then to provide nutrients and more calories. Teach the patient to avoid GI stimulants, such as caffeinated beverages and alcohol.

Fistula Management

Fistulas (abnormal tracts between two or more body areas) are common with acute exacerbations of Crohn's disease. They can be between the bowel and bladder (enterovesical), between two segments of bowel (enteroenteric), between the skin and bowel (enterocutaneous), or between the bowel and vagina (enterovaginal) (see Fig. 60-4). The patient with one or more fistulas often has complications such as systemic infections, skin problems, malnutrition, and fluid and electrolyte imbalances. Treatment of the patient with a fistula is complicated and includes nutrition and electrolyte therapy, skin care, and prevention of infection.

! NURSING SAFETY PRIORITY

Action Alert

Adequate nutrition and fluid and electrolyte balance are priorities in the care of the patient with a fistula. GI secretions are high in volume and rich in electrolytes and enzymes. The patient is at high risk for malnutrition, dehydration, and hypokalemia (decreased serum potassium). Assess for these complications, and collaborate with the health care team to manage them. Monitor urinary output. A decrease indicates possible dehydration, which should be treated immediately by providing additional fluids.

The patient requires at least 3000 calories daily to promote healing of the fistula. If he or she cannot take adequate oral fluids and nutrients, total enteral nutrition (TEN) or TPN may be prescribed. For patients who do not require TEN or TPN, collaborate with the dietitian to:

- Carefully monitor the patient's tolerance to the prescribed diet.
- Assist the patient in selecting high-calorie, high-protein, high-vitamin, low-fiber meals.
- Offer enteral supplements, such as Ensure and Vivonex PLUS.
- Record food intake for accurate calorie counts.

Providing enteral supplements, recording intake and output, and taking daily weights may be delegated to unlicensed assistive personnel (UAP) under the supervision of the RN.

Collaborate with the wound or ostomy nurse to select the most appropriate wound management for each patient.

! NURSING SAFETY PRIORITY

Action Alert

For patients with fistulas, preserving and protecting the skin is the nursing priority. *Be sure that wound drainage is not in direct contact with skin because intestinal fluid enzymes are caustic!* Clean the skin promptly to prevent skin breakdown or fungal infection, which can cause major discomfort for the patient.

Enzymes and bile in the stool contribute to the problem of skin irritation and excoriation. Skin irritation needs to be prevented. This may be accomplished through the use of skin

FIG. 60-5 Skin barriers, such as wafers (**A**) are cut to fit $\frac{1}{8}$ inch around the fistula. A drainable pouch (**B**) is applied over the wafer and clamped (**C**) until the pouch is to be emptied. Effluent should drain into the bag and not contact the skin.

barriers, pouching systems, and insertion of drains (Fig. 60-5). Skin barriers or dressings are used when the fistula drainage is less than 100 mL in 24 hours. A pouch is used for heavily draining fistulas to reduce the risk for skin breakdown and measure the **effluent** (drainage). However, they are very challenging because of location and drainage amount. Treatment with an antifungal powder applied to the skin around the fistula is often very helpful to prevent or treat *Candida* infection.

For some fistulas, pouching may not be possible because of their location. Drainage may need to be managed using regulated wall suction or a vacuum-assisted closure (VAC) device. Continuous low wall suction is attached to a suction catheter in the wound bed of the fistula, not into the fistula tract. These systems are not meant for long-term management.

VAC therapy promotes wound healing by secondary intention as it prepares the wound bed for closure, reduces edema, promotes granulation and perfusion, and removes exudate and infectious material. It should not be used for patients who are at risk for bleeding or only for the purpose of drainage containment. Chapter 27 describes this therapy in detail.

Patients with fistulas are also at high risk for intra-abdominal abscesses and sepsis. Antibiotic therapy is commonly prescribed. Observe for signs of systemic infection or sepsis, such as fever, abdominal pain, or a change in mental status. Monitor for increased WBC levels that could indicate a systemic infection.

Other helpful interventions for the patient with CD are those that relax the patient and soothe the GI tract. Such therapies may include naturopathy, herbs (e.g., ginger), acupuncture, hypnotherapy, and ayurveda (a combination of diet, herbs, yoga, breathing exercises). The evidence supporting the use of these substances for CD is lacking, but

many patients find them helpful for overall physical and emotional health. Teach patients about the availability of these therapies, and recommend that they include them in their collaborative plan of care.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration; Informatics

A 29-year-old woman who practices as a licensed practical nurse in a long-term care setting is admitted to the hospital with a draining enterocutaneous fistula as a result of long-term Crohn's disease. She has been taking infliximab (Remicade) for about 10 months but has noticed a return in her symptoms over the past week. The patient tells you that she is very upset about her condition and that she needs to go back to work as soon as she can. She is single but works extra shifts to help support her mother, who has advanced colon cancer.

1. What is your best response to the patient at this time?
2. What patient assessments will you perform on admission and why?
3. Based on the patient data provided, what priority problems do you identify?
4. Using best, current evidence, how will you plan care with other members of the health care team? What members of the health care team will be involved in this patient's care and why?

Surgical Management

Surgery for Crohn's disease may be performed for those patients who have not improved with medical management or for those who have complications from the disease. Surgery to manage CD is not as successful as that for ulcerative colitis due to the extent of the disease. The patient with a fistula may undergo resection of the diseased area. Other indications for surgical treatment include perforation, massive hemorrhage, intestinal obstruction or strictures, abscesses, or cancer.

In some cases, a resection (removal of part of the small bowel) can be performed as minimally invasive surgery (MIS) via laparoscopy. This surgery involves one or more small incisions, less pain, and a quicker surgical recovery. Both small-bowel resection (usually the ileum) and ileocecal resection can be done using this procedure. For other patients, an open surgical approach is used to allow for better visual access to the bowel.

Strictureplasty may be performed for bowel strictures related to Crohn's disease. This procedure increases the bowel diameter. Care before and after each of these surgical procedures is similar to care for patients undergoing other types of abdominal surgery (see [Chapters 16 and 18](#)).

Community-Based Care

The discharge care plan for the patient with Crohn's disease is similar to that for the patient with ulcerative colitis (see p. 1278 in the discussion of Community-Based Care in the Ulcerative Colitis section). Collaborate with the case manager and wound nurse to help the patient plan self-management.

The interventions that were started in the hospital to manage the disease should be continued in the home. Reinforce measures to control the disease and related symptoms and manage nutrition. Teach the patient and family to make arrangements for the patient to have easy access to the bathroom, as well as privacy to perform fistula care, if needed.

The teaching plan for Crohn's disease is similar to that for the patient with ulcerative colitis. Teach the patient about the usual course of the disease, symptoms of complications, and when to notify the health care provider. Provide health teaching for drug therapy, including purpose, dose, and side effects. In addition to other drugs, vitamin supplements, including monthly vitamin B₁₂ injections, may be needed because of the inability of the ileum to absorb these nutrients. In collaboration with the dietitian, instruct the patient to follow a low-residue, high-calorie diet and to avoid foods that cause discomfort, such as milk, gluten, and other GI stimulants like caffeine.

Remind the patient to take rest periods, especially during exacerbations of the disease. If stress appears to increase symptoms of the disease, recommend stress management techniques, counseling, and/or physical activity to improve quality of life (Crumbock et al., 2009). For long-term follow-up, teach the patient about the increased risk for bowel cancer and the importance of having frequent colonoscopies.

If a patient has a fistula, explain and demonstrate fistula care. Provide the opportunity for the patient to practice this care in the hospital. Ideally, he or she should be independent in fistula care before leaving the hospital. However, because of location of the fistula (perirectal or vaginal) or a large abdomen, assistance may be needed. If this is the case, teach a family member or other caregiver how to manage the fistula. Patients may be transferred to a transitional or skilled nursing unit for collaborative care.

Patients who are discharged to home after undergoing resection and anastomosis may require visits from a home care nurse to assess the surgical wound and monitor for complications (see [Chart 60-5](#)). Assess the patient's and family's ability to monitor the progress of fistula healing and to watch for indications of infection and sepsis. A home care aide or other service might be helpful for the patient who cannot

meet nutritional needs or who needs help with grocery shopping and meal preparation.

In collaboration with the CM, assist with obtaining the equipment and supplies for fistula care, such as skin barriers and wound drainage bags. A support group sponsored by the United Ostomy Associations of America (www.uoaa.org) or a local hospital in the community may also be available to help with meeting physical and psychosocial needs.

DIVERTICULAR DISEASE

Diverticula are pouchlike herniations of the mucosa through the muscular wall of any portion of the gut but most commonly the colon. **Diverticulosis** is the presence of many abnormal pouchlike herniations (diverticula) in the wall of the intestine. **Diverticulitis** is the inflammation of one or more diverticula.

Pathophysiology

Diverticula can occur in any part of the small or large intestine but usually occur in the sigmoid colon ([Fig. 60-6](#)). The muscle of the colon hypertrophies, thickens, and becomes rigid, and herniation of the mucosa and submucosa through the colon wall is seen. Diverticula seem to occur at points of weakness in the intestinal wall, often at areas where blood vessels interrupt the muscle layer. Muscle weakness develops as part of the aging process or as a result of a lack of fiber in the diet.

Without inflammation, diverticula cause few problems. If undigested food or bacteria become trapped in a diverticulum, however, blood supply to that area is reduced. Bacteria invade the diverticulum, resulting in diverticulitis, which then can perforate and develop a local abscess. A perforated diverticulum can progress to an intra-abdominal perforation with peritonitis (inflammation of the peritoneum).

Bleeding from diverticula can range from minor local bleeding to massive hemorrhage. Minor bleeding is often due to inflammation in areas of new blood vessel tissue at the base of the diverticulum. Hemorrhage can result when a blood

FIG. 60-6 Several abnormal outpouchings, or herniations, in the wall of the intestine, which are diverticula. These can occur anywhere in the small or large intestine but are found most often in the sigmoid colon, as shown in this figure. Diverticulitis is the inflammation of a diverticulum that occurs when undigested food or bacteria become trapped in the diverticulum.

vessel breaks down within a diverticulum. Inflammation from recurrent diverticulitis can lead to scarring and narrowing of the bowel lumen, which may then result in obstruction. Inflammation can also result in fistulas to other organs, such as the bladder and the vagina.

High intraluminal pressure forces the formation of a pouch in the weakened area of the mucosa, frequently near blood vessels. Diets low in fiber that cause less bulky stool and constipation have been implicated in the formation of diverticula. Retained undigested food in diverticula is suggested to be one cause of diverticulitis. The retained food reduces blood flow to that area and makes bacterial invasion of the sac easier.

The exact incidence of diverticulosis is unknown, but millions of people are affected by the problem. Diverticulitis is found in one half of adults older than 60 years, with more men than women affected. The cause for this difference is not known. Although diverticulosis is common, only one of five people with this disease has noticeable symptoms.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The patient with *diverticulosis* usually has no symptoms. Unless pain or bleeding develops, the condition may go undiagnosed. Occasionally, diverticulosis will cause symptoms. For the patient with uncomplicated diverticulosis, ask about intermittent pain in the left lower quadrant and a history of constipation. If diverticulitis is suspected, ask about a history of low-grade fever, nausea, and abdominal pain. Inquire about recent bowel elimination patterns because constipation may develop as a result of intestinal inflammation. Also ask about any bleeding from the rectum.

On physical examination, uncomplicated *diverticulosis* may produce no clinical manifestations. Occasionally, tenderness occurs on abdominal palpation.

The patient with *diverticulitis* may have abdominal pain, most often localized to the left lower quadrant. It is intermittent at first but becomes progressively steady. Occasionally, pain may be just above the pubic bone or may occur on one side. Abdominal pain is generalized if peritonitis has occurred. Nausea and vomiting are common. The patient's temperature is elevated, ranging from a low-grade fever to 101° F (38.3° C). Chills may be present. Often an increased heart rate (tachycardia) occurs with fever.

CONSIDERATIONS FOR OLDER ADULTS

The first sign of peritonitis in older adults may be a sudden change in mental status (e.g., acute confusion). For those who have dementia, the confusion worsens. Fever and chills may not be present due to normal physiologic changes associated with aging.

On examination of the abdomen, observe for distention. The patient may report tenderness over the involved area. Localized muscle spasm, guarded movement, and rebound tenderness may be present with peritoneal irritation. If generalized peritonitis is present, profound guarding occurs; rebound tenderness is more widespread; and sepsis, hypotension, or hypovolemic shock can occur. If the perforated

diverticulum is close to the rectum, the health care provider may palpate a tender mass during the rectal examination. Blood pressure checks may show orthostatic changes. *If bleeding is massive, the patient may have hypotension and dehydration that result in shock.*

For the patient with uncomplicated diverticulosis, laboratory studies are not indicated. The patient with diverticulitis, however, has an *elevated white blood cell (WBC) count. Decreased hematocrit and hemoglobin* values are common if chronic or severe bleeding occurs. Stool tests for occult blood, if requested, are sometimes positive. Urinalysis may show a few red blood cells (RBCs) if the left ureter is near a perforated diverticulum.

X-rays of the intestinal tract with barium contrast may show diverticula. An upper GI series with small-bowel follow-through shows diverticula of the small intestine, and barium enema shows diverticula of the large intestine. Diverticula are most often diagnosed during routine colonoscopy.

The patient with diverticulitis usually does *not* undergo a barium enema procedure in the acute phase of the illness because of the risk for rupture of the inflamed diverticulum. A barium enema may be completed after the patient has been treated with antibiotics and the inflammation has resolved. Abdominal x-rays may be done to evaluate for free air and fluid indicating perforation. A computed tomography (CT) scan may be performed to diagnose an abscess or thickening of the bowel related to diverticulitis.

Abdominal ultrasonography, a noninvasive test, may also reveal bowel thickening or an abscess. The physician may recommend a colonoscopy 4 to 8 weeks *after the acute phase* of the illness to rule out a tumor in the large intestine, particularly if the patient has rectal bleeding.

INTERVENTIONS

Patients are managed on an ambulatory care basis if the symptoms are mild. Monitor the patient for any prolonged or increased fever, abdominal pain, or blood in the stool.

The patient with moderate to severe diverticulitis may be hospitalized, especially if the patient is older. Manifestations suggesting the need for admission are a temperature higher than 101° F (38.3° C), persistent and severe abdominal pain for more than 3 days, and/or lower GI bleeding.

Nonsurgical Management

A combination of drug and nutrition therapy with rest is used to decrease the inflammation associated with diverticular disease. Broad-spectrum antimicrobial drugs, such as metronidazole (Flagyl) plus trimethoprim/sulfamethoxazole (TMZ) (Bactrim or Bactrim DS, Septra) or ciprofloxacin (Cipro) are often prescribed. A mild analgesic may be given for pain. [Chart 60-6](#) lists nursing interventions needed for care of older adults with diverticulitis.

The patient with more severe pain may be admitted to the hospital for IV fluids to correct dehydration and IV drug therapy. For patients with moderate to severe diverticulitis, an opioid analgesic, such as morphine sulfate, may alleviate pain.

Laxatives and enemas are avoided because they increase intestinal motility. Assess the patient on an ongoing basis for manifestations of fluid and electrolyte imbalance.

Teach the patient to rest during the acute phase of illness. Remind him or her to refrain from lifting, straining,

CHART 60-6 NURSING FOCUS ON THE OLDER ADULT

Diverticulitis

- Provide antibiotics, analgesics, and anticholinergics as prescribed. Observe older patients carefully for side effects of these drugs, especially confusion (or increased confusion), urinary retention or failure, and orthostatic hypotension.
- Do not give laxatives or enemas. Teach the patient and the family about the importance of avoiding these measures.
- Encourage the patient to rest and to avoid activities that may increase intra-abdominal pressure, such as straining and bending.
- While diverticulitis is active, provide a *low-fiber* diet. When the inflammation resolves, provide a *high-fiber* diet. Teach the patient and family about these diets and when they are appropriate.
- Because older patients do not always experience the typical pain or fever expected, observe carefully for other signs of active disease, such as a sudden change in mental status.
- Perform frequent abdominal assessments to determine distention and tenderness on palpation.
- Check stools for occult or frank bleeding.

coughing, or bending to avoid an increase in intra-abdominal pressure, which can result in perforation of the diverticulum. Nutrition therapy should be restricted to low fiber or clear liquids based on symptoms. The patient with more severe symptoms is NPO. A nasogastric tube (NGT) is inserted if nausea, vomiting, or abdominal distention is severe. Infuse IV fluids as prescribed for hydration. In collaboration with the dietitian, the patient increases dietary intake slowly as symptoms subside. When inflammation has resolved and bowel function returns to normal, a fiber-containing diet is introduced gradually.

Surgical Management

Diverticulitis can result in rupture of the diverticulum with peritonitis, pelvic abscess, bowel obstruction, fistula, persistent fever or pain, or uncontrolled bleeding. The surgeon performs emergency surgery if peritonitis, bowel obstruction, or pelvic abscess is present. Colon resection, with or without a colostomy, is the most common surgical procedure for patients with diverticular disease. The surgeon removes the portion that is inflamed or diseased and, if possible, creates an anastomosis of the colon to restore patency. Inflammation and infection, however, may prevent an anastomosis. If this is the case, the surgeon may perform a colostomy (see Fig. 60-3, B for appearance of a stoma). Some patients may have colostomy closure and anastomosis after the bowel has been allowed to rest for 3 to 6 months.

Preparation of the patient for surgery depends on the severity of the condition and whether it is an emergency or is performed a few weeks after the acute stage. The surgeon informs the patient whether a temporary or permanent colostomy might be required. If a colostomy is a possible outcome, collaborate with the certified wound, ostomy, and continence nurse (CWCN) or an enterostomal therapist (ET) (ostomy nurse) to describe its function and care.

The patient may have one of two surgical approaches: conventional open approach or minimally invasive surgery (MIS) via a laparoscopy. The advantage of MIS is that patients are discharged from the hospital quicker, have less pain after surgery, and have fewer postoperative complications. They

are able to resume normal activities much faster than patients having the conventional open surgery.

The nursing care for patients after an open colon resection for diverticulitis is the same as that for any patient who has undergone open abdominal surgery. The patient may have a drain in place at the abdominal incision site for several days. If a colostomy has been performed, the stoma may be covered with a petroleum gauze dressing because the colostomy does not drain for about 2 days, or a colostomy bag may be placed over the stoma. If the stoma is visible, monitor for color and integrity. The stoma should be pinkish to cherry red without retraction into the abdomen or prolapse.

The patient may be NPO with an NGT until peristalsis returns if open surgery is performed. Clear liquids are then introduced; the diet is advanced to solids, depending on the return of peristalsis and bowel function. Patients who had laparoscopic surgery usually do not have an NGT.

Most patients with a colostomy for diverticulitis have a sigmoid colostomy because the sigmoid colon is the most common site of diverticulitis. Drainage from a sigmoid colostomy at first consists of loose stool, but eventually the stool becomes formed. A tight seal around the stoma is essential to avoid contact of feces with the skin. Colostomy care is detailed in Chapter 59.

Give the patient an opportunity to express feelings about the ostomy if it was created. Discuss these feelings with the patient, reinforcing that anger and depression are normal responses. When he or she is physically able, encourage the patient to look at the stoma and touch the pouching system. Collaborate with the ostomy nurse to teach the patient how to self-manage ostomy care.

Community-Based Care

The length of stay for patients hospitalized for diverticulitis ranges from 1 to 4 days, depending on the response to treatment and the surgical procedure performed. Discharge plans vary according to the treatment. The patient who has surgical intervention has the added responsibilities of incision care and possibly colostomy care with temporary limitations placed on activities.

Patients with diverticular disease need education regarding a high-fiber diet. Encourage the patient with *diverticulosis* to eat a diet high in cellulose and hemicellulose types of fiber. These substances can be found in wheat bran, whole-grain breads, and cereals. Teach the patient to eat at least 25 to 35 g of fiber per day. Fresh fruits and vegetables with high fiber content are added to add bulk to stools.

If not accustomed to eating high-fiber foods, teach the patient to add them to the diet gradually to avoid flatulence and abdominal cramping. If he or she cannot tolerate the recommended fiber requirement, a bulk-forming laxative, such as psyllium hydrophilic mucilloid (Metamucil), can be taken to increase fecal size and consistency. Teach the patient to drink plenty of fluids to help prevent bloating that may occur with a high-fiber diet. Alcohol should be avoided because it irritates the bowel. Foods containing seeds or indigestible material that may block a diverticulum, such as nuts, corn, popcorn, cucumbers, tomatoes, figs, and strawberries, may be eliminated. Teach the patient that dietary fat intake should not exceed 30% of the total daily caloric intake.

Teach the patient to avoid all fiber when symptoms of *diverticulitis* are present, because high-fiber foods are then

irritating. As inflammation resolves, fiber can gradually be added until progression to a high-fiber diet is established. The patient who has undergone surgery is usually taking solid food by the time of discharge from the hospital.

Provide oral and written instructions on incision care and the signs and symptoms to report to the health care provider for the patient who had abdominal surgery. If a colostomy was created, reinforce ostomy care as needed. Encourage the patient to express concerns about body image. Allow time and address sexual concerns regarding the changed body image.

Instruct the patient with any type of diverticular disease, orally and in writing, about the manifestations of acute diverticulitis, including fever, abdominal pain, and bloody, mahogany, or tarry stools. Advise patients to avoid the use of laxatives (other than bulk-forming types) and enemas. Reassure them that this disorder should not cause problems if a proper diet is followed.

In collaboration with the case manager, arrange for a home care nurse, if needed, to assess wound healing and proper functioning of the ostomy and the appliance. If the patient is interested, arrange for a visit from an ostomy volunteer (ostomate) or an ostomy nurse. For information about other community resources, remind the patient to contact the United Ostomy Associations of America (www.uoaa.org).

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

An older adult with a history of diverticulitis is admitted to the emergency department stating that she has severe abdominal pain and has not had a bowel movement in 6 days. What priority assessment will the nurse perform?

- A. Listen to the client's breath sounds.
- B. Take the client's height and weight.
- C. Auscultate the client's bowel sounds.
- D. Perform a rectal examination.

ANAL DISORDERS

Anorectal Abscess

Anorectal abscess is a localized area of induration and pus caused by inflammation of the soft tissue near the rectum or anus. It is most often the result of obstruction of the ducts of glands in the anorectal region. Feces, foreign bodies, or trauma can be the cause of the obstruction and stasis, leading to infection that spreads into nearby tissue.

Rectal pain is often the first symptom. There may be no other manifestations at first, but local swelling, redness, and tenderness are present within a few days after the onset of pain. If the abscess becomes chronic, discharge, bleeding, and pruritus (itching) may exist. Fever occurs if larger abscesses are present.

Anorectal abscesses are managed by surgical incision and drainage (I&D). The physician can often incise (surgically remove) simple perianal and ischioanal abscesses using a local anesthetic. For patients with more extensive abscesses, a regional or general anesthetic may be needed. Systemic antibiotics are given only for patients who are immunocompromised, are diabetic, have valvular disease or a prosthetic valve, or are obese.

CHART 60-7 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Promoting Perineal Comfort

- Keep the perineal area clean with mild soap.
- Pat the perineal area dry instead of rubbing it.
- Provide warm sitz baths, or apply warm compresses to the area.
- If the area is acutely inflamed, apply cold packs.
- Provide a chair cushion for the seated patient. For the older or debilitated patient, monitor the skin carefully to prevent pressure sores.
- Use absorbent pads for drainage, if any, and change them often.
- Use premoistened wipes for cleaning the perineal area after a bowel movement.
- Use witch hazel wipes (e.g., Tucks) to relieve pain.
- Give bulk-forming agents, such as psyllium mucilloid (Metamucil), as prescribed, to reduce pain associated with defecation.
- Apply a topical anesthetic cream to the perineal area, as prescribed.
- Give oral analgesics, as prescribed, for pain relief.
- Do not administer enemas or give potent laxatives.

NURSING SAFETY PRIORITY

Action Alert

For patients with an anorectal abscess, nursing interventions are focused on comfort and helping the patient maintain optimal perineal hygiene (Chart 60-7). Encourage the use of warm sitz baths, analgesics, bulk-producing agents, and stool softeners after the surgery until healing occurs. *Stress the importance of good perineal hygiene after all bowel movements and the maintenance of a regular bowel pattern with a high-fiber diet.*

Patients are often embarrassed about having anal problems. Provide privacy and maintain the patient's dignity during the examination and treatment.

Anal Fissure

An **anal fissure** is a tear in the anal lining, which can be very painful. Smaller fissures occur with straining to have a stool, such as with diarrhea or constipation. Larger, deeper fissures may occur as a result of another disorder (e.g., Crohn's disease, tuberculosis, leukemia, neoplasm) or from trauma (e.g., from a foreign body, rough anal intercourse, perirectal surgery).

An *acute* anal fissure is superficial and usually resolves on its own or heals quickly with conservative treatment. *Chronic* fissures recur, and surgical treatment may be needed. Pain during and after defecation and bright red blood in the stool are the most common symptoms. Other manifestations include pruritus, urinary frequency or retention, dysuria, and **dyspareunia** (painful intercourse).

The diagnosis is made by stretching and inspecting the perianal skin. If the patient is having pain at the time of the examination, diagnostic testing is usually limited to inspection. If he or she is not in severe pain, a digital examination and possibly a sigmoidoscopy are performed. When painless or multiple fissures are present, a colonoscopy may be performed to rule out any inflammatory bowel disorder.

Management of an acute fissure is usually aimed at local pain relief and softening of stools to reduce trauma to the area. Teach the patient to use warm sitz baths, analgesics, and

bulk-producing agents (e.g., psyllium hydrophilic mucilloid [Metamucil]) to help minimize the pain from defecation. Topical anti-inflammatory agents (hydrocortisone creams and suppositories) may be helpful for some patients.

Explain pain control measures to the patient. Remind him or her to notify the health care provider if pain is not relieved within a few days. If fissures do not respond to management within several days to weeks, surgical repair under a local anesthetic may be needed. Teach the patient to report any drainage or bleeding from the rectum to the health care provider.

Anal Fistula

An anal fistula, or *fistula in ano*, is an abnormal tract leading from the anal canal to the perianal skin. Most anal fistulas result from anorectal abscesses, which are caused by obstruction of anal glands (see [Anorectal Abscess](#), p. 1287). Fistulas can also occur with tuberculosis, Crohn's disease, or cancer. Intermittent discharge is usually noted over the perianal area.

The patient with an anal fistula has pruritus (itching), purulent discharge, and tenderness or pain that is worsened by bowel movements. A proctoscope may be used to identify the source of symptoms and to locate the fistula. Because fistulas do not heal spontaneously, surgery is necessary. To perform a fistulotomy, the surgeon opens the tissue over the tract and scrapes the base. The incision site then heals by secondary intention. For a fistula higher in the anus, a special surgical technique is used to preserve important sphincters. After surgery, instruct the patient about sitz baths, analgesics, and the use of bulk-producing agents or stool softeners to reduce pain.

PARASITIC INFECTION

Pathophysiology

Parasites can enter and invade the GI tract and cause infections. They commonly enter through the mouth (oral-fecal transmission) from contaminated food or water, oral-anal sexual practices, or contact with feces from a contaminated person. Common parasites that cause infection in humans are *Giardia lamblia*, which causes giardiasis; *Entamoeba histolytica*, which causes amebiasis (amebic dysentery); and *Cryptosporidium*. *Handwashing is the best way to prevent the spread of parasitic infections.*

G. lamblia is a protozoal parasite that causes superficial invasion, destruction, and inflammation of the mucosa in the small intestine. This organism occurs in cysts and trophozoites (sporozoan parasites). Trophozoites die rapidly after they leave the body in stool. Cysts, however, can remain alive in the right type of environment for weeks or months. Humans who eliminate cysts are infectious. Flies can spread the cysts, and the problem is more common in areas that use human excrement for fertilizer. Humans are hosts to this organism, but beavers and dogs may be reservoirs for infection.

Giardiasis is a well-recognized problem in international travelers, campers, and immunosuppressed patients. In the United States, giardiasis is prevalent and is the most common parasitic infection. This disorder affects only the intestinal system, causing acute diarrhea, chronic diarrhea, or malabsorption syndrome. The acute phase usually is self-limiting, lasting days or weeks. The chronic phase can last for years.

Diarrhea is usually mild in both forms, but it can be severe. As stools increase in frequency, they become more watery, greasy, frothy, and malodorous with mucus. Weight loss and weakness are also common. Malabsorption can occur with diarrhea that continues for longer than 3 weeks. Manifestations result from malabsorption of fat, protein, and vitamin B₁₂ and lactase deficiency.

Humans are the only known hosts for *E. histolytica* (also known as *amebiasis*). This organism also occurs in cysts and trophozoites. Amebiasis occurs worldwide, but it is most common in tropical areas. Prevalence rates are as high in areas with poor sanitation, crowding, and poor nutrition. Amebiasis causes tens of thousands of deaths annually worldwide. The disease causes less severe symptoms and often goes undiagnosed in temperate climates.

E. histolytica either feeds on bacteria in the intestine or invades and ulcerates the mucosa of the large intestine. The parasite can be limited to the GI tract (intestinal amebiasis), or it can extend outside the intestines (extraintestinal amebiasis). People can have intestinal amebiasis without having any symptoms, or symptoms can range from mild to severe.

Cryptosporidium is manifested by diarrhea. This infection occurs most commonly in immunosuppressed patients, particularly those with human immune deficiency virus (HIV). It can also occur in children and older adults from contaminated swimming pools. (See [Chapter 21](#) for a discussion of HIV infection.)

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

A thorough history can help determine potential sources of exposure to parasitic infection. A history of travel to parts of the world where such infections are prevalent increases suspicion for infection with parasites. GI symptoms related to travel may be delayed as long as 1 to 2 weeks after the return home. Immigrants (newcomers) may have the infection upon entering a new country. A nutrition history is especially helpful if several people in a group become ill. Common water supplies or bodies of water may be infected with *Giardia* or *Cryptosporidium*. Trichinosis should be considered if the patient has eaten pork products.

Mild to moderate *E. histolytica* infestation causes the daily passage of several strongly foul-smelling stools, possibly with mucus but without blood, accompanied by abdominal cramping, flatulence (gas), fatigue, and weight loss.

The infected patient usually experiences remissions and recurrences. Severe amebic dysentery is manifested by frequent, more liquid, and foul-smelling stools with mucus and blood. Fever up to 104° F (40° C), [tenesmus](#) (feeling the urge to defecate), generalized abdominal tenderness, and vomiting can also occur. The ulcerations of invading amebiasis that occur in the colon can cause pain, bleeding, and obstruction. Ulcerations can also occur in the rectum, resulting in formed stool with blood. Complications are rare but include appendicitis and bowel perforation.

Extraintestinal amebiasis can occur without symptoms of intestinal infection. The most common form is amebic liver abscess, which causes symptoms of fever, pain, and an

enlarged liver. The abscess can rupture, and death can result if the infection and complications are not treated.

The diagnosis of *amebiasis* is made by examining the stool for parasites. Because *E. histolytica* is difficult to detect, serial stool examinations are needed if the disease is suspected. The use of sigmoidoscopy may detect ulcerations in the rectum or colon. Exudate obtained during sigmoidoscopic examination is studied for the parasite. The white blood cell (WBC) count can be very high when severe dysentery is present.

The diagnosis of *giardiasis* is also confirmed by the presence of parasites in the stool. Because organisms may not be detected for at least 1 week after symptoms appear, multiple stool samples should be examined.

INTERVENTIONS

Treatment for all types of *amebiasis* involves the use of amebicide drugs. Metronidazole (Flagyl, Novonidazole) and diloxanide furoate (Entamide) or diloxanide furoate and tetracycline hydrochloride (Sumycin) followed by chloroquine are commonly prescribed. The patient with severe dysentery requires IV fluids replacement and possibly opiates, such as diphenoxylate hydrochloride and atropine sulfate (Lomotil), to control bowel motility. The patient with extraintestinal amebiasis or severe dehydration is hospitalized, especially the older adult. The patient with asymptomatic, mild, or moderate disease is treated with drug therapy on an ambulatory care basis. Therapy effectiveness is based on the examination of at least three stools at 2- to 3-day intervals, starting 2 to 4 weeks after drug therapy has been completed. *Teach patients the importance of keeping their follow-up appointments and taking all drugs as prescribed.*

Treatment for *giardiasis* is drug therapy. Metronidazole is the drug of choice, 250 mg orally three times daily for 5 days. Tinidazole (Fasigyn) can be used as an alternative. Stools are examined 2 weeks after treatment to assess for drug effectiveness.

Infection with *Cryptosporidium* is usually self-limiting in people who have normal immune function. Drug therapy for

patients who are immunosuppressed may include paromomycin (Paromycin), an aminoglycoside antibiotic. Teach patients that this drug can cause dizziness.

FOOD POISONING

Foodborne illnesses are a common problem in the United States and all other parts of the world and can cause death. The problem results when a person ingests infectious organisms in food. Unlike gastroenteritis, food poisoning is not directly communicable from person to person and incubation periods are shorter. However, like gastroenteritis, it causes diarrhea, nausea, and vomiting. Food poisoning can be differentiated from gastroenteritis by obtaining a thorough history of common food intake in patients who have common symptoms of acute diarrhea, nausea, and vomiting.

Food poisoning is caused by over 250 pathogens. Examples include gram-negative *Salmonella*, *Staphylococcal aureus*, *Escherichia coli*, and botulism. Table 60-6 lists more information about these microbes. All cases of botulism and salmonellosis need to be reported to the local health department. Cases of staphylococcal and *E. coli* food poisoning are reported if epidemic outbreaks occur.

Salmonellosis

Salmonellosis is a bacterial infection caused by the *Salmonella* organism and affects many people each year in the United States. *Salmonella* bacteria live in the intestinal tracts of humans and animals. They can be transmitted by the “five Fs”: flies, fingers, food, feces, and fomites. Incubation is 8 to 48 hours after the person has ingested the contaminated food or liquid, the most common source. Foods that are most commonly contaminated are eggs, beef, poultry, and green leafy vegetables (e.g., spinach). In 2008, contaminated jalapeno peppers from Mexico caused *Salmonella* infection in hundreds of people in the United States.

NURSING SAFETY PRIORITY

Action Alert

Explain modes of transmission of parasitic infections and means to avoid the spread of infection and recurrent contact with parasitic organisms. *Inform the patient that the infection can be transmitted to others until amebicides effectively kill the parasites. Teach the patient to:*

- Avoid contact with stool.
- Keep toilet areas clean.
- Wash hands meticulously with an antimicrobial soap after bowel movements.
- Maintain good personal hygiene by bathing or showering daily.
- Avoid stool from dogs and beavers.

Advise the patient to avoid sexual practices that allow rectal contact until drug therapy is completed. *All household and sexual partners should have stool examinations for parasites.* If the water supply is suspected as the source, a sample is obtained and sent for analysis. Multiple infections are common in households, often as a result of contaminated water supplies. Well water and water from areas with inadequate or no filtration equipment can be sources of contamination.

TABLE 60-6 COMMON TYPES OF FOOD POISONING

Staphylococcal Infection

- Caused by contaminated meats and dairy products
- Can be transmitted by human carriers
- Causes abrupt onset of vomiting and diarrhea without fever

Escherichia coli Infection

- Caused by meat contaminated with animal feces
- Causes abrupt vomiting, diarrhea, abdominal cramping, and fever

Botulism

- Commonly associated with improperly canned foods, especially fruits and vegetables
- Nausea, vomiting, diarrhea, and weakness progressing to paralysis
- Diplopia, dysphagia, and dysarthria

Salmonellosis

- Caused by contaminated food or drink but can be transmitted by the fecal-oral route
- Fever, nausea, vomiting, abdominal cramping, and diarrhea lasting for 3 to 5 days

Symptoms usually last for 4 to 7 days. Most people have fever, nausea, vomiting, cramping abdominal pain, and foul-smelling diarrhea, which may be bloody. In some patients, fever is very high.

Salmonellosis is usually self-limiting, but bacteremia that infects the joints or bone may occur later in the disease process. Diagnosis is made by stool culture. Treatment is symptomatic. If bacteremia occurs, antibiotics such as ampicillin or ciprofloxacin (Cipro) are prescribed. Unfortunately, some *Salmonella* bacteria have become resistant to antibiotics because of the use of these drugs in animals. Some patients, especially older adults, are hospitalized with severe diarrhea and dehydration.

Patients may be carriers of the bacterium for up to 1 year. Instruct those with *Salmonella* gastroenteritis and their contacts to wash their hands before meals and after defecating to avoid transmission of the organism.

Staphylococcal Infection

Staphylococcus is responsible for 25% of reported food poisoning outbreaks. It is found in meats and dairy products and can be transmitted by carriers of the organism. For staphylococcal food poisoning to occur, there must be contamination of food and a period of time (hours) during which the organisms multiply. This can take place during the slow cooling of food after it is cooked.

Symptoms of staphylococcal food poisoning include an abrupt onset of vomiting, abdominal cramping, and diarrhea. The person usually has symptoms 2 to 4 hours after ingesting the contaminated food. The patient is afebrile but weak.

A diagnosis can be made when stool culture yields 100,000 enterotoxin-producing staphylococci. However, symptoms rarely last more than 24 hours, and people do not always seek medical attention. Antimicrobial drug therapy is not usually indicated unless an agent produces progressive systemic involvement. Parenteral fluids may be needed for dehydration.

Escherichia coli Infection

Since 1992, a number of outbreaks of *E. coli* food poisoning have occurred in the United States. Many strains of *E. coli* exist, and not all of them cause harm. However, some cause disease by making a substance called *Shiga toxin*. The bacteria that make these substances are called *Shiga toxin-producing E. coli*, or *STEC* for short. The most commonly identified *STEC* in the United States is *E. coli* O157:H7 (sometimes called just O157). In 2007, prepackaged spinach processed in the United States was contaminated with these bacteria and caused hundreds of people to become ill.

Enterohemorrhagic strains of *E. coli* (EHEC) and *STEC* can cause serious complications, such as hemorrhagic colitis and hemolytic-uremic syndrome. These problems affect older adults most often.

The symptoms of *STEC* infections vary, but most people have severe abdominal cramping, vomiting, and diarrhea (often bloody). Treatment of the patient with *E. coli* food poisoning includes IV fluids and supportive therapy, possibly with antidiarrheal agents. Antibiotics are not effective. [Chart 60-8](#) outlines best practices for preventing *STEC* infections.

CHART 60-8 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Ways to Prevent *STEC* (*E. coli*) Infections

- Wash your hands *thoroughly* after using the bathroom and after changing diapers and before preparing or eating food.
- Wash your hands after contact with any animals or their environments (e.g., zoo).
- Cook meats thoroughly to at least 160° to 170° internal temperature; use a food thermometer to ensure doneness.
- Avoid raw milk, unpasteurized juices (like fresh apple cider), and unpasteurized dairy products.
- Avoid swallowing water when swimming.
- Prevent cross-contamination during food preparation by washing hands, counters, cutting boards, and utensils after they touch raw meat.

STEC, Shiga toxin-producing *Escherichia coli*.

Botulism

Botulism is a paralytic disease resulting from ingestion of a toxin in food contaminated with *Clostridium botulinum*. Botulism occurs most often with home-canned foods, particularly vegetables, fruits, condiments, and, less commonly, meat and fish. It can also occur in commercially prepared products and with products not adequately heated to destroy toxins before they are eaten.

Incubation is usually 18 to 36 hours. After this time, symptoms occur. Initial symptoms include diplopia (double vision), dysphagia (difficulty swallowing), and dysarthria (slurred speech). Illness may be mild or severe, with paralysis, respiratory failure, and death. Weakness can progress rapidly from the neck to the arms, chest, and legs. Paralytic ileus, severe constipation, and urinary retention can also occur. Nausea, vomiting, and abdominal pain may occur before or after the onset of paralysis. The diagnosis is made on the basis of the patient's history and a stool culture of *C. botulinum*. The blood may be positive for toxins.

Treatment with trivalent botulism antitoxin is given as soon as the diagnosis is made if the patient is not hypersensitive to it. The physician may lavage the stomach to stop absorption of toxin. All patients are hospitalized to observe for and treat respiratory paralysis. Nothing is given orally until swallowing and respiratory function are restored. The physician prescribes IV fluids as needed. If respiratory paralysis occurs, intubation and mechanical ventilation are implemented. If ventilation can be maintained, the patient can survive with no neurologic deficits after the illness.

NURSING SAFETY PRIORITY

Action Alert

To prevent botulism, teach patients the importance of discarding cans of food that are punctured or swollen or that have defective seals. Remind them to check for expiration dates and to not use any canned food that has expired. Containers for home-canned foods must be sterilized by boiling for 20 minutes to destroy *C. botulinum* spores before canning.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient has impaired digestion and inadequate nutrition as a result of inflammatory intestinal problems?

- Report of nausea
- Vomiting
- Report of epigastric or abdominal pain
- Diarrhea (sometimes bloody)
- Elevated temperature
- Weakness

What should you INTERPRET and how should you RESPOND to a patient with impaired digestion and inadequate nutrition as a result of inflammatory intestinal problems?

Perform and interpret focused physical assessment findings, including:

- Vital signs
- Complete pain assessment
- Skin turgor and mucous membrane dryness
- Abdominal assessment
- Current and previous weight
- History of recent food intake
- History of recent travel

Respond:

- Prevent pain and aspiration by placing patient in sitting position.
- Place IV catheter (large-bore) to replace fluids.
- Provide privacy, and assist with hygiene.
- Provide rest.
- Check laboratory values for hemoglobin and hematocrit (anemia).
- Check serum electrolytes (dehydration, hypokalemia).
- Give antidiarrheal drugs if prescribed.
- Record intake and output.
- Assist with ADLs and ambulation as needed.

On what should you REFLECT?

- Continue to monitor for vomiting and diarrhea and changes in pain level.
- Think about what you need to document.
- Decide when you might need to call the health care provider or Rapid Response Team (for hospitalized patients).
- Determine what health teaching and community resources may be needed for this patient and family.
- Think about what you can do to help prevent complications of the health problem.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Teach patients to use infection control measures to prevent transmission of gastroenteritis as stated in [Chart 60-2](#).
- Collaborate with a CWOCN or ET nurse for ileostomy teaching and care; collaborate with a case manager when planning for patient discharge.

Health Promotion and Maintenance

- Teach patients with chronic IBD to avoid GI stimulants, such as alcohol and caffeine; each patient's response to foods differs.
- Instruct patients with diverticulosis about nutrition modifications, such as avoiding nuts, foods with seeds, and GI stimulants.
- Teach patients with diverticulosis to eat a high-fiber diet; diverticulitis requires a low-fiber diet.

Psychosocial Integrity

- Be aware that all inflammatory bowel diseases (acute and chronic) are very disruptive to one's daily routine; chronic IBD requires a lifetime of modifications.

- Recognize that having an ileostomy impacts the patient's body image and self-esteem; assess for coping strategies that the patient has previously used, and identify personal support systems to assist in coping.

Physiological Integrity

- Assess for the classic clinical manifestations of appendicitis, which include abdominal pain, nausea and vomiting, and abdominal tenderness upon palpation (McBurney's point); some patients also have leukocytosis.
- Assess for the key features of peritonitis as listed in [Chart 60-1](#).
- Assess for signs and symptoms of dehydration in patients who have inflammatory bowel disease.
- Administer antidiarrheal medications as prescribed to decrease stools and therefore prevent dehydration in patients with inflammatory bowel diseases.
- Be aware that there are two major types of chronic inflammatory bowel disease (IBD): ulcerative colitis (UC) and Crohn's disease; both have similarities but also have differences (see [Table 60-2](#)).
- Recognize that perforation (rupture) of the appendix requires prompt intervention and can result in peritonitis.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Be alert for GI bleeding in the patient with chronic inflammatory bowel disease (IBD).
- Be aware that patients with Crohn's disease are at high risk for malnutrition as a result of an inability to absorb nutrients via the small intestine.
- Teach patients how to provide ileostomy care, paying particular attention to skin care; the effluent has a high enzyme content that can easily cause severe skin excoriation (see [Chart 60-4](#)).
- Monitor for complications of UC as listed in [Table 60-4](#).
- Provide nursing interventions for patients with IBD as listed in [Chart 60-3](#).
- Administer 5-aminosalicylic acid (5-ASA) drugs as prescribed (e.g., Pentasa) to decrease inflammation in patients with UC; most of these same drugs are also used for Crohn's disease management.
- Administer infliximab (Remicade) or other monoclonal antibody agent as prescribed for patients with Crohn's disease; these drugs may also be useful for those with UC in selected cases.
- Observe for manifestations of lower GI bleeding in patients with chronic inflammatory and diverticular disease.
- Instruct patients with anorectal disorders to use sitz baths, bulk-forming agents (e.g., Metamucil), and stool softeners to decrease pain.
- Be aware that GI problems, including diarrhea, may also be caused by parasites and food poisoning.

Care of Patients with Liver Problems

Donna D. Ignatavicius

<http://evolve.elsevier.com/Iggy/>

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges
Audio Glossary
Concept Map Creator

Concept Map: Cirrhosis
Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Describe the need to collaborate with health care team members to provide care for patients with liver problems.

Health Promotion and Maintenance

2. Identify community resources for patients with chronic liver disease.
3. Identify risk factors for cirrhosis and hepatitis.
4. Develop a health teaching plan for patients and families to prevent hepatitis and its spread to others.
5. Develop a health teaching plan for patients and families to prevent or slow the progress of alcohol-induced cirrhosis.

Psychosocial Integrity

6. Explain the psychosocial needs of patients with hepatitis.

Physiological Integrity

7. Explain the pathophysiology and complications associated with cirrhosis of the liver.
8. Interpret laboratory test findings commonly seen in patients with cirrhosis.

9. Analyze assessment data from patients with cirrhosis to determine priority patient problems.
10. Develop a collaborative plan of care for the patient with late-stage cirrhosis.
11. Describe the role of the nurse in monitoring for and managing potentially life-threatening complications of cirrhosis.
12. Identify emergency interventions for the patient with bleeding esophageal varices.
13. Explain the role of the nurse when assisting with a paracentesis procedure.
14. Compare and contrast the transmission of hepatitis viral infections.
15. Explain ways in which each type of hepatitis can be prevented.
16. Identify potentially life-threatening complications of liver trauma.
17. Describe treatment options for patients with cancer of the liver.
18. Describe the common complications that result from liver transplantation.

The liver is the largest and one of the most vital internal organs, performing more than 400 functions and affecting every system in the body. When the liver is diseased or damaged, it cannot provide these activities. As a result, *digestion, nutrition, and metabolism* can be severely affected. Liver diseases range in severity from mild hepatic inflammation to chronic end-stage cirrhosis.

CIRRHOSIS

Cirrhosis is extensive, irreversible scarring of the liver, usually caused by a chronic reaction to hepatic inflammation and necrosis. The disease typically develops slowly and has a progressive, prolonged, destructive course resulting in end-stage liver disease. The most common causes for cirrhosis in the

United States are hepatitis C, alcoholism, and biliary obstruction. Worldwide, hepatitis B and hepatitis D are the leading causes. Without liver transplantation, cirrhosis is usually fatal (Kelso, 2008).

Pathophysiology

Cirrhosis is characterized by widespread fibrotic (scarred) bands of connective tissue that change the liver's normal makeup. Inflammation caused by either toxins or disease results in extensive degeneration and destruction of **hepatocytes** (liver cells). As cirrhosis develops, the tissue becomes nodular. These nodules can block bile ducts and normal blood flow throughout the liver. Impairments in blood and lymph flow result from compression caused by excessive fibrous tissue. In early disease, the liver is usually enlarged, firm, and hard. As the pathologic process continues, the liver shrinks in size, resulting in decreased liver function, which can occur in weeks to years. Some patients with cirrhosis have no symptoms until serious complications occur. The impaired liver function results in elevated serum liver enzymes (Pagana & Pagana, 2010).

Cirrhosis of the liver can be divided into several common types, depending on the cause of the disease (McCance et al., 2010):

- Postnecrotic cirrhosis (caused by viral hepatitis [especially hepatitis C] and certain drugs or other toxins)
- Laennec's or alcoholic cirrhosis (caused by chronic alcoholism)
- Biliary cirrhosis (also called *cholestatic*; caused by chronic biliary obstruction or autoimmune disease)

Complications of Cirrhosis

Common problems and complications associated with hepatic cirrhosis depend on the amount of damage sustained by the liver. In **compensated cirrhosis**, the liver is scarred but can still perform essential functions without causing major symptoms. In **decompensated cirrhosis**, liver function is impaired with obvious manifestations of liver failure.

The loss of hepatic function contributes to the development of metabolic abnormalities. Hepatic cell damage may lead to these common complications:

- Portal hypertension
- Ascites and esophageal varices
- Coagulation defects
- Jaundice
- Portal-systemic encephalopathy (PSE) with hepatic coma
- Hepatorenal syndrome
- Spontaneous bacterial peritonitis

Portal Hypertension. **Portal hypertension**, a persistent increase in pressure within the portal vein greater than 5 mm Hg, is a major complication of cirrhosis (Minano & Garcia-Tsao, 2010). It results from increased resistance to or obstruction (blockage) of the flow of blood through the portal vein and its branches. The blood meets resistance to flow and seeks collateral (alternative) venous channels around the high-pressure area.

Blood flow backs into the spleen, causing **splenomegaly** (spleen enlargement). Veins in the esophagus, stomach, intestines, abdomen, and rectum become dilated. Portal hypertension can result in ascites (abdominal fluid), esophageal varices

(distended veins), prominent abdominal veins (caput medusae), and hemorrhoids.

Ascites and Esophageal Varices. **Ascites** is the collection of free fluid within the peritoneal cavity caused by increased hydrostatic pressure from portal hypertension (McCance et al., 2010). The collection of plasma protein in the peritoneal fluid reduces the amount of circulating plasma protein in the blood. When this decrease is combined with the inability of the liver to produce albumin because of impaired liver cell functioning, the serum colloid osmotic pressure is decreased in the circulatory system. The result is a fluid shift from the vascular system into the abdomen, a form of "third spacing." As a result, the patient may have hypovolemia and edema at the same time.

Massive ascites may cause renal vasoconstriction, triggering the renin-angiotensin system. This results in sodium and water retention, which increases hydrostatic pressure and the vascular volume and leads to more ascites.

As a result of portal hypertension, the blood backs up from the liver and enters the esophageal and gastric veins. **Esophageal varices** occur when fragile, thin-walled esophageal veins become distended and tortuous from increased pressure. The potential for varices to bleed depends on their size; size is determined by direct endoscopic observation. Varices occur most often in the distal esophagus but can also be present in the stomach and rectum.

Bleeding esophageal varices is a life-threatening medical emergency. Severe blood loss may occur, resulting in shock from hypovolemia. The bleeding may be either **hematemesis** (vomiting blood) or **melena** (black, tarry stools). Loss of consciousness may occur before any observed bleeding. Variceal bleeding can occur spontaneously with no precipitating factors. However, any activity that increases abdominal pressure may increase the likelihood of a variceal bleed, including heavy lifting or vigorous physical exercise. In addition, chest trauma or dry, hard food in the esophagus can cause bleeding.

Patients with portal hypertension may also have **portal hypertensive gastropathy**. This complication can occur with or without esophageal varices. Slow gastric mucosal bleeding occurs, which may result in chronic slow blood loss, occult-positive stools, and anemia.

Splenomegaly (enlarged spleen) results from the backup of blood into the spleen. The enlarged spleen destroys platelets, causing thrombocytopenia (low serum platelet count) and increased risk for bleeding. Thrombocytopenia is often the first clinical sign that a patient has liver dysfunction.

Biliary Obstruction. In patients with cirrhosis, the production of bile in the liver is decreased. This prevents the absorption of fat-soluble vitamins (e.g., vitamin K). Without vitamin K, clotting factors II, VII, IX, and X are not produced in sufficient quantities and the patient is susceptible to bleeding and easy bruising. These abnormalities are confirmed by coagulation studies.

Jaundice (yellowish coloration of the skin) in patients with cirrhosis is caused by one of two mechanisms: hepatocellular disease or intrahepatic obstruction (Table 61-1). **Hepatocellular** jaundice develops because the liver cells cannot effectively excrete bilirubin. This decreased excretion results in excessive circulating bilirubin levels. **Intrahepatic obstructive** jaundice results from edema, fibrosis, or scarring of the hepatic bile channels and bile ducts, which interferes with

TABLE 61-1 LABORATORY DIAGNOSTIC DIFFERENTIATION OF JAUNDICE

TEST	HEPATOCELLULAR JAUNDICE	OBSTRUCTIVE JAUNDICE	HEMOLYTIC JAUNDICE
Serum bilirubin			
Indirect (unconjugated)	Increased	Slightly increased	Increased
Direct (conjugated)	Increased	Moderately increased	Normal
Urine bilirubin	Increased	Increased	None
Urobilinogen			
Stool	Normal to decreased	None	Increased
Urine	Normal to increased	None	Increased

TABLE 61-2 STAGES OF PORTAL-SYSTEMIC ENCEPHALOPATHY

Stage I Prodromal • Subtle manifestations that may not be recognized immediately • Personality changes • Behavior changes (agitation, belligerence) • Emotional lability (euphoria, depression) • Impaired thinking • Inability to concentrate • Fatigue, drowsiness • Slurred or slowed speech • Sleep pattern disturbances	Stage III Stuporous • Progressive deterioration • Marked mental confusion • Stuporous, drowsy but arousable • Abnormal electroencephalogram tracing • Muscle twitching • Hyperreflexia • Asterixis
Stage II Impending • Continuing mental changes • Mental confusion • Disorientation to time, place, or person • Asterixis (hand flapping)	Stage IV Comatose • Unresponsiveness, leading to death in most patients progressing to this stage • Unarousable, obtunded • Usually no response to painful stimulus • No asterixis • Positive Babinski's sign • Muscle rigidity • Fetus hepaticus (characteristic liver breath—musty, sweet odor) • Seizures

normal bile and bilirubin excretion. Patients with jaundice often report pruritus (itching).

Hepatic Encephalopathy. Hepatic encephalopathy (also called **portal-systemic encephalopathy [PSE]**) is a complex cognitive syndrome that results from liver failure and cirrhosis. Patients report sleep disturbance, mood disturbance, mental status changes, and speech problems early as this complication begins. Hepatic encephalopathy may be reversible with early intervention. Later neurologic symptoms include an altered level of consciousness, impaired thinking processes, and neuromuscular problems.

Hepatic encephalopathy may develop slowly in patients with chronic liver disease and go undetected until the late stages. Symptoms develop rapidly in acute liver dysfunction. Four stages of development have been identified: prodromal, impending, stuporous, and comatose (Table 61-2). The patient's symptoms may gradually progress to coma or fluctuate among the four stages.

The exact mechanisms causing hepatic encephalopathy are not clearly understood but probably are the result of the shunting of portal venous blood into the central circulation so that the liver is bypassed. As a result, substances absorbed by the intestine are not broken down or detoxified and may lead to metabolic abnormalities, such as elevated serum

ammonia and gamma-aminobutyric acid (GABA) (Kelso, 2008). Elevated serum ammonia results from the inability of the liver to detoxify protein by-products and is common in patients with hepatic encephalopathy. However, it is not a clear indicator of the presence of encephalopathy. Some patients may have major impairment without high elevations of serum ammonia, and elevations of ammonia can occur without evidence of encephalopathy.

Factors that may lead to hepatic encephalopathy in patients with cirrhosis include:

- High-protein diet
- Infections
- Hypovolemia (decreased fluid volume)
- Hypokalemia (decreased serum potassium)
- Constipation
- GI bleeding (causes a large protein load in the intestines)
- Drugs (e.g., hypnotics, opioids, sedatives, analgesics, diuretics, illicit drugs)

The prognosis depends on the severity of the underlying cause, the precipitating factors, and the degree of liver dysfunction.

Other Complications. The development of **hepatorenal syndrome (HRS)** indicates a poor prognosis for the patient with liver failure. It is often the cause of death in these patients. This syndrome is manifested by:

- A sudden decrease in urinary flow (<500 mL/24 hr) (oliguria)
- Elevated blood urea nitrogen (BUN) and creatinine levels with abnormally decreased urine sodium excretion
- Increased urine osmolality

HRS often occurs after clinical deterioration from GI bleeding or the onset of hepatic encephalopathy. It may also complicate other liver diseases, including acute hepatitis and fulminant liver failure.

Patients with cirrhosis and ascites may develop acute *spontaneous bacterial peritonitis (SBP)*. Those who are particularly susceptible are patients with very advanced liver disease. This may be the result of low concentrations of proteins; proteins normally provide some protection against bacteria.

The bacteria responsible for SBP are typically from the bowel and reach the ascitic fluid after migrating through the bowel wall and transversing the lymphatics. Clinical manifestations vary but may include fever, chills, and abdominal pain and tenderness. However, manifestations can also be minimal with only mild symptoms in the absence of fever. Worsening encephalopathy and increased jaundice may also be present without abdominal symptoms.

The diagnosis of SBP is made when a sample of ascitic fluid is obtained by paracentesis for cell counts and culture. An ascitic fluid leukocyte count of more than 250 polymorphonuclear (PMN) leukocytes may indicate the need for treatment.

Etiology and Genetic Risk

Hepatitis C is the leading cause of cirrhosis and liver failure in the United States. It is an infectious bloodborne illness that usually causes chronic disease. Inflammation caused by infection over time leads to progressive scarring of the liver. It usually takes decades for cirrhosis to develop, although alcohol use in combination with hepatitis C may speed the process.

Hepatitis B and hepatitis D are the most common causes of cirrhosis worldwide. Hepatitis B also causes inflammation and low-grade damage over decades that can ultimately lead to cirrhosis. Hepatitis D is another virus that infects the liver but only in people who already have hepatitis B (see discussion of hepatitis on p. 1305).

Cirrhosis can occur as a result of other factors. For example, *alcohol* has a direct toxic effect on the hepatocytes and causes liver inflammation (**alcoholic hepatitis**). The liver becomes enlarged, with cellular degeneration and infiltration by fat, leukocytes, and lymphocytes. Over time, the inflammatory process decreases and the destructive phase increases. Early scar formation is caused by fibroblast infiltration and collagen formation. Damage to the liver tissue progresses as malnutrition and repeated exposure to the alcohol continue. If alcohol is withheld, the fatty infiltration and inflammation is reversible. If alcohol abuse continues, widespread scar tissue formation and fibrosis infiltrate the liver as a result of cellular necrosis. The long-term use of illicit drugs, such as cocaine, has similar effects on the liver.

The amount of alcohol necessary to cause cirrhosis varies widely from person to person, and there are gender differences. In women, it may take as few as two to three drinks per day over a minimum of 10 years. In men, perhaps six drinks per day over the same time period may be needed to cause disease. Binge drinking can increase risk for hepatitis and fatty liver.

Biliary cirrhosis occurs as a result of obstruction of the bile duct, usually from gallbladder disease or an autoimmune form of the disease called *primary biliary cirrhosis (PBC)*. Patients with PBC typically have a genetic predisposition to the disease and a positive antimitochondrial antibody (AMA) (Lindor et al., 2009). [Table 61-3](#) summarizes known causes of liver cirrhosis.

Incidence/Prevalence

The incidence of cirrhosis in the United States is not well known, but about 27,000 die from it each year. The disease affects twice as many men as women (Kelso, 2008).

TABLE 61-3 COMMON CAUSES OF CIRRHOSIS

• Alcoholic liver disease	• Drugs and chemical toxins
• Viral hepatitis	• Gallbladder disease
• Autoimmune hepatitis	• Metabolic/genetic causes
• Steatohepatitis (from fatty liver)	• Cardiovascular disease

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Obtain data from patients with suspected cirrhosis, including age, gender, and employment history, especially history of exposure to alcohol, drugs (prescribed and illicit), and chemical toxins. Keep in mind that all exposures are important regardless of how long ago they occurred. Determine whether there has ever been a needle stick injury. Sexual history and orientation may be important in determining an infectious cause for liver disease, because men having sex with men (MSM) are at high risk for hepatitis A, hepatitis B, and hepatitis C. People with hepatitis can develop cirrhosis ([American Liver Foundation, 2011](#)).

Inquire about whether there is a family history of alcoholism and/or liver disease. Ask the patient to describe his or her alcohol intake, including the amount consumed during a given period. Is there a history of illicit drug use, including oral, IV, and intranasal forms? Is there a history of tattoos? Has the patient been in the military or in prison? Is the patient a health care worker, firefighter, or police officer? For patients previously or currently in an alcohol or drug recovery program, how long have they been sober? This information is sensitive and often difficult for the patient to answer. Be sure to establish why you are asking these questions, and accept answers in a nonjudgmental manner. Provide privacy during the interview. For many people, the behaviors causing the liver disease occurred years before the onset of their current illness and they are regretful and often embarrassed.

Ask the patient about previous medical conditions, such as an episode of jaundice or acute viral hepatitis, biliary tract disorders (such as cholecystitis), viral infections, surgery, blood transfusions, autoimmune disorders, obesity, altered lipid profile, heart failure, respiratory disorders, or liver injury.

Physical Assessment/Clinical Manifestations

Because cirrhosis has a slow onset, many of the *early* manifestations are vague and nonspecific. Assess for:

- Fatigue
- Significant change in weight
- GI symptoms, such as anorexia and vomiting
- Abdominal pain and liver tenderness (both of which may be ignored by the patient)

Liver function problems are often found during a routine physical examination or when laboratory tests are completed for an unrelated illness or problem. The patient with *compensated cirrhosis* may be completely unaware that there is a liver problem. The first sign may present before the onset of symptoms when routine laboratory tests, presurgical evaluations, or life and health insurance assessments show abnormalities. These tests could indicate abnormal liver function or thrombocytopenia, requiring a more thorough diagnostic workup.

The development of late signs of *advanced cirrhosis* (also called “end-stage liver failure”) usually causes the patient to seek medical treatment. GI bleeding, jaundice, ascites, and spontaneous bruising indicate poor liver function and complications of cirrhosis.

Thoroughly assess the patient with liver dysfunction or failure because it affects every body system ([Fig. 61-1](#)). The

NEUROLOGIC FINDINGS

Asterixis
Paresthesias of feet
Peripheral nerve degeneration
Portal-systemic encephalopathy
Reversal of sleep-wake pattern
Sensory disturbances

GASTROINTESTINAL (GI)
FINDINGS

Abdominal pain
Anorexia
Ascites
Clay-colored stools
Diarrhea
Esophageal varices
Fetor hepaticus
Gallstones
Gastritis
Gastrointestinal bleeding
Hemorrhoidal varices
Hepatomegaly
Hiatal hernia
Hypersplenism
Malnutrition
Nausea
Small nodular liver
Vomiting

RENAL FINDINGS

Hepatorenal syndrome
Increased urine bilirubin

ENDOCRINE FINDINGS

Increased aldosterone
Increased antidiuretic hormone
Increased circulating estrogens
Increased glucocorticoids
Gynecomastia

IMMUNE SYSTEM DISTURBANCES

Increased susceptibility to infection
Leukopenia

Hypokalemia
Peripheral edema
Water retention

FIG. 61-1 The clinical picture of a patient with liver dysfunction. Manifestations vary according to the progression of the disease.

clinical picture and course vary from patient to patient depending on the severity of the disease. Assess for:

- Obvious yellowing of the skin (jaundice) and sclerae (icterus)
- Dry skin
- Rashes
- Purpuric lesions, such as **petechiae** (round, pinpoint, red-purple lesions) or **ecchymosis** (large purple, blue, or yellow bruises)
- Warm and bright red palms of the hands (palmar erythema)
- Vascular lesions with a red center and radiating branches, known as **“spider angiomas”** (telangiectases, spider nevi, or vascular spiders), on the nose, cheeks, upper thorax, and shoulders
- Ascites (abdominal fluid)
- Peripheral dependent edema of the extremities and sacrum
- Sicca syndrome (in patients with primary biliary cirrhosis [PBC]) (Lindor et al., 2009)

- Osteoporosis (especially in patients with PBC) (Lindor et al., 2009)
- Vitamin deficiency (especially fat-soluble vitamins A, D, E, and K)

Abdominal Assessment. Massive ascites can be detected as a distended abdomen with bulging flanks. The umbilicus may protrude, and dilated abdominal veins (caput medusae) may radiate from the umbilicus. Ascites can cause physical problems. For example, orthopnea and dyspnea from increased abdominal distention can interfere with lung expansion. The patient may have difficulty maintaining an erect body posture, and problems with balance may affect walking. Inspect and palpate for the presence of inguinal or umbilical hernias, which are likely to develop because of increased intra-abdominal pressure.

Minimal ascites is often more difficult to detect, especially in the obese patient. Advanced assessment techniques, such as the percussion test for shifting dullness and the presence of a fluid wave, may be performed by the health care provider.

FIG. 61-2 How to measure abdominal girth. With the patient supine, bring the tape measure around the patient and take a measurement at the level of the umbilicus. Before removing the tape, mark the abdomen along the sides of the tape on the patient's flanks (sides) and midline to ensure that later measurements are taken in the same place.

When performing an assessment of the abdomen, keep in mind that **hepatomegaly** (liver enlargement) occurs in many cases of early cirrhosis. Splenomegaly is common in nonalcoholic causes of cirrhosis. As the liver deteriorates, it may become hard and small. The advanced practice nurse or other health care provider palpates the right upper quadrant for hepatomegaly below the costal (rib cage) border. It may also be assessed by percussing for dullness over the enlarged liver.

Measure the patient's abdominal girth to evaluate the progression of ascites (Fig. 61-2). To measure abdominal girth, the patient lies flat while the nurse or other examiner pulls a tape measure around the largest diameter (usually over the umbilicus) of the abdomen. The girth is measured at the end of exhalation. Mark the abdominal skin and flanks to ensure the same tape measure placement on subsequent readings. *Taking daily weights, however, is the most reliable indicator of fluid retention.*

Other Physical Assessment. Observe vomitus and stool for blood. This may be indicated by frank blood in the excrement or by a positive fecal occult blood test (FOBT) (Hema-Check, Hematest). Gastritis, stomach ulceration, or oozing esophageal varices may be responsible for the blood in the stool.

Note the presence of **fetor hepaticus**, which is the distinctive breath odor of chronic liver disease and hepatic encephalopathy and is characterized by a fruity or musty odor. Fetor hepaticus results from the inability of the damaged liver to metabolize and detoxify mercaptan, which is produced by bacterial breakdown of methionine, a sulfurous amino acid.

Amenorrhea (no menstrual period) may occur in women and men may exhibit testicular atrophy, **gynecomastia** (enlarged breasts), and impotence as a result of inactive hormones. Patients with problems of the hematologic system caused by hepatic failure may have bruising and petechiae (small, purplish hemorrhagic spots on the skin).

Continually assess the patient's neurologic function. Subtle changes in mental status and personality often progress to coma, a late complication of encephalopathy. Monitor for **asterixis**, a coarse tremor characterized by rapid, nonrhythmic extensions and flexions in the wrists and fingers.

Psychosocial Assessment

The patient with hepatic cirrhosis may undergo subtle or obvious personality, cognitive, and behavior changes, such as agitation. He or she may experience sleep pattern disturbances or may exhibit signs of emotional lability (fluctuations in emotions), euphoria (a very elevated mood), or depression. A psychosocial assessment identifies needs and helps guide care.

Repeated hospitalizations are common for patients with cirrhosis. It is a life-altering chronic disease, impacting not only the patient but also the immediate and extended family members and significant others. There are significant emotional, physical, and financial changes. Substance abuse may continue even as health worsens. It is important, whenever possible, to use resources available to these patients and their families. Collaborate with social workers, substance abuse counselors, and mental health/behavioral health care professionals as needed for patient assessment and management.

Laboratory Assessment

Laboratory study abnormalities are common in patients with liver disease (Table 61-4). Serum levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT), and lactate dehydrogenase (LDH) may be elevated because these enzymes are released into the blood during hepatic inflammation. However, as the liver deteriorates, the hepatocytes may be unable to create an inflammatory response and the AST and ALT may be normal. ALT levels are more specific to the liver whereas AST can be found in muscle, kidney, brain, and heart. An AST/ALT ratio greater than 2 is usually found in alcoholic liver disease.

Increased alkaline phosphatase and gamma-glutamyl transpeptidase (GGT) levels are caused by biliary obstruction and therefore may increase in patients with cirrhosis (Kelso, 2008). However, alkaline phosphatase also increases when bone disease, such as osteoporosis, is present. Total serum bilirubin levels also rise. Indirect bilirubin levels increase in patients with cirrhosis because of the inability of the failing liver to excrete bilirubin. Therefore bilirubin is present in the urine (urobilinogen) in increased amounts. Fecal urobilinogen concentration is decreased in patients with biliary tract obstruction. These patients have light- or clay-colored stools.

Total serum protein and albumin levels are decreased in patients with severe or chronic liver disease as a result of decreased synthesis by the liver (Pagana & Pagana, 2010). Loss of osmotic "pull" proteins like albumin promotes the movement of intravascular fluid into the interstitial tissues (e.g., ascites). Prothrombin time/international normalized ratio (PT/INR) is prolonged because the liver decreases the production of prothrombin. The platelet count is low, resulting in a characteristic thrombocytopenia of cirrhosis. Anemia may be reflected by decreased red blood cell (RBC), hemoglobin, and hematocrit values. The white blood cell (WBC) count may also be decreased. Ammonia levels are usually elevated in patients with advanced liver disease. Serum creatinine may be elevated in patients with deteriorating kidney

TABLE 61-4 ASSESSMENT OF ABNORMAL LABORATORY FINDINGS IN LIVER DISEASE

ABNORMAL FINDING	SIGNIFICANCE
Serum Enzymes	
Elevated serum aspartate aminotransferase (AST)	Hepatic cell destruction, hepatitis (most specific indicator)
Elevated serum alanine aminotransferase (ALT)	Hepatic cell destruction, hepatitis
Elevated lactate dehydrogenase (LDH)	Hepatic cell destruction
Elevated serum alkaline phosphatase	Obstructive jaundice, hepatic metastasis
Bilirubin	
Elevated serum total bilirubin	Hepatic cell disease
Elevated serum direct conjugated bilirubin	Hepatitis, liver metastasis
Elevated serum indirect unconjugated bilirubin	Cirrhosis
Elevated urine bilirubin	Hepatocellular obstruction, viral or toxic liver disease
Elevated urine urobilinogen	Hepatic dysfunction
Decreased fecal urobilinogen	Obstructive liver disease
Serum Proteins	
Increased serum total protein	Acute liver disease
Decreased serum total protein	Chronic liver disease
Decreased serum albumin	Severe liver disease
Elevated serum globulin	Immune response to liver disease
Other Tests	
Elevated serum ammonia	Advanced liver disease or portal-systemic encephalopathy (PSE)
Prolonged prothrombin time (PT) or international normalized ratio (INR)	Hepatic cell damage and decreased synthesis of prothrombin

function. Dilutional hyponatremia (low serum sodium) may occur in patients with ascites.

Patients with primary biliary cirrhosis, an autoimmune disease, usually have high disease-specific AMA and anti-nuclear antibody (ANA) titers and elevated levels of immunoglobulin M (IgM) (Lindor et al., 2009).

Imaging Assessment

Plain x-rays of the abdomen may show hepatomegaly, splenomegaly, or massive ascites. A computed tomography (CT) scan may be requested.

Magnetic resonance imaging (MRI) is another test used to diagnose the patient with liver disease. It can reveal mass lesions, giving additional specific information. This information is helpful in determining whether the condition is malignant or benign.

Other Diagnostic Assessment

Ultrasound (US) of the liver is often the first assessment for a person with suspected liver disease to detect ascites, hepatomegaly, and splenomegaly. It can also determine the presence of biliary stones or biliary duct obstruction. Liver US is useful

in detecting portal vein thrombosis and evaluating whether the direction of portal blood flow is normal.

Some patients being assessed for liver disease require biopsies to determine the exact pathology and the extent of disease progression. This procedure can be problematic because a large number of patients are at risk for bleeding. Even a **percutaneous** (through the skin) biopsy can pose a significant risk to the patient. To minimize this risk, an interventional radiologist can perform a liver biopsy using a long sheath through a jugular vein that then is threaded into the hepatic vein and liver. A tissue sample is obtained for microscopic evaluation. If a biopsy procedure is not possible, a radioisotope liver scan may be used to identify cirrhosis or other diffuse disease.

The physician may request *arteriography* if US is not conclusive in finding portal vein thrombosis. To evaluate the portal vein and its branches, a portal venogram may be performed instead, by passing a catheter into the liver and into the portal vein. This procedure is described on p. 1302 in the Transjugular Intrahepatic Portal-Systemic Shunt section.

The physician may perform an **esophagogastroduodenoscopy (EGD)** to directly visualize the upper GI tract and to detect the presence of bleeding or oozing esophageal varices, stomach irritation and ulceration, or duodenal ulceration and bleeding. EGD is performed by introducing a flexible fiberoptic endoscope into the mouth, esophagus, and stomach while the patient is under moderate sedation. A camera attached to the scope permits direct visualization of the mucosal lining of the upper GI tract. An **endoscopic retrograde cholangiopancreatography (ERCP)** uses the endoscope to inject contrast material via the sphincter of Oddi to view the biliary tract and allow for stone removals, sphincteromies, biopsies, and stent placements if required. These procedures are described in more detail in [Chapter 55](#).

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

When caring for a client with advanced cirrhosis, what laboratory assessment findings will the nurse expect? **Select all that apply.**

- A. Increased serum albumin
- B. Decreased bilirubin in the urine
- C. Increased alanine aminotransferase
- D. Increased alkaline phosphatase
- E. Decreased bilirubin in the stool
- F. Increased platelets

ANALYSIS

The priority problems for patients with cirrhosis include:

1. Excess Fluid Volume related to third spacing of abdominal and peripheral fluid
2. Potential for hemorrhage due to portal hypertension
3. Potential for hepatic encephalopathy due to shunting of portal venous blood and/or increased serum ammonia levels

PLANNING AND IMPLEMENTATION

Managing Fluid Volume

Planning: Expected Outcomes. The patient with cirrhosis is expected to have less excess fluid volume as evidenced by decreased ascites and peripheral edema and adequate circulatory volume. If ascites continues, the patient will not have

respiratory distress and will manage ascites by adhering to the collaborative plan of care (see the Concept Map for liver failure due to cirrhosis on p. 1301).

Interventions. Fluid accumulations are minimal during the early stages of ascites. Therefore interventions are aimed at preventing the accumulation of additional fluid and moving the existing fluid collection. Nonsurgical treatment measures are used to treat ascites in most cases.

Supportive measures to control abdominal ascites include nutrition therapy, drug therapy, paracentesis, and respiratory support. The patient's fluid and electrolyte status is also carefully monitored. If the patient is jaundiced, he or she will likely scratch the skin because the excess bilirubin products cause irritation and pruritus (itching).

! NURSING SAFETY PRIORITY

Action Alert

For skin irritation and pruritus associated with jaundice, teach the patient to use cool rather than warm water on the skin and to not use an excessive amount of soap. Teach unlicensed assistive personnel to use lotion to soothe the skin. Assess for open skin areas from scratching, which could become infected.

Nutrition Therapy. The health care provider usually places the patient with abdominal ascites on a low-sodium diet as an initial means of controlling fluid accumulation in the abdominal cavity. The amount of daily sodium (Na^+) intake restriction varies, but a 1- to 2-gram (2000 mg) Na^+ restriction may be tried first. In collaboration with the dietitian, explain the purpose of the restriction and advise the patient and family to read the sodium content labels on all food and beverages. Table salt should be completely excluded. Low-sodium diets may be distasteful, so suggest alternative flavoring additives such as lemon, vinegar, parsley, oregano, and pepper. Remind the patient that seasoned and salty food is an acquired taste; in time, he or she will become used to the decrease in dietary sodium.

In general, patients with late-stage cirrhosis are malnourished and have multiple dietary deficiencies. Vitamin supplements such as thiamine (due to alcohol withdrawal), folate, and multivitamin preparations are typically added to the IV fluids because the liver cannot store vitamins. For patients with biliary cirrhosis, bile may not be available for fat-soluble vitamin transport and absorption. Oral vitamins are prescribed when IV fluid administration is discontinued.

Drug Therapy. The health care provider usually prescribes a *diuretic* to reduce fluid accumulation and to prevent cardiac and respiratory problems. Monitor the effect of diuretic therapy by weighing the patient daily, measuring daily intake and output, measuring abdominal girth, documenting peripheral edema, and assessing electrolyte levels. Serious electrolyte imbalances, such as hypokalemia (decreased potassium) and hyponatremia (decreased sodium), may occur with loop diuretic therapy. Depending on the diuretic selected, the provider may prescribe an oral or IV potassium supplement. Some clinicians prescribe a combination of furosemide (Lasix) and spironolactone (Aldactone) as a combination diuretic therapy for the treatment of ascites. Because these drugs work differently, they are used for maintenance of sodium and potassium balance. For example, furosemide causes potassium loss, whereas spironolactone conserves it in the body.

CHART 61-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

The Patient with Paracentesis

- Explain the procedure, and answer patient questions.
- Obtain vital signs, including weight.
- *Ask the patient to void before the procedure to prevent injury to the bladder!*
- Position the patient in bed with the head of the bed elevated.
- Monitor vital signs per protocol or physician's request.
- Measure the drainage, and record accurately.
- Describe the collected fluid.
- Label and send the fluid for laboratory analysis; document in the patient record that specimens were sent.
- After the physician removes the catheter, apply a dressing to the site; assess for leakage.
- Maintain bedrest per protocol.
- Weigh the patient after the paracentesis; document in the patient record weight both before and after paracentesis.

All patients with ascites have the potential to develop **spontaneous bacterial peritonitis (SBP)** from bacteria in the collected ascitic fluid. In some patients, mild symptoms such as low-grade fever and loss of appetite occur. In others, there may be abdominal pain, fever, and change in mental status. When performing an abdominal assessment, listen for bowel sounds and assess for abdominal wall rigidity. Send a sample of ascitic fluid for a culture before drug therapy begins. Quinolones such as norfloxacin (Noroxin) are the drugs of choice for SBP. If the patient is allergic to this class of *antibiotics*, combination antibiotics like trimethoprim-sulfamethoxazole (Bactrim) are given.

Paracentesis. For some patients, abdominal **paracentesis** may be needed. Nursing implications associated with this procedure are described in [Chart 61-1](#). The procedure is performed at the bedside, in an interventional radiology department, or in an ambulatory care setting. The physician inserts a trocar catheter or drain into the abdomen to remove the ascitic fluid from the peritoneal cavity. This procedure is done using ultrasound for added safety. In some situations, a short-term ascites drain catheter may be placed while the patient is awaiting surgical intervention, or new tunneled ascites drains (e.g., PleurX drains) can allow a patient or family caregiver to drain ascites at home.

If SBP is suspected, a sample of fluid is withdrawn and sent for cell count and culture. If the patient has symptoms of infection, the physician may prescribe antibiotics while awaiting the culture results.

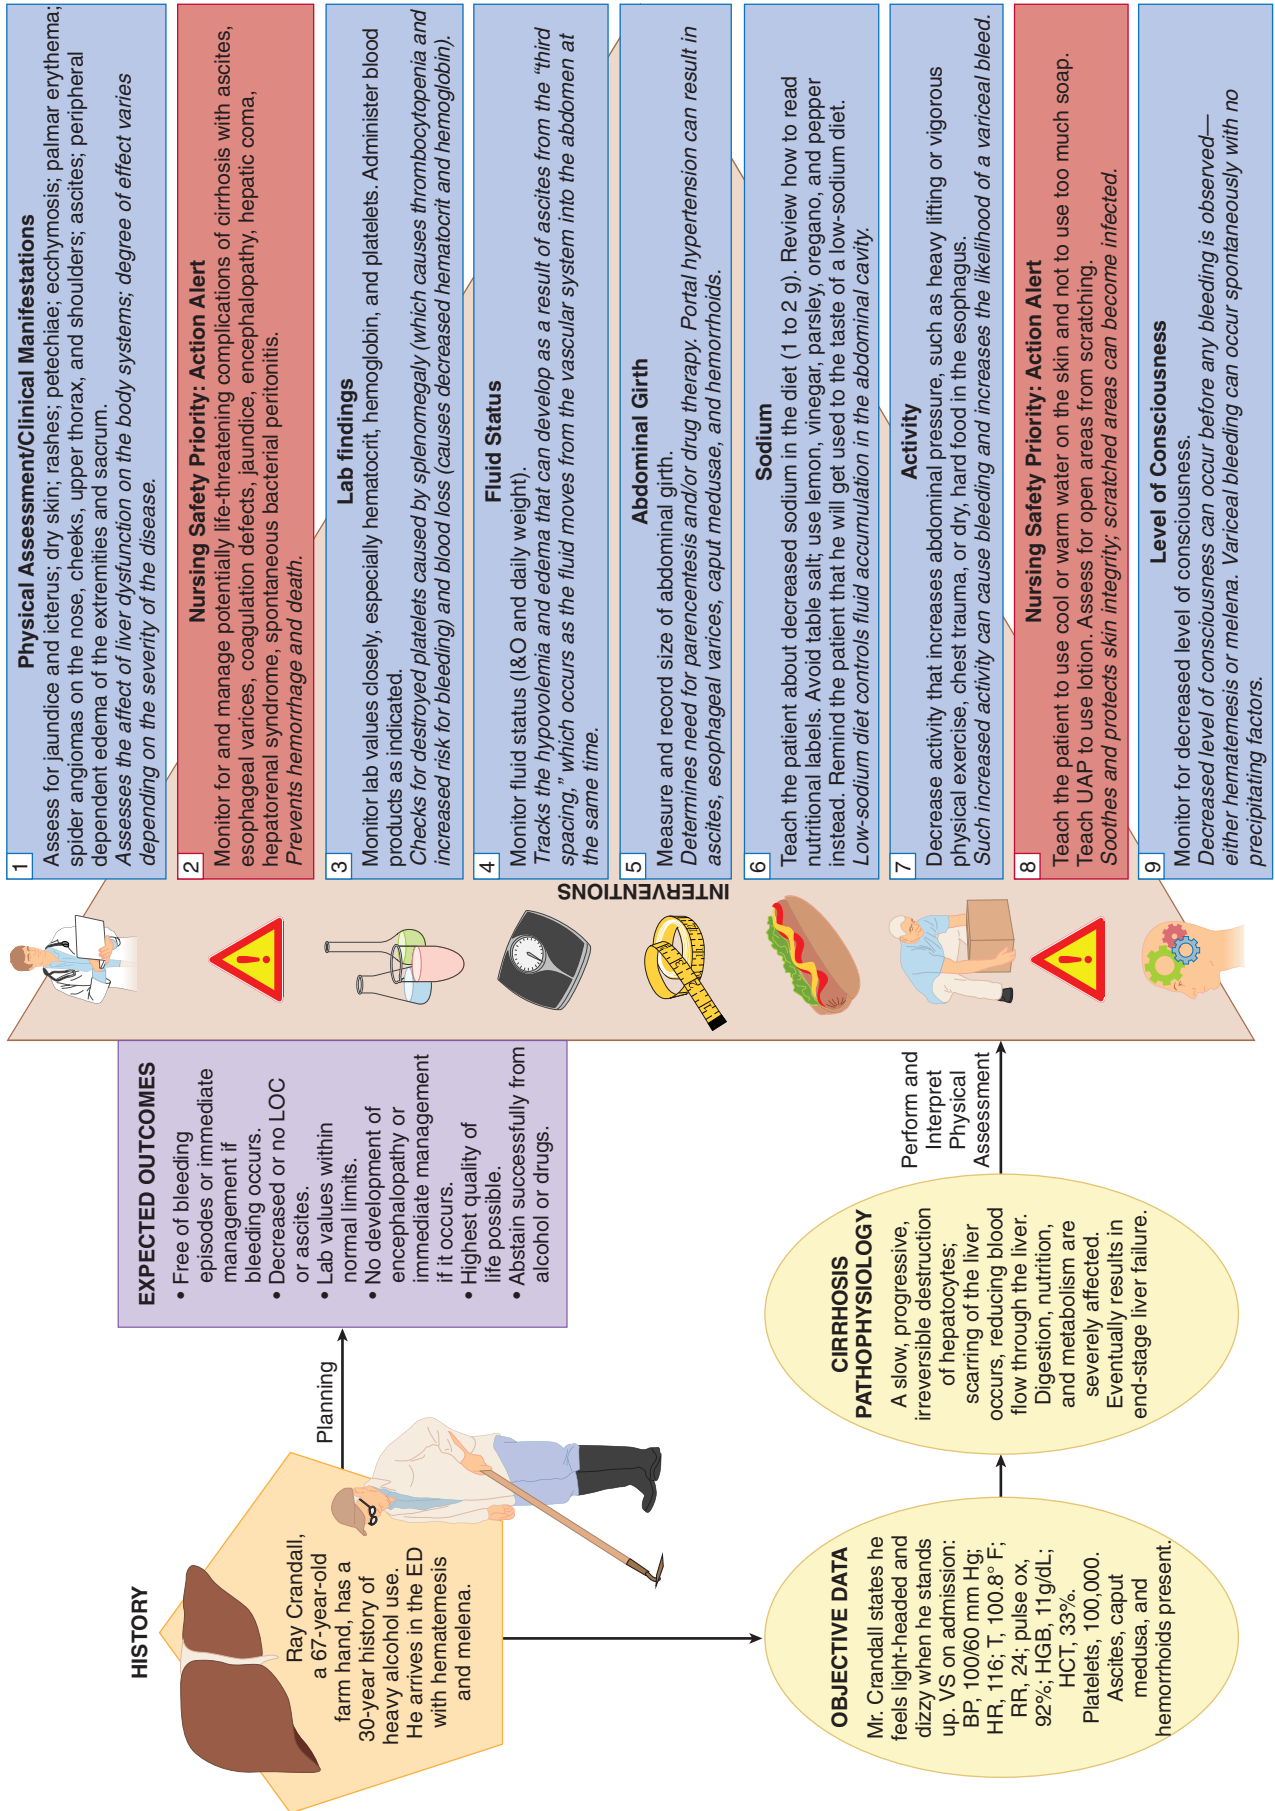

Respiratory Support. Excessive ascitic fluid volume may cause the patient to have respiratory problems. He or she may develop **hepatopulmonary syndrome**. Dyspnea develops as a

! NURSING SAFETY PRIORITY

Action Alert

For the patient with hepatopulmonary syndrome, monitor his or her oxygen saturation with pulse oximetry. If needed, apply oxygen therapy to ease breathing. Elevate the head of the bed to at least 30 degrees or as high as the patient wants to improve breathing. This position, with his or her feet elevated to decrease dependent ankle edema, often relieves dyspnea. Weigh the patient daily, or delegate and supervise this activity.

Concept Map: Cirrhosis

result of increased intra-abdominal pressure, which limits thoracic expansion and diaphragmatic excursion. Auscultate lungs every 4 to 8 hours for crackles that could indicate pulmonary complications, depending on the patient's overall condition.

Fluid and electrolyte imbalances are common as a result of the disease or treatment. Laboratory tests, such as blood urea nitrogen (BUN), serum protein, hematocrit, and electrolytes, help determine fluid and electrolyte status. An elevated BUN, decreased serum proteins, and increased hematocrit may indicate hypovolemia.

If medical management fails to control ascites, the physician may choose to divert ascites into the venous system by creating a shunt. Patients with ascites are poor surgical risks. The transjugular intrahepatic portal-systemic shunt (TIPS) is a nonsurgical procedure that is used to control long-term ascites and to reduce variceal bleeding. This procedure is described in the discussion of Interventions in the Preventing or Managing Hemorrhage section that follows.

Preventing or Managing Hemorrhage

Planning: Expected Outcomes. The patient is expected to be free of bleeding episodes. However, if he or she has a hemorrhage, it is expected to be controlled by prompt, evidence-based interdisciplinary interventions. Esophageal variceal bleeds are the most common type of upper GI bleeding.

Interventions. All patients with cirrhosis should be screened for esophageal varices by endoscopy to detect them early *before they bleed*. If patients have varices, they are placed on preventive therapy. If acute bleeding occurs, early interventions are used to manage it. *Because massive esophageal bleeding can cause rapid blood loss, emergency interventions are needed.*

Drug Therapy. The role of early drug therapy is to *prevent* bleeding and infection in patients who have varices. A non-selective *beta-blocking agent* such as propranolol (Inderal) is usually prescribed to prevent bleeding. By decreasing heart rate and the hepatic venous pressure gradient, the chance of bleeding may be reduced.

Up to 20% of cirrhotic patients who are admitted to the hospital due to upper GI bleeding have bacterial infections, and even more patients develop health care–associated infections, usually urinary tract infections or pneumonia. Infection is one of the most common indicators that patients will have an acute variceal bleed (AVB). Therefore cirrhotic patients with GI bleeding should receive *antibiotics* on admission to the hospital. The recommended antibiotic is oral norfloxacin (Noroxin) or ciprofloxacin (Cipro). IV ceftriaxone (Cefizox) may be more effective for some patients (Augustin et al., 2010).

If bleeding occurs, the health care team intervenes quickly to control it by combining vasoactive drugs with endoscopic

therapies. *Vasoactive drugs* reduce portal pressure. Research shows that IV terlipressin (a synthetic vasopressin) and natural somatostatin are the most effective (Augustin et al., 2010). Octreotide, a synthetic somatostatin, and vasopressin may be used as a last resort because they have multiple side effects.

Endoscopic Therapies. Endoscopic therapies include ligation of the bleeding veins or sclerotherapy. Both procedures have been very effective in controlling bleeding and improving patient survival rates. Esophageal varices may be managed with **endoscopic variceal ligation (EVL) (banding)**. This procedure involves the application of small “O” bands around the base of the varices to decrease the blood supply to the varices. The patient is unaware of the bands, and they cause no discomfort.

Endoscopic sclerotherapy (EST), also called injection **sclerotherapy**, may be done to stop bleeding. The varices are injected with a sclerosing agent via a catheter. This procedure is associated with complications such as mucosal ulceration, which could result in further bleeding.

Rescue Therapies. If rebleeding occurs, rescue therapies are used. These procedures include a second endoscopic procedure, balloon tamponade and esophageal stents, and shunting procedures. Short-term esophagogastric balloon tamponade using a Minnesota or Sengstaken-Blakemore tube with esophageal stents is a very effective way to control bleeding. However, the procedure can cause potentially life-threatening complications, such as aspiration, asphyxia, and esophageal perforation (Augustin et al., 2010). Similar to a nasogastric tube, the tube is placed through the nose and into the stomach. An attached balloon is inflated to apply pressure to the bleeding variceal area. Before this tamponade, the patient is usually intubated and placed on a mechanical ventilator to protect the airway (Kelso, 2008). This therapy is used if the patient is not able to have a second endoscopy or TIPS procedure.

Transjugular Intrahepatic Portal-Systemic Shunt. The transjugular intrahepatic portal-systemic shunt (TIPS) is a nonsurgical procedure performed in interventional radiology departments. This procedure is used for patients who have not responded to other modalities for hemorrhage or long-term ascites. If time permits, patients have a Doppler ultrasound to assess vein anatomy and patency. The patient receives heavy IV sedation or general anesthesia for this procedure. The radiologist places a large sheath through the jugular vein. A needle is guided through the sheath and pushed through the liver into the portal vein. A balloon enlarges this tract, and a stent keeps it open. Most patients also have a Doppler ultrasound study of the liver after the TIPS procedure to record the blood flow through the shunt.

Serious complications of TIPS are not common. Patients are usually discharged in 1 or 2 days and are followed up with ultrasounds for the first year after the shunt is placed. Some of them require re-opening at least once during the first year as an ambulatory care procedure.

Other Interventions. Depending on the procedure done to control esophageal bleeding, patients usually have a nasogastric tube (NGT) inserted to detect any new bleeding episodes. Patients often receive packed red blood cells, fresh frozen plasma, dextran, albumin, and platelets through large-bore IV catheters.

Monitor vital signs every hour, and check coagulation studies, including prothrombin time (PT), partial

NURSING SAFETY PRIORITY

Drug Alert

Both terlipressin and somatostatin can cause ischemic complications and serious dysrhythmias. Observe patients for significant changes in cardiac rhythm, apical pulse rate, and blood pressure. Monitor for clinical manifestations of a stroke, and report any changes immediately to the physician. The patient is managed in the critical care setting.

thromboplastin time (PTT), platelet count, and international normalized ratio (INR).

Additional interventions for upper GI bleeding are discussed in [Chapter 58](#). All patients with GI bleeding from esophageal varices should be considered for liver transplantation to prevent further bleeding episodes.

Preventing or Managing Hepatic Encephalopathy

Planning: Expected Outcomes. The patient is expected to be free of encephalopathy. However, if it occurs, it is expected that the interdisciplinary team will intervene early to prevent further health problems or death.

Interventions. The mechanisms that cause hepatic encephalopathy are not completely clear, but ammonia probably plays a significant role. The poorly functioning liver cannot convert ammonia and other by-products of protein metabolism to a less toxic form. They are carried by the circulatory system to the brain, where they affect cerebral function. The aim of management is to stop or slow this process.

Because ammonia is formed in the GI tract by the action of bacteria on protein, nonsurgical treatment measures to decrease ammonia production include dietary limitations and drug therapy to reduce bacterial breakdown. Collaborate with the dietitian, pharmacist, and physician to plan and implement these interventions.

Nutrition Therapy. Patients with cirrhosis have increased nutritional requirements—high-carbohydrate, moderate-fat, and high-protein foods. However, the diet may be changed for those who have elevated serum ammonia levels with signs of encephalopathy. Patients should have a moderate amount of protein and fat foods and simple carbohydrates. Strict protein restrictions are not required because patients need protein for healing. In collaboration with the dietitian, be sure to include family members or significant others in nutrition counseling. The patient is often weak and unable to remember complicated guidelines. Brief, simple directions regarding dietary dos and don'ts are recommended. Keep in mind any financial, cultural, or personal preferences when discussing food choices, including the patient's food allergies.

When a patient with cirrhosis has GI bleeding, it can result in the formation of increased amounts of ammonia as intestinal bacteria attempt to metabolize the blood cells. GI bleeding may lead to hepatic coma.

Drug Therapy. Drugs are used sparingly because they are difficult for the failing liver to metabolize. In particular, opioid analgesics, sedatives, and barbiturates should be restricted, especially for the patient with a history of encephalopathy.

Several types of drugs, however, may eliminate or reduce ammonia levels in the body. These include lactulose (e.g., Evalose, Heptalac) or lactitol and nonabsorbable antibiotics. However, these drugs are often not effective.

The health care provider may prescribe *lactulose* (or lactitol) to promote the excretion of ammonia in the stool. This drug is a viscous, sticky, sweet-tasting liquid that is given either orally or by NG tube. The purpose is to obtain a laxative effect. Cleansing the bowels may rid the intestinal tract of the toxins that contribute to encephalopathy. It works by increasing osmotic pressure to draw fluid into the colon and prevents absorption of ammonia in the colon. The drug may be prescribed to the patient who has manifested signs of

encephalopathy, regardless of the stage. The desired effect of the drug is production of two or three soft stools per day and a decrease in patient confusion caused by this complication.

Observe for response to lactulose. The patient may report intestinal bloating and cramping. Serum ammonia levels may be monitored but do not always correlate with symptoms. Hypokalemia and dehydration may result from excessive stools. Remind unlicensed nursing personnel to help the patient with skin care if needed to prevent breakdown caused by excessive stools.

Several *nonabsorbable antibiotics* may be given if lactulose does not help the patient meet the desired outcome or if he or she cannot tolerate the drug. These drugs should not be given together. Older adults can become weak and dehydrated from having multiple stools. Neomycin sulfate (Mycifradin), a broad-spectrum antibiotic, may be given to act as an intestinal antiseptic. It destroys the normal flora in the bowel, diminishing protein breakdown and decreasing the rate of ammonia production. Maintenance doses of neomycin are given orally but may also be administered as a retention enema. Long-term use has the potential for kidney toxicity and therefore is not commonly used. It cannot be used for patients with existing kidney disease.

Metronidazole (Flagyl, Novonidazole ) is another broad-spectrum antibiotic with similar action to neomycin, but it has less potential for renal toxicity. However, it should also be used for a short period of time and is therefore not commonly used. Rifaximin (Xifaxan) seems to be the most effective and safest for long-term use.

Frequently assess for changes in level of consciousness and orientation. Check for asterixis (liver flap) and fetor hepaticus (liver breath). These signs suggest worsening encephalopathy. Thiamine supplements and benzodiazepines may be needed if the patient is at risk for alcohol withdrawal.

Community-Based Care

If the patient with late-stage cirrhosis survives life-threatening complications, he or she is usually discharged to the home or to a long-term care facility after treatment measures have managed the acute medical problems. A home care referral may be needed if the patient is discharged to the home. These chronically ill patients are often readmitted multiple times, and community-based care is aimed at preventing rehospitalization. Patients with end-stage disease may benefit from hospice care. Collaborate with the case manager (CM) or other discharge planner to coordinate interdisciplinary continuing care.

Home Care Management

In collaboration with the patient, family, and CM, assess physical adaptations needed to prepare the patient's home for recovery. Referrals for physical therapy, nutrition therapy, and transportation for physician and laboratory follow-up may be needed. The patient's rest area needs to be close to a bathroom because diuretic and/or lactulose therapy increases the frequency of urination and stools. If the patient has difficulty reaching the toilet, additional equipment (e.g., bedside commode) is necessary. Special, adult-size incontinence pads or briefs may be helpful if the patient has an altered mental status and has incontinence. If the patient has shortness of breath from massive ascites, elevating the head of the bed and maintaining the patient in a semi-Fowler's to high Fowler's

CHART 61-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Cirrhosis

Nutrition Therapy

- Consume a diet that adheres to the guidelines set by your physician, nurse, or dietitian.
- If you have excessive fluid in your abdomen, follow the low-sodium diet prescribed for you.
- Eat small, frequent meals that are nutritionally well balanced.
- Include in your diet daily supplemental liquids (e.g., Ensure or Ensure Plus) and a multivitamin.

Drug Therapy

- Take the diuretics or preventive beta blocker prescribed for you. If you experience muscle weakness, irregular heartbeat, or lightheadedness, contact your health care provider right away.
- Take the medication prescribed for you that helps prevent gastrointestinal bleeding.
- Take the lactulose syrup as prescribed to maintain two or three bowel movements every day.
- Do *not* take any other medication (prescribed or over the counter) unless specifically prescribed by your health care provider.

Alcohol Abstinence

- Do not consume any alcohol.
- Seek support services for help if needed.

position may help alleviate respiratory distress. Alternatively, a reclining chair with a foot elevator may be used.

Teaching for Self-Management

The patient is discharged to the home setting with an individualized teaching plan (Chart 61-2) that includes nutrition therapy, drug therapy, and alcohol abstinence, if needed. The patient who has a tunneled ascites drain (e.g., PleurX drain) will need teaching about how to access the drain and remove excess fluid. If needed, family teaching is also required.

In collaboration with the dietitian and in keeping with the patient's financial, cultural, and personal food preferences, provide information on eating a well-balanced diet. The patient with encephalopathy often finds that small, frequent meals are best tolerated. If the patient's nutritional intake or albumin/pre-albumin is decreased after discharge, multivitamin supplements and supplemental liquid feedings (e.g., Ensure, Boost) are usually needed. Teach patients to avoid excessive vitamins and minerals that can be toxic to the liver, such as fat-soluble vitamins, excessive iron supplements, and niacin. Remind patients to check labels for these substances before taking any vitamin supplement.

The patient is often discharged while receiving diuretics. Provide instructions regarding the health care provider's prescription for the diuretic. Teach about side effects of therapy, such as hypokalemia. The patient may need to take a potassium supplement if he or she is taking a diuretic that is not potassium-sparing.

If the patient has had problems with bleeding from gastric ulcers, the provider may prescribe an H₂-receptor antagonist agent or proton pump inhibitor to reduce acid reflux (see Chapter 57). Patients who have had episodes of spontaneous bacterial peritonitis (SBP) may be on a daily maintenance antibiotic. Because some patients may have alienated relatives

over the years because of substance abuse, it may be necessary to help them identify a friend, neighbor, or person in their recovery group for support.

Teach family members about how to recognize signs of encephalopathy and to contact the health care provider if these signs develop. Reinforce that constipation, bleeding, and infections can increase the risk for encephalopathy.

Advise the patient to avoid all over-the-counter drugs, especially NSAIDs and hepatic toxic herbs, vitamins, and minerals. Reinforce the need to keep appointments for follow-up medical care. Remind the patient and family to notify the physician immediately if any GI bleeding (overt bleeding or melena) is noted so that re-evaluation can begin quickly.

! NURSING SAFETY PRIORITY

Action Alert

One of the most important aspects of ongoing care for the patient with cirrhosis is to stress the need to avoid alcohol and illicit drugs. By avoiding alcohol and drugs, the patient may:

- Prevent further fibrosis of the liver from scarring
- Allow the liver to heal and regenerate
- Prevent gastric and esophageal irritation
- Reduce the incidence of bleeding
- Prevent other life-threatening complications

Health Care Resources

The patient with chronic cirrhosis may require a home care nurse for several visits after hospital discharge. The home care nurse can monitor the effectiveness of treatment in controlling ascites. The encephalopathic patient may need to be monitored for adherence to drug therapy and alcohol abstinence, if appropriate. Individual and group therapy sessions may be arranged to assist patients in dealing with alcohol abstinence if they are too ill to attend a formal treatment program. If needed, refer the patient and family to self-help groups, such as Alcoholics Anonymous and Al-Anon.

The patient with cirrhosis may also desire spiritual support. Finances are frequently a problem for the chronically ill patient and family; social support and community services need to be identified. The American Liver Foundation (www.liverfoundation.org) and American Gastroenterological Association (www.gastro.org) are excellent sources for more information about liver disease.

For patients who are not candidates for liver transplantation, address end-of-life issues. Discuss options such as hospice care with patients and their families. Be aware that they will go through a grieving process and will perhaps be in denial or very angry (see Chapter 9).

EVALUATION: OUTCOMES

Evaluate the care of the patient with cirrhosis based on the identified priority patient problems. The expected outcomes include that the patient will:

- Have a decrease in or have no ascites
- Have electrolytes within normal limits (WNL)
- Not have hemorrhage or will be managed immediately if bleeding occurs
- Not develop encephalopathy or will be managed immediately if it occurs

- Have the highest quality of life possible
- Successfully abstain from alcohol or drugs (if disease is caused by these substances)

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

The nurse is providing discharge teaching for the client with advanced liver disease. Which statement by the client indicates a need for further teaching?

- A. "I don't need hospice because I'm only 55 years old."
- B. "I'll ask my wife to contact our local support group."
- C. "I plan to talk with the pastor at our church."
- D. "My wife and I plan to get Meals on Wheels."

HEPATITIS

Pathophysiology

Hepatitis is the widespread inflammation of liver cells. **Viral hepatitis** is the most common type and can be either acute or chronic. Less common types of hepatitis are caused by chemicals, drugs, and some herbs. This section discusses hepatitis caused by a virus. **Viral hepatitis** results from an infection caused by one of five major categories of viruses:

- Hepatitis A virus (HAV)
- Hepatitis B virus (HBV)
- Hepatitis C virus (HCV)
- Hepatitis D virus (HDV)
- Hepatitis E virus (HEV)

Some cases of viral hepatitis are not any of these viruses. These patients have non-A-E hepatitis.

Liver injury with inflammation can develop after exposure to a number of drugs and chemicals by inhalation, ingestion, or parenteral (IV) administration. **Toxic and drug-induced hepatitis** can result from exposure to hepatotoxins (e.g., industrial toxins, alcohol, and drugs). Hepatitis may also occur as a secondary infection during the course of infections with other viruses, such as Epstein-Barr, herpes simplex, varicella-zoster, and cytomegalovirus.

After the liver has been exposed to any causative agent (e.g., a virus), it becomes enlarged and congested with inflammatory cells, lymphocytes, and fluid, resulting in right upper quadrant pain and discomfort. As the disease progresses, the liver's normal lobular pattern becomes distorted as a result of widespread inflammation, necrosis, and hepatocellular regeneration. This distortion increases pressure within the portal circulation, interfering with the blood flow into the hepatic lobules. Edema of the liver's bile channels results in obstructive **jaundice** (yellowing of the skin).

Classification of Hepatitis and Etiologies

The five major types of acute viral hepatitis vary by mode of transmission, manner of onset, and incubation periods. Hepatitis cases must be reported to the local public health department, which then notifies the Centers for Disease Control and Prevention (CDC).

Hepatitis A. The causative agent of **hepatitis A**, hepatitis A virus (HAV), is a ribonucleic acid (RNA) virus of the enterovirus family. *It is a hardy virus and survives on human hands.* The virus is resistant to detergents and acids but is destroyed by chlorine (bleach) and extremely high temperatures.

TABLE 61-5 EXAMPLES OF EXTRAHEPATIC MANIFESTATIONS OF HEPATITIS A

Neurologic Findings • Post-viral encephalitis • Guillain-Barré syndrome • Transverse myelitis	Renal Findings • Acute tubular necrosis (ATN) • Nephrotic syndrome
Hematologic Findings • Aplastic anemia • Autoimmune hemolysis • Anemia	Gastrointestinal Findings • Pancreatitis • Acalculous cholecystitis
	Other Findings • Reactive arthritis • Cutaneous vasculitis

HAV usually has a mild course similar to that of a typical flu-like infection and often goes unrecognized. It is spread most often by the fecal-oral route by fecal contamination either from person-to-person contact (e.g., oral-anal sexual activity) or by consuming contaminated food or water. Common sources of infection include shellfish caught in contaminated water and food contaminated by food handlers infected with HAV. The incubation period of hepatitis A is usually 15 to 50 days, with a peak of 25 to 30 days. The disease is usually not life threatening, but its course may be more severe in people older than 40 years and those with pre-existing liver disease such as hepatitis C.

In a small percentage of HAV cases, severe illness with extrahepatic manifestations can occur (Table 61-5). Advanced age and conditions such as chronic liver disease may cause widespread damage that requires a liver transplant. In some cases, death may occur from HAV.

The incidence of hepatitis A is particularly high in non-affluent countries in which sanitation is poor. However, over 35,000 cases are diagnosed each year in the United States (American Liver Foundation, 2010). Some adults have hepatitis A and do not know it. The course is similar to that of a GI illness, and the disease and recovery are usually uneventful.

Hepatitis B. The **hepatitis B** virus (HBV) is not transmitted like HAV. It is a double-shelled particle containing DNA composed of a core antigen (HBcAg), a surface antigen (HBsAg), and another antigen found within the core (HBeAg) that circulates in the blood. HBV may be spread through these common modes of transmission (Lok & McMahon, 2009):

- Unprotected sexual intercourse with an infected partner
- Sharing needles
- Accidental needle sticks or injuries from sharp instruments primarily in health care workers (low incidence)
- Blood transfusions (that have not been screened for the virus, before 1992)
- Hemodialysis
- Maternal-fetal route (more common in Asia)
- Close person-to-person contact by open cuts and sores

In addition, patients who are immunosuppressed either by disease or drug therapy are more likely to develop hepatitis B.

The clinical course of hepatitis B may be varied. Symptoms usually occur within 25 to 180 days of exposure and include:

- Anorexia, nausea, and vomiting
- Fever
- Fatigue
- Right upper quadrant pain
- Dark urine with light stool
- Joint pain
- Jaundice

Blood tests confirm the disease, although many people with hepatitis B have no symptoms.

Most adults who get hepatitis B recover, clear the virus from their body, and develop immunity. However, a small percentage of people do not develop immunity and become carriers. **Hepatitis carriers** can infect others even though they are not sick and have no obvious signs of hepatitis B. Chronic carriers are at high risk for cirrhosis and liver cancer. Because of the high number of newcomers from endemic areas, the incidence of hepatitis B has increased in the United States.

Hepatitis C. The causative virus of **hepatitis C** (HCV) is an enveloped, single-stranded RNA virus. Transmission is blood to blood. The rate of sexual transmission is very low in a single-couple relationship but increases with multiple sex partners.

HCV is spread most commonly by:

- Illicit IV drug needle sharing (highest incidence)
- Blood, blood products, or organ transplants received before 1992
- Needle stick injury with HCV-contaminated blood (health care workers at high risk)
- Unsanitary tattoo equipment
- Sharing of intranasal cocaine paraphernalia

The disease is **not** transmitted by casual contact or by intimate household contact. However, those infected are advised not to share razors, toothbrushes, or pierced earrings because microscopic blood may be on these items.

The average incubation period is 7 weeks. Acute infection and illness are not common. Most people are completely unaware that they have been infected. They are asymptomatic and not diagnosed until many months or years after the initial exposure when an abnormality is detected during a routine laboratory evaluation or when liver problems occur. Unlike with hepatitis B, most people infected with hepatitis C do not clear the virus and a chronic infection develops.

HCV usually does its damage over decades by causing a chronic inflammation in the liver that eventually causes the liver cells to scar. This scarring may progress to cirrhosis. Alcohol use increases the progression and severity of cirrhosis.

Hepatitis C–induced cirrhosis is the leading indication for liver transplantation in the United States. Unfortunately, the newly transplanted liver often becomes re-infected with the virus.

Hepatitis D. **Hepatitis D** (delta hepatitis, or HDV) is caused by a defective RNA virus that needs the helper function of HBV. It occurs only with HBV to cause viral replication. This usually develops into chronic HDV. The incubation period is about 14 to 56 days. As with HBV, the disease is transmitted primarily by parenteral routes, especially patients who are IV drug abusers. Having sexual contact with a person with HDV is also a high risk factor.

Hepatitis E. The **hepatitis E** virus (HEV) causes a water-borne infection associated with epidemics in the Indian

subcontinent, Asia, Africa, the Middle East, Mexico, and Central and South America. Many large outbreaks have occurred after heavy rains and flooding. Like hepatitis A, HEV is caused by fecal contamination of food and water.

In the United States, hepatitis E has been found only in international travelers. It is transmitted via the fecal-oral route, and the clinical course resembles that of hepatitis A. HEV has an incubation period of 15 to 64 days. There is no evidence at this time of a chronic form of HEV. The disease tends to be self-limiting and resolves on its own.

Complications of Hepatitis

Failure of the liver cells to regenerate, with progression of the necrotic process, results in a severe acute and often fatal form of hepatitis known as **fulminant hepatitis**. Hepatitis is considered to be chronic when liver inflammation lasts longer than 6 months. **Chronic hepatitis** usually occurs as a result of hepatitis B or hepatitis C. Superimposed infection with hepatitis D (HDV) in patients with chronic HBV may also result in chronic hepatitis. Chronic hepatitis can lead to cirrhosis and liver cancer. Many patients have multiple infections, especially the combination of HBV with either HCV, HDV, or HIV infections.

Incidence/Prevalence

The incidence of hepatitis A and hepatitis B is declining as a result of CDC recommendations for vaccination. However, hepatitis B and hepatitis C are a concern because of their association with cirrhosis and liver cancer. Although exact numbers are not known, it is estimated that about 200 million people worldwide have the hepatitis C virus (HCV), making this type of hepatitis the most common type. Currently there is no vaccine for HCV. Therefore it is expected that the cases of HCV will rise over the next several decades as a result of increasing illicit drug use. This increase will require a major increase in transplantations and lead to many more deaths (Lok & McMahon, 2009).

Health Promotion and Maintenance

Hepatitis vaccines for infants, children, and adolescents have helped decrease the incidence of hepatitis A and hepatitis B. Some adults are also advised to receive these immunizations.

Measures for preventing hepatitis A (HAV) in adults include:

- Proper handwashing, especially after handling shellfish
- Avoiding contaminated food or water (including tap water in countries with high incidence)
- Receiving immunoglobulin within 14 days if exposed to the virus
- Receiving the HAV vaccine before traveling to areas where the disease is common (e.g., Mexico, Caribbean)
- Receiving the vaccine if living or working in enclosed areas with others, such as college dormitories, correctional institutions, day-care centers, and long-term care facilities

Several HAV vaccines are available (e.g., Havrix and Vaqta). Both of these vaccines are made of inactivated hepatitis A virus and are given in the deltoid muscle.

Several vaccines can also provide protection against hepatitis B (HBV) infection (e.g., Engerix-B and Recombivax-HB). Twinrix is a combination HAV and HBV vaccine that is also available for adults. Examples of groups for whom

immunization against HBV should be used include (Lok & McMahon, 2009):

- People who have sexual intercourse with more than one partner
- People with sexually transmitted disease (STD) or a history of STD
- Men having sex with men (MSM)
- People with any chronic liver disease (such as hepatitis C or cirrhosis)
- Patients with human immune deficiency virus (HIV) infection
- People who are exposed to blood or body fluids in the workplace, including health care workers, firefighters, and police
- People in correctional facilities
- Patients needing immunosuppressant drugs
- Family members, household members, and sexual contacts of people with HBV infection

Additional measures to prevent viral hepatitis for health care workers and others in contact with infected patients are listed in [Charts 61-3 and 61-4](#).

CHART 61-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Prevention of Viral Hepatitis in Health Care Workers

- Use Standard Precautions to prevent the transmission of disease between patients or between patients and health care staff (see [Chapter 25](#)).
- Eliminate needles and other sharp instruments by substituting needleless systems. (Needle sticks are the major source of hepatitis B transmission in health care workers.)
- Take the hepatitis B vaccine (e.g., Recombivax HB), which is given in a series of three injections. This vaccine also prevents hepatitis D by preventing HBV.
- For postexposure prevention of hepatitis A, seek medical attention immediately for immunoglobulin (Ig) administration.
- Report all cases of hepatitis to the local health department.

CHART 61-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Health Practices to Prevent Viral Hepatitis

- Maintain adequate sanitation and personal hygiene. Wash your hands before eating and after using the toilet.
- Drink water treated by a water purification system.
- If traveling in underdeveloped or nonindustrialized countries, drink only bottled water. Avoid food washed or prepared with tap water, such as raw vegetables, fruits, and soups. Avoid ice.
- Use adequate sanitation practices to prevent the spread of the disease among family members.
- Do not share bed linens, towels, eating utensils, or drinking glasses.
- Do not share needles for injection, body piercing, or tattooing.
- Do not share razors, nail clippers, toothbrushes, or Waterpiks.
- Use a condom during sexual intercourse, or abstain from this activity.
- Cover cuts or sores with bandages.
- If ever infected with hepatitis, never donate blood, body organs, or other body tissue.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Begin by asking the patient whether he or she has had known exposure to a person with hepatitis. For the patient who presents with few or no symptoms of liver disease but has abnormal laboratory tests (e.g., elevated alanine aminotransferase [ALT] or aspartate aminotransferase [AST] level), the history may need to include additional questions regarding risk factors such as:

- Exposure to either inhaled or ingested chemical
- Use of herbal supplements
- Use of any new prescribed drug or over-the-counter (OTC) medication
- Recent ingestion of shellfish
- Exposure to a possibly contaminated water source
- Travel to another country
- Sexual activities with men, women, or both, and whether it was protected or unprotected
- Illicit drug use, IV or intranasal
- For health care workers, recent needle stick exposure
- Body piercing or tattooing
- Close living accommodations (e.g., military barracks, correctional institutions, overcrowded dormitories, long-term facilities, day-care centers) or employment in any such setting
- Blood or blood products or organ transplants received before 1992
- Military service
- Place of birth (United States or other country) and parents' place of birth
- History of alcohol use (how many drinks each day or week)
- Human immune deficiency virus (HIV)

Physical Assessment/Clinical Manifestations

Assess whether the patient has:

- Abdominal pain
- Changes in skin or sclera (icterus)
- **Arthralgia** (joint pain) or **myalgia** (muscle pain)
- Diarrhea/constipation
- Changes in color of urine or stool
- Fever
- Lethargy
- Malaise
- Nausea/vomiting
- Pruritus (itching)

Lightly palpate the right upper abdominal quadrant to assess for liver tenderness. The patient may report right upper quadrant pain with jarring movements. Inspect the skin, sclerae, and mucous membranes for jaundice. He or she may present for medical treatment only after jaundice appears, believing that other vague symptoms are related to an influenza-like syndrome.

Jaundice in hepatitis results from intrahepatic obstruction and is caused by edema of the liver's bile channels. Dark urine and clay-colored stools are often reported by the patient. If possible, obtain a urine and stool specimen for visual inspection and laboratory analysis. The patient may also have skin abrasions from pruritus (itching).

Psychosocial Assessment

Viral hepatitis has various presentations, but for most infected people the initial course is mild with few or no symptoms. The long-term complications of fibrosis and cirrhosis cause the more serious problem. This is especially true for patients who have chronic HBV and HCV infection.

Emotional problems for affected patients may center on their feeling sick and fatigued. General malaise, inactivity, and vague symptoms contribute to depression. Some patients often feel guilty and are remorseful about decisions made that caused the disease. These feelings are most likely to occur when the source of infection is from drug abuse. Family members may be angry that the patient caused the disease.

Infectious diseases such as hepatitis continue to have a social stigma. The patient may feel embarrassed by the precautions that are imposed in the hospital and continue to be necessary at home. This embarrassment may cause the patient to limit social interactions. Patients may be afraid that they will spread the virus to family and friends.

Family members are sometimes afraid of getting the disease and may distance themselves from the patient. Allow them to verbalize these feelings, and explore the reasons for these fears. Educate the patient and family members about modes of transmission, and clarify information as needed.

Patients may be unable to return to work for several weeks during the acute phases of illness. The loss of wages and the cost of hospitalization for a patient without insurance coverage may produce great anxiety and financial burden. This situation may last for months or years if hepatitis becomes chronic.

Laboratory Assessment

Hepatitis A, hepatitis B, and hepatitis C are usually confirmed by acute elevations in levels of liver enzymes, indicating liver cellular damage, and by specific serologic markers.

Levels of ALT and AST levels may possibly rise into the thousands in acute or fulminant cases of hepatitis. Alkaline phosphatase levels may be normal or elevated. Serum total bilirubin levels are elevated and are consistent with the clinical appearance of jaundice. Elevated levels of bilirubin are also present in the urine (Pagana & Pagana, 2010).

The presence of *hepatitis A* is established when hepatitis A virus (HAV) antibodies (anti-HAV) are found in the blood. Ongoing inflammation of the liver by HAV is indicated by the presence of immunoglobulin M (IgM) antibodies, which persist in the blood for 4 to 6 weeks. Previous infection is identified by the presence of immunoglobulin G (IgG) antibodies. These antibodies persist in the serum and provide permanent immunity to HAV.

The presence of the *hepatitis B* virus (HBV) is established when serologic testing confirms the presence of hepatitis B antigen-antibody systems in the blood and a detectable viral count (HBV polymerase chain reaction [PCR] DNA). Antigens located on the surface (shell) of the virus (HBsAg) and IgM antibodies to hepatitis B core antigen (anti-HBcAg IgM) are the most significant serologic markers. The presence of these markers establishes the diagnosis of hepatitis B. *The patient is infectious as long as HBsAg (hepatitis B surface antigen) is present in the blood.* Persistence of this serologic marker after 6 months or longer indicates a carrier state or chronic hepatitis. HBsAg levels normally decline and disappear after the acute hepatitis B episode. The presence of antibodies to hepatitis B surface antibody (HBsAb) in the blood indicates recovery and immunity to hepatitis B. *People who*

have been vaccinated against HBV have a positive HBsAb because they also have immunity to the disease (Pagana & Pagana, 2010).

Enzyme-linked immunosorbent assay (ELISA) is the initial screening test for patients suspected of being infected with *hepatitis C* virus (HCV). It is also the most commonly used enzyme test for HCV antibodies (anti-HCV). The antibodies can be detected within 4 weeks of the infection (Pagana & Pagana, 2010). A more specific assay called the *recombinant immunoblot assay (RIBA)* can be used as a confirmatory test. These tests show that the patient has been exposed to HCV and has developed the antibody. To identify the actual circulating virus, the HCV PCR RNA test is used. This confirms active virus and can measure the viral load. A new diagnostic tool called the OraQuick HCV Rapid Antibody Test was approved by the Food and Drug Administration in the United States in 2010. It has the advantage of providing a quick diagnosis of the disease as a point-of-care test.

The presence of *hepatitis D* virus (HDV) can be confirmed by the identification of intrahepatic delta antigen or, more often, by a rise in the hepatitis D virus antibodies (anti-HDV) titer. This increase can be seen within a few days of infection (Pagana & Pagana, 2010).

Hepatitis E virus (HEV) testing is usually reserved for travelers in whom hepatitis is present but the virus cannot be detected. Hepatitis E antibodies (anti-HEV) are found in people infected with the virus.

Other Diagnostic Assessment

Liver biopsy may be used to confirm the diagnosis of hepatitis and to establish the stage and grade of liver damage. Characteristic changes help the pathologist distinguish among a virus, drug, toxin, fatty liver, iron, and other disease. It is usually performed in an ambulatory care setting as a percutaneous procedure (through the skin) after a local anesthetic is given. If coagulation is abnormal, however, it may be done using either a computed tomography (CT)-guided or transjugular route to reduce the risk for pneumothorax or hemothorax. Ultrasound may also be used.

INTERVENTIONS

The patient with viral hepatitis can be mildly or acutely ill depending on the severity of the inflammation. Most patients are not hospitalized, although older adults and those with dehydration may be admitted for a short-term stay. The plan of care for all patients with viral hepatitis is based on measures to rest the liver, promote cellular regeneration, and prevent complications, if possible.

During the acute stage of viral hepatitis, interventions are aimed at resting the inflamed liver to promote hepatic cell regeneration. *Rest* is an essential intervention to reduce the liver's metabolic demands and increase its blood supply. Collaborative care is generally supportive. The patient is usually tired and expresses feelings of general malaise. Complete bedrest is usually not required, but rest periods alternating with periods of activity are indicated and are often enough to promote hepatic healing. Individualize the patient's plan of care and change it as needed to reflect the severity of symptoms, fatigue, and the results of liver function tests and enzyme determinations. Activities such as self-care and ambulating are gradually added to the activity schedule as tolerated.

The diet should be high in carbohydrates and calories with moderate amounts of fat and protein after nausea and

anorexia subside. Small, frequent meals are often preferable to three standard meals. Ask the patient about food preferences because favorite foods are tolerated better than randomly selected foods. Encourage the patient to eat foods that are appealing. High-calorie snacks may be needed. Supplemental vitamins are often prescribed.

Drugs of any kind are used sparingly for patients with hepatitis to allow the liver to rest. An antiemetic to relieve nausea may be prescribed.

For patients with chronic hepatitis B and hepatitis C, a number of drugs are given, including antiviral and immunomodulating drugs. Examples of antiviral drugs that may be used for HBV include:

- Tenofovir or entecavir (Baraclude) (as first-line therapy for patients who develop cirrhosis, but no co-infection)
- Interferon (as a first-line drug for patients who do *not* have cirrhosis)
- Adefovir dipivoxil (Hepsera) (as second-line therapy)
- Lamivudine (Epivir-HBV)
- Telbivudine (Tyzeka)

Teach patients taking these drugs to report any muscle weakness or aching because most of them can cause myopathy (muscle weakness).

The current standard of care for hepatitis C is a combination of drugs, typically subcutaneous pegylated interferon alpha once a week and oral ribavirin (Copegus, Rebetol) daily. Ribavirin should never be given to a pregnant patient. Women of childbearing age must agree to use contraception if they are receiving treatment or if they are sexual partners of patients taking this drug. A new drug that can better achieve a sustained viral response, telaprevir (Incivek), has recently been approved by the FDA. In addition, a new protease inhibitor, boceprevir (Victrelis), has been approved by the FDA to treat chronic hepatitis C in adults who have not been treated previously or have failed the typical treatment.

The length of treatment for hepatitis C depends on genotype or strain of hepatitis. There are several different genotypes; most Americans who have hepatitis C are genotype 1. This genotype usually requires 48 weeks of treatment. Genotypes 2 and 3 have a better response rate if the viral load is low and usually need only 24 weeks of treatment.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Safety

A 27-year-old secretary is preparing to fly home to visit her mother. Her best friend, who is a nurse, notices that the woman has yellowish skin and icterus. He asks if she has noticed any changes in her urine and bowel movements. She responds that she has noticed that her urine is dark and her stool has been much lighter for the past week. He tells her that she may have hepatitis or some other liver problem and takes her to the emergency department, where she is diagnosed with hepatitis A. She is very dehydrated and weak and is admitted for overnight hydration, additional testing, and observation. You have been assigned to take care of her this AM.

1. What transmission precautions will you provide for this patient and why? Should her friend who is a nurse be treated in any way? Why or why not?
2. The patient is very upset that she is not able to fly home and see her mother, who is ill. She asks you when she will be able to take the trip. What is your best response to her concerns?
3. How will you determine when the patient is adequately rehydrated?
4. What health teaching will you provide before she goes home?

CHART 61-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Viral Hepatitis

- Avoid all medications, including over-the-counter drugs such as acetaminophen (Tylenol, Exdol ) , unless prescribed by your physician.
- Avoid all alcohol.
- Rest frequently throughout the day, and get adequate sleep at night.
- Eat small, frequent meals with a high-carbohydrate, moderate-fat, and moderate-protein content.
- Avoid sexual intercourse until antibody testing results are negative.
- Follow the guidelines for preventing transmission of the disease (see Chart 61-4).

Genotypes 4 and 5 are typically treated for 48 weeks. The desired outcome of treatment is to have a negative HCV PCR RNA level and to sustain a negative level after treatment has ended. The secondary expected outcome is improvement in liver function. Response rates vary, but adults who are young, have a low viral load, and have minimal scarring on liver biopsy have a better chance of clearing the virus and remaining free of hepatitis C after treatment has ended.

Community-Based Care

Home care management varies according to the type of hepatitis and whether the disease is acute or chronic. A primary focus in any case is preventing the spread of the infection. For hepatitis transmitted by the fecal-oral route, careful handwashing and sanitary disposal of feces are important. Standard Precautions are used for hepatitis transmitted percutaneously and permucosally. Education is therefore very important. Collaborate with the certified infection control practitioner and infectious disease specialist if needed in caring for these patients. These experts can also suggest resources for the patient and family.

! NURSING SAFETY PRIORITY

Action Alert

Teach the patient with viral hepatitis and the family to use measures to prevent infection transmission (see Chart 61-4). *In addition, instruct the patient to avoid alcohol and to check with the health care provider before taking any medication or vitamin, supplement, or herbal preparation.*

Encourage the patient to increase activity gradually to prevent fatigue. Suggest that he or she eat small, frequent meals of high-carbohydrate foods (Chart 61-5).

FATTY LIVER (STEATOSIS)

Fatty liver is caused by the accumulation of fats in and around the hepatic cells. It may be caused by alcohol abuse or other factors. Nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) are types of fatty liver disease. Causes include:

- Diabetes mellitus
- Obesity
- Elevated lipid profile

Fatty infiltration of the liver may result from faulty fat metabolism in the liver and the movement of fatty acids from adipose tissue (fat). Many patients are asymptomatic. The most common and typical finding is an elevated ALT and AST or normal ALT and elevated AST (part of a group of liver function tests [LFTs]).

Magnetic resonance imaging (MRI), ultrasound, and nuclear medicine examinations can be used to confirm excessive fat in the liver. A percutaneous biopsy can also confirm the diagnosis. Interventions are aimed at removing the underlying cause of the infiltration. Weight loss, glucose control, and aggressive treatment using lipid-lowering agents are recommended. Monitoring liver function tests is essential in disease management.

HEPATIC ABSCESS

Although hepatic abscesses are not common, they carry a high mortality (death) rate. Abscesses occur when the liver is invaded by bacteria or protozoa. These organisms destroy the liver tissue, producing a necrotic cavity filled with infective agents, liquefied liver cells and tissue, and leukocytes. The infectious necrotic tissue walls off the abscess from the healthy liver.

A **pyogenic liver abscess** occurs when bacteria invade the liver. Infecting organisms include *Escherichia coli* and *Klebsiella*, *Enterobacter*, *Salmonella*, *Staphylococcus*, and *Enterococcus* species. A pyogenic abscess is generally solitary and confined to the right lobe, but occasionally abscesses are multiple. The usual cause is acute cholangitis, which occurs as a complication of cholelithiasis. Pyogenic liver abscesses may also result from liver trauma, abdominal peritonitis, and sepsis, or an abscess can extend to the liver after pneumonia or bacterial endocarditis. Symptoms are usually sudden.

The protozoan *Entamoeba histolytica* causes an **amebic hepatic abscess**, which may occur after amebic dysentery. These abscesses usually occur in the form of a single abscess in the right hepatic lobe, and the symptoms develop slowly.

Patients with hepatic abscesses are generally quite ill. On occasion, an abscess is not diagnosed until autopsy. Common manifestations include:

- Right upper abdominal pain with a palpable, tender liver
- Anorexia
- Weight loss
- Nausea and vomiting
- Fever and chills
- Weakness and malaise
- Shoulder pain
- Dyspnea
- Pleural pain if the diaphragm is involved

A liver abscess is usually diagnosed by contrast-enhanced CT scan or ultrasound. These abscesses are usually drained under CT or ultrasound guidance. Specimens may be sent for laboratory analysis so that the optimal antibiotic can be selected.

LIVER TRAUMA

The liver is one of the most common organs to be injured in patients with abdominal trauma. Damage or injury should be suspected whenever any upper abdominal or lower chest trauma is sustained. The liver is often injured by steering

CHART 61-6

KEY FEATURES

Liver Trauma

- Right upper quadrant pain with abdominal tenderness
- Abdominal distention and rigidity
- Guarding of the abdomen
- Increased abdominal pain exaggerated by deep breathing and referred to the right shoulder (Kehr's sign)
- Indicators of hemorrhage and hypovolemic shock:
 - Hypotension
 - Tachycardia
 - Tachypnea
 - Pallor
 - Diaphoresis
 - Cool, clammy skin
 - Confusion or other change in mental state

wheels in vehicular accidents. Common injuries include simple lacerations, multiple lacerations, avulsions (tears), and crush injuries.

The liver is a highly vascular organ and receives almost a third of the body's cardiac output. When hepatic trauma occurs, blood loss can be massive. *Observe for early signs of hypovolemic shock (Chart 61-6).*

An ultrasound or CT scan of the abdomen is often done to determine the presence of a hematoma (blood clot). A decreased hematocrit may confirm suspected blood loss. Clinical manifestations include right upper quadrant pain with abdominal tenderness, distention, guarding, and rigidity. Abdominal pain exaggerated by deep breathing and referred to the right shoulder may indicate diaphragmatic irritation.

When organ damage is confirmed, a surgeon uses a laparoscope or performs an open exploratory laparotomy to identify and control the source and type of bleeding. Minor surgical interventions, such as suture placement, wound packing, decompression, or a combination of these procedures, are often performed to stop the bleeding. Liver lobe resection is required in some extensive liver injuries. This procedure may be done using laparoscopy. Catheter-directed embolization of an intrahepatic blood vessel as an interventional radiologic procedure may be a useful alternative to surgical resection.

Patients with hepatic trauma require multiple blood products such as packed red blood cells and fresh frozen plasma, as well as massive volume infusion to maintain adequate hydration. After surgery, the patient is admitted to a critical care unit. Monitor the patient for persistent or new bleeding. Closely monitor complete blood count and coagulation studies for trends in changes.

CANCER OF THE LIVER

Pathophysiology

Cancers may be *primary* tumors (hepatocellular carcinoma) starting in the liver, or they may be *metastatic* cancers that spread from another organ to the liver. They are most often seen in regions of Asia and the Mediterranean area. Worldwide, the disease kills about 1 million people each year and affects Vietnamese men more than any other group. Black and Hispanic populations have twice the rate of the disease as Euro-Americans, and older adults are affected more than

other age-groups (Rossi et al., 2010). In the United States and worldwide, the incidence of liver cancer is increasing because there is an increase in cases of hepatitis C (HCV).

Chronic infection with HBV and HCV frequently lead to cirrhosis, which is a risk factor for developing liver cancer. It is important to remember that cirrhosis from any cause, including alcoholic liver disease, increases the risk for cancer.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

In the early stage of cancer, most patients are without symptoms. Later in the disease, they report weight loss, anorexia, and weakness. Ask the patient if he or she has or has had recent abdominal pain, the most common concern. It is most often felt in the right upper quadrant before jaundice, bleeding, ascites, and edema develop. Palpation may reveal an enlarged, nodular liver.

Elevated serum alpha-fetoprotein (AFP) (a tumor marker for cancers of the liver, testis, and ovary) and increased alkaline phosphatase are also common (Pagana & Pagana, 2010). Ultrasound (US) and contrast-enhanced CT are both useful in detecting metastasis. If the primary tumor site is not known, a CT- or ultrasound-guided liver biopsy can confirm the diagnosis, although this procedure is risky because of possible bleeding and spread of the cancer cells.

INTERVENTIONS

Surgical resection and liver transplantation offer the only treatments for long-term survival. Unfortunately, most patients are not candidates for surgical removal because their tumors are unresectable. Selective internal radiation therapy (SIRT) has been successful for some patients. Other palliative approaches include hepatic artery embolization, ablation techniques, and drug therapy.

Hepatic artery embolization causes cell death by blocking blood supply to the tumor in the liver. It is performed under moderate sedation by an interventional radiologist who threads a catheter through the femoral artery to inject small particles into the hepatic artery. The patient usually stays overnight in the hospital for observation in case of bleeding. This procedure may be followed by infusing a chemotherapy agent directly into the hepatic artery (chemoembolization).

Common *ablation* procedures include radiofrequency ablation (RFA), percutaneous ethanol injection, and cryotherapy. RFA uses energy waves to heat cancer cells and kill them. It is most often performed as an ambulatory care procedure using a percutaneous laparoscopic approach. Ethanol may also be injected directly into the tumor to destroy tumor cells, although this procedure is not as commonly done as RFA (Rossi et al., 2010). Cryotherapy uses liquid nitrogen to freeze and destroy liver tumors. The general nursing care for patients having these procedures is described in Chapter 24.

Chemotherapy may be administered orally or IV. However, it is not effective in many cases. Examples of drugs used are doxorubicin (Adriamycin), 5-fluorouracil (5-FU), and cisplatin. Sorafenib (Nexavar) is a kinase inhibitor that is approved for inoperable liver cancer. Other drugs are targeted therapies that are being investigated and used with some success.

Another drug route is a catheter-directed method directly into the hepatic artery, a procedure called *hepatic arterial infusion (HAI)*. The interventional radiologist places a catheter into the artery that supplies the tumor and injects a mixture of chemotherapy and contrast agent into the tumor. This procedure has the unique effect of depositing chemotherapeutic drugs directly into the tumor without causing major systemic effects. Examples of agents given are fluorodeoxyuridine (FUDR) with or without dexamethasone (the most commonly used), oxaliplatin, mitomycin-C, or irinotecan (Moore, 2007). Chapter 24 describes the general nursing care for patients receiving chemotherapy.

Patients with advanced liver cancer usually need end-of-life care and hospice services. Collaborate with the case manager to help patients and their families find the best community resources that meet their needs. Chapter 9 describes end-of-life care and hospice services in detail.

LIVER TRANSPLANTATION

Liver transplantation has become a common procedure worldwide. The patient with end-stage liver disease or acute liver failure who has not responded to conventional medical or surgical intervention is a potential candidate for liver transplantation. The most common reason for a liver transplant is hepatitis C. It may also be used for the patient with a *primary* liver tumor.

The patient for potential transplantation has extensive physiologic and psychological assessment and evaluation by physicians and transplant coordinators. Alternative treatment should be extensively explored before committing a patient for a liver transplant. Patients who are *not* considered candidates for transplantation are those with:

- Severe cardiovascular instability with advanced cardiac disease
- Severe respiratory disease
- Metastatic tumors
- Inability to follow instructions regarding drug therapy and self-management

Liver transplantation has become the most effective treatment for an increasing number of patients with acute and chronic liver diseases. Inclusion and exclusion criteria vary among transplantation centers and are continually revised as treatment options change and surgical techniques improve.

Donor livers are obtained primarily from trauma victims who have not had liver damage. They are distributed through a nationwide program—the United Network of Organ Sharing (UNOS). This system distributes donor livers based on regional considerations and patient acuity. Candidates with the highest level of acuity receive highest priority.

The donor liver is transported to the surgery center in a solution that preserves the organ for up to 8 hours. The diseased liver is removed through an incision made in the upper abdomen. The new liver is carefully put in its place and is attached to the patient's blood vessels and bile ducts. The procedure can take many hours to complete and requires a highly specialized team and large volumes of fluid and blood replacement.

Living donors have also been used and are usually close family members or spouse. This is done on a voluntary basis after careful psychological and physiologic preparation and testing. The donor's liver is resected (usually removal of one

lobe) and implanted into the recipient after removal of the diseased liver. In both the donor and the recipient, the liver regenerates and grows in size to meet the demands of the body.

Pathophysiology

Although liver transplantations are commonly done, complications can occur. Some problems can be medically managed, whereas others require removal of the transplant. The two most common complications are acute graft rejection and infection.

The success of all transplantations has greatly improved since the introduction many years ago of cyclosporine (cyclosporin A), an immunosuppressant drug. Today, many other anti-rejection drugs are used. (See [Chapter 19](#) for a complete discussion of rejection and preventive drug therapy.)

! NURSING SAFETY PRIORITY

Action Alert

For the patient who has undergone liver transplantation, monitor for clinical manifestations of rejection, which may include tachycardia, fever, right upper quadrant or flank pain, decreased bile pigment and volume, and increasing jaundice. Laboratory findings include elevated serum bilirubin, rising ALT and AST levels, elevated alkaline phosphatase levels, and increased prothrombin time/international normalized ratio (PT/INR).

Transplant rejection is treated aggressively with immunosuppressive drugs. As with all rejection treatments, the patient is at a greater risk for infection. If therapy is not effective, liver

function rapidly deteriorates. Multi-system organ failure, including respiratory and renal involvement, develops along with diffuse coagulopathies and portal-systemic encephalopathy (PSE). The only alternative for treatment is emergency retransplantation.

Infection is another potential threat to the transplanted graft and the patient's survival. Vaccinations and prophylactic antibiotics are helpful in prevention. Immunosuppressant therapy, which must be used to prevent and treat organ rejection, significantly increases the patient's risk for infection. Other risk factors include the presence of multiple tubes and intravascular lines, immobility, and prolonged anesthesia.

In the early post-transplantation period, common infections include pneumonia, wound infections, and urinary tract infections. Opportunistic infections usually develop after the first postoperative month and include cytomegalovirus, mycobacterial infections, and parasitic infections. Latent infections such as tuberculosis and herpes simplex may be reactivated.

The physician prescribes broad-spectrum antibiotics for prophylaxis during and after surgery. Obtain culture specimens from all lines and tubes and collect specimens for culture at predetermined time intervals as dictated by the agency's policy. If an infection is detected, the physician prescribes organism-specific anti-infective agents.

The biliary anastomosis is susceptible to breakdown, obstruction, and infection. If leakage occurs or if the site becomes necrotic or obstructed, an abscess can form or peritonitis, bacteremia, and cirrhosis may develop. Observe for potential complications, which are listed in [Table 61-6](#).

TABLE 61-6 ASSESSMENT AND PREVENTION OF COMMON POSTOPERATIVE COMPLICATIONS ASSOCIATED WITH LIVER TRANSPLANTATION

ASSESSMENT	PREVENTION
Acute Graft Rejection Occurs from the 4th to 10th postoperative day Manifested by tachycardia, fever, right upper quadrant (RUQ) or flank pain, diminished bile drainage or change in bile color, or increased jaundice Laboratory changes: (1) increased levels of serum bilirubin, transaminases, and alkaline phosphatase; (2) prolonged prothrombin time	Prophylaxis with immunosuppressant agents, such as cyclosporine Early diagnosis to treat with more potent anti-rejection drugs
Infection Can occur at any time during recovery Manifested by fever or excessive, foul-smelling drainage (urine, wound, or bile); other indicators depend on location and type of infection	Antibiotic prophylaxis; vaccinations Frequent cultures of tubes, lines, and drainage Early removal of invasive lines Good handwashing Early diagnosis and treatment with organism-specific anti-infective agents
Hepatic Complications (Bile Leakage, Abscess Formation, Hepatic Thrombosis) Manifested by decreased bile drainage, increased RUQ abdominal pain with distention and guarding, nausea or vomiting, increased jaundice, and clay-colored stools Laboratory changes: increased levels of serum bilirubin and transaminases	If present, keep T-tube in dependent position and secure to patient; empty frequently, recording quality and quantity of drainage Report manifestations to physician immediately May necessitate surgical intervention
Acute Renal Failure Caused by hypotension, antibiotics, cyclosporine, acute liver failure, or hypothermia Indicators of hypothermia: shivering, hyperventilation, increased cardiac output, vasoconstriction, and alkalemia Early indicators of renal failure: changes in urine output, increased blood urea nitrogen (BUN) and creatinine levels, and electrolyte imbalance	Monitor all drug levels with nephrotoxic side effects Prevent hypotension Observe for early signs of renal failure, and report them immediately to the physician

PATIENT-CENTERED COLLABORATIVE CARE

Care of the patient undergoing liver transplantation requires an interdisciplinary team approach. Receiving a transplant has a major psychosocial impact. Transplant complications cause patients to be very anxious. In collaboration with the members of the health care team, assure them and their families that these problems are common and usually successfully treated.

After the patient is identified as a candidate and a donor organ is procured, the actual liver transplantation surgical procedure usually takes many hours. The length of the procedure can vary greatly.

In the immediate postoperative period, the patient is managed in the critical care unit and requires aggressive

monitoring and care. Assess for signs and symptoms of complications of surgery, and immediately report them to the surgeon (see Table 61-6).

! NURSING SAFETY PRIORITY

Action Alert

For the patient who has had a liver transplantation, monitor the temperature frequently per hospital protocol, and report elevations, increased abdominal pain, distention, and rigidity, which are indicators of peritonitis. Nursing assessment also includes monitoring for a change in neurologic status that could indicate encephalopathy from a nonfunctioning liver. Report signs of clotting problems (e.g., bloody oozing from a catheter, petechiae, ecchymosis) to the surgeon immediately because they may indicate impaired function of the transplanted liver.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate digestion, nutrition, and metabolism as a result of impaired liver function?

- Jaundice
- Icterus
- Report of nausea and anorexia
- Vomiting
- Weight loss
- Bruising or bleeding
- Ascites

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate digestion, nutrition, and metabolism as a result of impaired liver function?

Perform and interpret physical assessment findings, including:

- Assess respiratory status to check for dyspnea or shallow breathing.
- Check level of consciousness and cognition.
- Take vital signs (look for fever or decreased BP) and oxygen saturation.
- Check for blood in the vomitus.
- Perform an abdominal assessment, including measuring girth.

- Check urine for dark color and stool for clay-colored appearance.
- Take current weight, and compare with previous weight.
- Assess skin for open areas.
- Check most recent laboratory values for coagulation studies and LFTs.

Respond by:

- Applying oxygen to assist in ease of breathing
- Keeping head of bed elevated to at least 30 degrees
- Maintaining rest
- Collaborating with dietitian and pharmacist as needed
- Prioritizing and pacing activities to prevent fatigue
- Monitoring patient closely for complications, such as bleeding; call the Rapid Response Team if bleeding occurs

On what should you REFLECT?

- Monitor the patient for restored digestion and nutrition, such as increased appetite.
- Think about what may have caused the liver problem.
- Consider for what complications the patient is at risk.
- Think about what members of the health care team need to provide care for this patient.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Monitor the patient with cirrhosis for bleeding and neurologic changes.
- When caring for patients with cirrhosis, collaborate with the dietitian, physician, and pharmacist.

- Refer patients with liver disorders to the American Liver Foundation; refer dying patients to hospice and other community resources as needed.

Health Promotion and Maintenance

- Follow the guidelines listed in Chart 61-3 to prevent viral hepatitis in the workplace.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Teach patients to take precautions to prevent viral hepatitis in the community as described in [Chart 61-4](#).
- For patients with viral hepatitis, instruct them to follow the guidelines listed in [Chart 61-5](#).

Psychosocial Integrity

- Recognize that patients with cirrhosis have mental and emotional changes due to hepatic encephalopathy.
- Be aware that patients with cirrhosis and/or chronic hepatitis may feel guilty about their disease because of past habits such as drug and alcohol abuse.
- Be aware that family members and friends may fear getting hepatitis from the patient.
- Be aware that patients having liver transplantation have major concerns about the possibility of complications, such as organ rejection.

Physiological Integrity

- Be aware that cirrhosis has many causes other than alcohol abuse (see [Table 61-3](#)).
- Monitor laboratory values of patients suspected of or diagnosed with cirrhosis of the liver as listed in [Tables 61-1](#) and [61-4](#).

- Observe for clinical manifestations of hepatic encephalopathy (PSE) as listed in [Table 61-2](#).
- Assess for manifestations of cirrhosis as shown in [Fig. 61-1](#).
- Provide care for the patient having a paracentesis as described in [Chart 61-1](#).
- Administer drug therapy to decrease ammonia levels (which cause PSE) in patients with cirrhosis, such as lactulose and nonabsorbable antibiotics.
- Differentiate the five major types of hepatitis: A, B, C, D, and E. HDV occurs only with HBV and is transmitted most commonly by blood and body fluid exposure. Hepatitis A is transmitted via the fecal-oral route. Hepatitis C is the most common type and is also transmitted via blood and body fluids.
- Be aware that patients with chronic viral hepatitis often develop cirrhosis and cancer of the liver.
- Recognize that potent immunomodulators and antivirals are given to treat hepatitis B and hepatitis C.
- Monitor for bleeding in the patient with liver trauma; assume that any abdominal trauma has damaged the liver.
- Observe the patient having a liver transplantation for complications, such as those described in [Table 61-6](#).

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Collaborate with health care team members to provide care for patients with pancreatic disorders.

Health Promotion and Maintenance

2. Teach people about health promotion practices to prevent gallbladder disease.
3. Teach people about health promotion practices to prevent pancreatitis.
4. Identify community-based resources for patients with pancreatic disorders.

Psychosocial Integrity

5. Describe the psychosocial needs of patients with pancreatic cancer and their families.
6. Assess patient and family response to a diagnosis of pancreatic cancer.

Physiological Integrity

7. Identify risk factors for gallbladder disease.
8. Interpret diagnostic test results associated with gallbladder disease.
9. Compare postoperative care of patients undergoing a traditional cholecystectomy with that of patients having laparoscopic cholecystectomy.
10. Compare and contrast the pathophysiology of acute and chronic pancreatitis.
11. Interpret laboratory test results associated with acute pancreatitis.
12. Interpret common assessment findings associated with acute and chronic pancreatitis.
13. Prioritize nursing care for patients with acute pancreatitis and patients with chronic pancreatitis.
14. Explain the use and precautions associated with enzyme replacement for chronic pancreatitis.
15. Develop a postoperative plan of care for patients having a Whipple procedure.

The biliary system (liver and gallbladder) and pancreas secrete enzymes and other substances that promote food digestion in the stomach and small intestine. When these organs do not work properly, the person has impaired *digestion*, which may result in inadequate *nutrition*. Collaborative care for patients with problems of the biliary system and pancreas includes the need to promote nutrition for healthy cellular function. This chapter focuses on problems of the

gallbladder and pancreas. Liver disorders were described in [Chapter 61](#).

Because of the close anatomic location of these organs, disorders of the gallbladder and pancreas may extend to other organs if the primary health problem is not treated early. Inflammation is caused by **obstruction** (blockage) in the biliary system from gallstones, edema, stricture, or tumors. For example, gallstones in the cystic duct cause cholecystitis.

FIG. 62-1 Gallstones within the gallbladder and obstructing the common bile and cystic ducts.

Gallstones lodged in the ampulla of Vater block the flow of bile and pancreatic secretions, which can result in pancreatitis.

GALLBLADDER DISORDERS

CHOLECYSTITIS

Pathophysiology

Cholecystitis is an inflammation of the gallbladder that affects many people, most commonly in affluent countries. It may be either acute or chronic, although most patients have the acute type. Over 500,000 surgeries for this health problem are done in the United States each year (Comstock, 2008).

Acute Cholecystitis

Two types of acute cholecystitis can occur: calculous and acalculous cholecystitis. The most common type is **calculous cholecystitis**, in which chemical irritation and inflammation result from gallstones (**cholelithiasis**) that obstruct the cystic duct (most often), gallbladder neck, or common bile duct (choledocholithiasis) (Fig. 62-1). When the gallbladder is inflamed, trapped bile is reabsorbed and acts as a chemical irritant to the gallbladder wall; that is, the bile has a toxic effect. Reabsorbed bile, in combination with impaired circulation, edema, and distention of the gallbladder, causes ischemia and infection. The result is tissue sloughing with necrosis and gangrene. The gallbladder wall may eventually perforate (rupture). If the perforation is small and localized, an abscess may form. **Peritonitis**, infection of the peritoneum, may result if the perforation is large.

The exact pathophysiology of gallstone formation is not clearly understood, but abnormal metabolism of cholesterol and bile salts plays an important role in their formation. The gallbladder provides an excellent environment for the production of stones because it only occasionally mixes its normally abundant mucus with its highly viscous,

concentrated bile. Impaired gallbladder motility can lead to stone formation by delaying bile emptying and causing biliary stasis.

Gallstones are composed of substances normally found in bile, such as cholesterol, bilirubin, bile salts, calcium, and various proteins. They are classified as either cholesterol stones or pigment stones. Cholesterol calculi form as a result of metabolic imbalances of cholesterol and bile salts. They are the most common type found in people in the United States. Pigmented stones are associated with cirrhosis of the liver (McCance et al., 2010).

Bacteria can collect around the stones in the biliary system. Severe bacterial invasion can lead to life-threatening *suppurative* cholangitis when symptoms are not recognized quickly and pus accumulates in the ductal system.

Acalculous cholecystitis (inflammation occurring without gallstones) is typically associated with biliary stasis caused by any condition that affects the regular filling or emptying of the gallbladder. For example, a decrease in blood flow to the gallbladder or anatomic problems such as twisting or kinking of the gallbladder neck or cystic duct can result in pancreatic enzyme reflux into the gallbladder, causing inflammation. Most cases of this type of cholecystitis occur in patients with:

- Sepsis
- Severe trauma or burns
- Long-term total parenteral nutrition
- Multi-system organ failure
- Major surgery
- Hypovolemia

Chronic Cholecystitis

Chronic cholecystitis results when repeated episodes of cystic duct obstruction cause chronic inflammation. Calculi are almost always present. In chronic cholecystitis, the gallbladder becomes fibrotic and contracted, which results in decreased motility and deficient absorption.

Pancreatitis and cholangitis (bile duct inflammation) can occur as chronic complications of cholecystitis. These problems result from the backup of bile throughout the biliary tract. Bile obstruction leads to jaundice.

Jaundice (yellow discoloration of the skin and mucous membranes) and **icterus** (yellow discoloration of the sclerae) can occur in patients with acute cholecystitis but are most commonly seen in those with the *chronic* form of the disease. Obstructed bile flow caused by edema of the ducts or gallstones contributes to **extrahepatic obstructive jaundice**. Jaundice in cholecystitis may also be caused by direct liver involvement. Inflammation of the liver's bile channels or bile ducts may cause *intrahepatic* obstructive jaundice, resulting in an increase in circulating levels of bilirubin, the major pigment of bile.

When the concentration of bilirubin in the blood increases, jaundice can occur. In a person with obstructive jaundice, the normal flow of bile into the duodenum is blocked, allowing excessive bile salts to accumulate in the skin. This accumulation of bile salts leads to **pruritus** (itching) or a burning sensation. The bile flow blockage also prevents bilirubin from reaching the large intestine, where it is converted to urobilinogen. Because urobilinogen accounts for the normal brown color of feces, clay-colored stools result. Water-soluble bilirubin is normally excreted by the kidneys in the urine. When

TABLE 62-1 RISK FACTORS FOR CHOLECYSTITIS

• Women • Aging • American Indian, Mexican American, or Caucasian • Obesity • Rapid weight loss or prolonged fasting • Increased serum cholesterol • Women on hormone replacement therapy (HRT) or older birth control pills	• Cholesterol-lowering drugs • Family history of gallstones • Prolonged total parenteral nutrition • Crohn's disease • Gastric bypass surgery • Sickle cell disease • Glucose intolerance/diabetes mellitus • Pregnancy • Genetic factors
--	---

an excess of circulating bilirubin occurs, the urine becomes dark and foamy because of the kidneys' effort to clear the bilirubin.

Etiology and Genetic Risk

A familial or genetic tendency appears to play a role in the development of cholelithiasis, but this may be partially related to familial nutrition habits (excessive dietary cholesterol intake) and sedentary lifestyles. Genetic-environment interactions may contribute to gallstone production (Attasaranya et al., 2008).

Cholelithiasis is seen more frequently in obese patients, probably as a result of impaired fat metabolism or increased cholesterol. The risk for developing gallstones increases as people age. Patients with diabetes mellitus are also at increased risk because they usually have higher levels of fatty acids (triglycerides). American Indians have a higher incidence of the disease than other groups, which may be due to the higher incidence of diabetes mellitus and obesity in this population (McCance et al., 2010). Risk factors for cholecystitis are listed in Table 62-1.

WOMEN'S HEALTH CONSIDERATIONS

Women who are between 20 and 60 years of age are twice as likely to develop gallstones as are men. Obesity is a major risk factor for gallstone formation, especially in women. Pregnancy and drugs such as hormone replacements and birth control pills (especially the older oral contraceptives) alter hormone levels and delay muscular contraction of the gallbladder, decreasing the rate of bile emptying. The incidence of gallstones is higher in women who have had multiple pregnancies. Combinations of causative factors increase the incidence of stone formation, especially in women. Therefore some clinicians refer to the patient most at risk for cholecystitis and gallstones by the four **Es**:

- **F**emale
- **F**orty
- **F**at
- **F**ertile

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

Patients with acute cholecystitis present with abdominal pain, although clinical manifestations vary in intensity and frequency (Chart 62-1).

CHART 62-1 KEY FEATURES

Cholecystitis

- Episodic or vague upper abdominal pain or discomfort that can radiate to the right shoulder
- Pain triggered by a high-fat or high-volume meal
- Anorexia
- Nausea and/or vomiting
- Dyspepsia (indigestion)
- Eructation (belching)
- Flatulence (gas)
- Feeling of abdominal fullness
- Rebound tenderness (Blumberg's sign)
- Fever
- Jaundice, clay-colored stools, dark urine, steatorrhea (most common with chronic cholecystitis)

Obtain the patient's height, weight, and vital signs, or delegate these activities to unlicensed assistive personnel (UAP). Ask about food preferences, and determine whether excessive fat and cholesterol are part of the diet. Inquire if any foods cause pain. Question whether any GI symptoms occur when fatty food is eaten: **flatulence** (gas), **dyspepsia** (indigestion), **eructation** (belching), anorexia, nausea, vomiting, and abdominal pain or discomfort.

Ask the patient to describe the pain, including its intensity and duration, precipitating factors, and any measures that relieve it. Pain may be described as indigestion of varying intensity, ranging from a mild, persistent ache to a steady, constant pain in the right upper abdominal quadrant. It may radiate to the right shoulder or scapula. In some cases, the abdominal pain of chronic cholecystitis may be vague and nonspecific. The usual pattern is episodic. Patients often refer to acute pain episodes as "gallbladder attacks."

CONSIDERATIONS FOR OLDER ADULTS

Older adults and patients with diabetes mellitus may have atypical manifestations of cholecystitis, including the absence of pain and fever. Localized tenderness may be the only presenting sign. The older patient may become acutely confused (delirium) as the first manifestation of gallbladder disease.

The severe pain of **biliary colic** is produced by obstruction of the cystic duct of the gallbladder or movement of one or more stones. When a stone is moving through or is lodged within the duct, tissue spasm occurs in an effort to get the stone through the small duct.

! NURSING SAFETY PRIORITY

Critical Rescue

Biliary colic may be so severe that it occurs with tachycardia, pallor, diaphoresis, and prostration (extreme exhaustion). Assess the patient for possible shock caused by biliary colic. Notify the health care provider or Rapid Response Team if these manifestations occur. Stay with the patient, and lower the head of the bed.

Ask patients to describe their daily activity or exercise routines to determine whether they are sedentary. Question whether there is a family history of gallbladder disease. If the patient is female, ask whether she takes hormone replacement therapy (HRT) or birth control pills.

Assessment for rebound tenderness (**Blumberg's sign**) and deep palpation are performed only by physicians and advanced practice nurses. To elicit rebound tenderness, the health care provider pushes his or her fingers deeply and steadily into the patient's abdomen and then quickly releases the pressure. Pain that results from the rebound of the palpated tissue may indicate peritoneal inflammation. Deep palpation below the liver border in the right upper quadrant may reveal a sausage-shaped mass, representing the distended, inflamed gallbladder. Percussion over the posterior rib cage worsens localized abdominal pain.

In *chronic* cholecystitis, patients may have slowly developing symptoms and may not seek medical treatment until late symptoms such as jaundice (yellowing of the skin), clay-colored stools, and dark urine occur from biliary obstruction. Yellowing of the sclerae (icterus) and oral mucous membranes may also be present. **Steatorrhea** (fatty stools) occurs because fat absorption is decreased because of the lack of bile. Bile is needed for the absorption of fats and fat-soluble vitamins in the intestine. As with any inflammatory process, the patient may have an elevated temperature of 99° to 102° F (37.2° to 38.9° C), tachycardia, and dehydration from fever and vomiting.

CONSIDERATIONS FOR OLDER ADULTS

Older adults become dehydrated much quicker than other age-groups, and they may not present with a fever. Monitor for a new onset of disorientation or acute confusion due to decreased blood volume available to oxygenate the cells of the brain (hypoxia).

Diagnostic Assessment

A differential diagnosis rules out other diseases that may cause similar symptoms, such as peptic ulcer disease, hepatitis, and pancreatitis. An increased white blood cell (WBC) count indicates inflammation. Serum levels of alkaline phosphatase, aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) may be elevated, indicating abnormalities in liver function in patients with severe biliary obstruction. The direct (conjugated) and indirect (unconjugated) serum bilirubin levels are also elevated. If the pancreas is involved, serum amylase and lipase levels are elevated.

Calcified gallstones are easily viewed on abdominal x-ray. Stones that are not calcified cannot be seen. *Ultrasonography (US) of the right upper quadrant is the best diagnostic test for cholecystitis.* It is safe, accurate, and painless. Acute cholecystitis is seen as edema of the gallbladder wall and pericholecystic fluid. A hepatobiliary scan can be performed to visualize the gallbladder and determine patency of the biliary system.

When the cause of cholecystitis or cholelithiasis is not known or the patient has manifestations of biliary obstruction (e.g., jaundice), an *endoscopic retrograde cholangiopancreatography* (ERCP) may be performed. Some patients have the less invasive and safer *magnetic resonance cholangiopancreatography* (MRCP), which can be performed by an interventional radiologist. For this procedure, the patient is given oral or IV contrast material (gadolinium) before having a magnetic resonance imaging (MRI) scan (Daniak et al., 2008). Before the test, ask the patient about any history of urticaria (hives) or other allergy. Gadolinium does not contain iodine, which decreases the risk for an allergic response. **Chapter 55** discusses these tests in more detail.

INTERVENTIONS

Most patients do not respond to nonsurgical interventions during the acute phase of cholecystitis. Surgery is the treatment of choice.

Nonsurgical Management

Many people with gallstones have no symptoms. Acute pain occurs when gallstones partially or totally obstruct the cystic or common bile duct. Most patients find that they need to avoid fatty foods to prevent further episodes of biliary colic. Withhold food and fluids if nausea and vomiting occur. IV therapy is used for hydration.

Acute biliary pain requires opioid analgesia, such as morphine or hydromorphone (Dilaudid). In the past, meperidine (Demerol) was the drug of choice because it was thought to cause fewer spasms of the sphincter of Oddi, which blocks bile flow. However, this drug breaks down into a toxic metabolite (normeperidine) and can cause seizures, especially in older adults. All opioids may cause some degree of sphincter spasm.

Ketorolac (Toradol, Acular) may be used for mild to moderate pain. The health care provider prescribes antiemetics to control nausea and vomiting. IV antibiotic therapy may also be given, depending on the cause of cholecystitis or as a one-time dose for surgery.

For some patients with small stones or for those who are not good surgical candidates, a treatment that is commonly used for kidney stones can be used to break up gallstones—*extracorporeal shock wave lithotripsy (ESWL)*. This procedure can be used only for patients who have a normal weight, cholesterol-based stones, and good gallbladder function. The patient lies on a water-filled pad, and shock waves break up the large stones into smaller ones that can be passed through the digestive system. During the procedure, he or she may have pain from the movement of the stones or duct or gallbladder spasms. A therapeutic bile acid, such as ursodeoxycholic acid (UDCA), may be used after the procedure to help dissolve the remaining stone fragments.

Another treatment option in people who cannot have surgery is the insertion of a percutaneous transhepatic biliary catheter to open the blocked duct(s) so that bile can flow. Catheters can be placed several ways, depending on the condition of the biliary ducts, in an internal, external, or internal/external drain. Biliary catheters usually divert bile from the liver into the duodenum to bypass a stricture. When all of the bile enters the duodenum, it is called an *internal* drain. However, in some cases, a patient has an *internal/external* drain in which part of the bile empties into a drainage bag. Patients who need this drain for an extended period may have the external drain capped. If jaundice or leakage around the catheter site occurs, teach the patient to reconnect the catheter to a drainage bag and have a follow-up cholangiogram injection done by an interventional radiologist. An *external* only catheter is connected either temporarily or permanently to a drainage bag. A reduction in bile drainage indicates that the drain is no longer working.

Surgical Management

Cholecystectomy is a surgical removal of the gallbladder. One of two procedures is performed: the laparoscopic cholecystectomy and, far less often, the traditional open approach cholecystectomy.

Laparoscopic Cholecystectomy. Laparoscopic cholecystectomy, a minimally invasive surgery (MIS), is currently the “gold standard” and is performed far more often than the traditional open approach. The advantages of MIS include:

- Complications are not common.
- The death rate is very low.
- Bile duct injuries are rare.
- Patient recovery is quicker.
- Postoperative pain is less severe.

The laparoscopic procedure (often called a “lap chole”) is commonly done on an ambulatory care basis in a same-day surgery suite. The surgeon explains the procedure. The nurse answers questions and reinforces the physician’s instructions. Reinforce what to expect after surgery, and review pain management, deep-breathing exercises, and incentive spirometry use. There is no special preoperative preparation other than the routine preparation for surgery under general anesthesia described in Chapter 16. An IV antibiotic is usually given immediately before or during surgery.

During the surgery, the surgeon makes a very small midline puncture at the umbilicus. Additional small incisions may be needed, although single-incision laparoscopic cholecystectomy (SILC) using a flexible endoscope can be done (Binenbaum et al., 2009). The abdominal cavity is insufflated with 3 to 4 L of carbon dioxide. Gasless laparoscopic cholecystectomy using abdominal wall lifting devices is a more recent innovation in some centers. This technique results in improved pulmonary and cardiac function. A trocar catheter is inserted, through which a laparoscope is introduced. The laparoscope is attached to a video camera, and the abdominal organs are viewed on a monitor. The gallbladder is dissected from the liver bed, and the cystic artery and duct are closed. The surgeon aspirates the bile and crushes any large stones and then extracts the gallbladder through the umbilical port.

Removing the gallbladder with the laparoscopic technique reduces the risk for wound complications. Some patients have discomfort from carbon dioxide retention in the abdomen.

! NURSING SAFETY PRIORITY

Action Alert

After a laparoscopic cholecystectomy, assess the patient’s oxygen saturation level frequently until the effects of the anesthesia have passed. Offer the patient food and water when fully awake, and monitor for nausea and vomiting. Be sure to have the head of the bed elevated in the same-day surgery unit to prevent aspiration from vomiting. Assist the patient to the bathroom to void. Early ambulation also promotes absorption of the carbon dioxide. Administer an oral opioid as needed after the laparoscopic procedure. IV pain control is usually not needed after the laparoscopic procedure because there is only one or a few small incisions that are covered with Steri-Strips and small adhesive bandages (e.g., Band-Aids).

The patient is usually discharged from the hospital or surgery center the same day, although older and obese patients may stay overnight. Provide postoperative teaching regarding pain management, incision care, and follow-up appointments. After laparoscopic surgery, the patient can return to usual activities much sooner than those having an open cholecystectomy. Most patients are able to resume usual activities within a week.

A newer procedure is *natural orifice transluminal endoscopic surgery* (NOTES) for removal of or repair of organs.

Surgery can be performed on many body organs through the mouth, vagina, and rectum. For removal of the gallbladder, the vagina is used most often in women because it can be easily decontaminated with Betadine or other antiseptic and allows easy access into the peritoneal cavity. The surgeon makes a small internal incision through the cul-de-sac of Douglas between the rectum and uterine wall to access the gallbladder. The main advantages of this procedure are the lack of visible incisions and minimal, if any, postoperative complications (Navarra et al., 2010).

Traditional Cholecystectomy. Use of the open surgical approach (abdominal laparotomy) has greatly declined during the past 20 years. Patients who have this type of surgery usually have severe biliary obstruction.

The surgical nurse provides the usual preoperative care and teaching in the operating suite on the day of surgery (see Chapter 16). The surgeon removes the gallbladder through an incision and explores the biliary ducts for the presence of stones or other cause of obstruction. If the common bile duct is explored, the surgeon may insert a T-tube drain to ensure patency of the duct, although this is not done commonly today. Trauma to the common bile duct stimulates inflammation, which can slow bile flow and contribute to bile stasis. In addition, the surgeon usually inserts a drainage tube such as a Jackson-Pratt (JP) drain. This tube is placed in the gallbladder bed to prevent fluid accumulation. The drainage is usually serosanguineous (serous fluid mixed with blood) and is stained with bile in the first 24 hours after surgery. Antibiotic therapy is given to prevent infection.

Patient care for a patient who has had a traditional open cholecystectomy is similar to the care for any patient who has had abdominal surgery under general anesthesia as described in Chapter 18. Postoperative incisional pain after a traditional cholecystectomy is controlled with opioids using a patient-controlled analgesia (PCA) pump. Encourage the patient to use coughing and deep-breathing exercises when pain is controlled and the incision is splinted.

Antiemetics may be necessary for episodes of postoperative nausea and vomiting. Administer the antiemetic early, as prescribed, to prevent retching associated with vomiting and thus to decrease pain related to muscle straining.

Provide care for the incision, the surgical drain, and possibly a T-tube to drain bile into a drainage bag via gravity flow. The surgeon typically removes the surgical dressing and drain within 24 hours after surgery.

! NURSING SAFETY PRIORITY

Action Alert

The priority for caring for the patient with a T-tube is to avoid raising the drainage system above the site of insertion to prevent backup of bile into the surgical area and causing infection. Although less commonly used today due to many complications, the T-tube may remain in place for over a week.

The patient is NPO until fully awake postoperatively. Document the patient’s level of consciousness, vital signs, and pain level. Assess the surgical incision for signs of infection, such as excessive redness or purulent drainage. Report changes to the surgeon immediately. Begin ambulation as soon as possible to prevent deep vein thrombosis and promote peristalsis.

TABLE 62-2 CAUSES OF POSTCHOLECYSTECTOMY SYNDROME

• Pseudocyst • Common bile duct (CBD) leak • CBD or pancreatic duct stricture or obstruction • Sphincter of Oddi dysfunction	• Retained or new CBD gallstone • Pancreatic or liver mass • Primary sclerosing cholangitis • Diverticular compression
---	---

Advance the diet from clear liquids to solid foods as peristalsis returns. The patient usually resumes solid foods and is discharged to home 1 to 2 days after surgery, depending on any complications and the patient's general condition. In the early postoperative period, if bile flow is reduced, a low-fat diet may reduce discomfort and prevent nausea. For most patients, a special diet is not required. Advise them to eat nutritious meals and avoid excessive intake of fatty foods, especially fried food, butter, and "fast food." If the patient is obese, recommend a weight-reduction program, such as Weight Watchers.

Teach the patient to keep the incision clean and report any changes that may indicate infection. Remind him or her to report repeat abdominal or epigastric pain with vomiting that may occur several weeks to months after surgery. These symptoms indicate possible **postcholecystectomy syndrome (PCS)**.

Although PCS occurs in a small number of patients, patients who have it are usually discouraged that they have pain after already having surgery to cure it (Comstock, 2008). Causes of PCS are listed in Table 62-2. Management depends on the exact cause but usually involves the use of endoscopic retrograde cholangiopancreatography (ERCP) to find the cause of the problem and repair it. This procedure and related nursing care are described in Chapter 55. Collaborative care includes pain management, antibiotics, nutrition and hydration therapy (possibly short-term parenteral nutrition), and control of nausea and vomiting.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client is admitted to the same-day surgery unit after recovery from a laparoscopic cholecystectomy. Which action is the nurse's priority in caring for the client?

- Turn the client on the right side to help the flow of bile into the drainage bag.
- Check that the nasogastric tube is connected to low intermittent suction.
- Document the client's use of the patient-controlled analgesia (PCA) pump.
- Monitor the client's oxygen saturation level via pulse oximetry.

CANCER OF THE GALLBLADDER

Pathophysiology

Primary cancer of the gallbladder is rare and is more common in women than in men. Adenocarcinoma and squamous cell cancer of the gallbladder account for the majority of the cases. The tumor tends to begin in the inner layer (mucosa) of the gallbladder wall. It then grows outward to include the entire gallbladder before it begins to metastasize (spread) to

close organs like the liver, small intestine, and pancreas. These rare cancers appear more frequently in patients with pre-existing chronic cholecystitis and cholelithiasis. They also tend to occur more often in American Indians than in any other group, but the reason for this finding is not known (McCance et al., 2010).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Early symptoms, when present, develop slowly and are similar to those of chronic cholecystitis and cholelithiasis. Assess for characteristic manifestations, which include:

- Anorexia
- Weight loss
- Nausea and vomiting
- Abdominal bloating
- Fever
- General malaise
- Jaundice (in advanced disease)
- Enlargement of the liver and spleen
- Severe abdominal pain (in advanced disease)

A moderately tender, irregularly shaped mass may be palpated. Gallbladder cancer is typically discovered during other procedures for diagnosis of suspected cholecystitis or during cholecystectomy.

The diagnosis of gallbladder cancer is usually made by ultrasonography, but other tests can be done. Some patients have a computed tomography (CT) scan or magnetic resonance cholangiopancreatography (MRCP) in which a contrast medium is injected into the bile ducts. Other more invasive tests, like endoscopic retrograde cholangiopancreatography (ERCP), may be performed. Liver function studies indicate liver involvement. Two serum tests that reveal the presence of cancer cells are carcinoembryonic antigen (CEA) assay and CA 19-9.

INTERVENTIONS

The prognosis for the patient with cancer of the gallbladder is poor because it is usually diagnosed in late disease due to the lack of specific manifestations. Three treatments are used: surgery, radiation therapy, and chemotherapy. Surgical intervention is either potentially curative (for an early resectable tumor) or palliative (for advanced disease with metastasis). The patient who is diagnosed with early disease has either a simple cholecystectomy (gallbladder removal) or extended cholecystectomy (removal of the gallbladder, surrounding lymph nodes, and a small margin of the liver). For palliative surgery to extend the patient's life or decrease discomfort, radical surgery is done.

Nursing care is similar to that for patients who have a cholecystectomy (see p. 1319) or Whipple procedure (see p. 1331), depending on the extent of disease. These procedures are described elsewhere in this chapter. Teach terminally ill patients and their families about end-of-life care and available hospice services (see Chapter 9).

Radiation therapy and chemotherapy alone are not effective for gallbladder cancer. However, they may be given as adjunctive procedures with surgery or instead of surgery in patients who are not surgical candidates to shrink the tumor.

Intensity-modulated radiation therapy that is much more advanced and intense than regular radiation is used. Chemotherapy with 5-fluorouracil (5-FU), doxorubicin, and mitomycin may be effective in reducing tumor size. [Chapter 24](#) describes in detail the care of the patient receiving radiation and chemotherapy.

PANCREATIC DISORDERS

ACUTE PANCREATITIS

Pathophysiology

Acute pancreatitis is a serious and, at times, life-threatening inflammatory process of the pancreas. This process is caused by a premature activation of excessive pancreatic enzymes that destroy ductal tissue and pancreatic cells, resulting in autodigestion and fibrosis of the pancreas. The pathologic changes occur in different degrees. The severity of pancreatitis depends on the extent of inflammation and tissue damage. Pancreatitis can range from mild involvement evidenced by edema and inflammation to **necrotizing hemorrhagic pancreatitis (NHP)**. NHP is diffusely bleeding pancreatic tissue with fibrosis and tissue death.

The pancreas is unusual in that it functions as both an exocrine gland and an endocrine gland. The primary *endocrine* disorder is diabetes mellitus and is discussed in [Chapter 67](#). The *exocrine* function of the pancreas is responsible for secreting enzymes that assist in the breakdown of starches, proteins, and fats. These enzymes are normally secreted in the inactive form and become activated once they enter the small

intestine. Early activation (i.e., activation within the pancreas rather than the intestinal lumen) results in the inflammatory process of pancreatitis. Direct toxic injury to the pancreatic cells and the production and release of pancreatic enzymes (e.g., trypsin, lipase, elastase) result from the obstructive damage. After pancreatic duct obstruction, increased pressure may contribute to ductal rupture allowing spillage of trypsin and other enzymes into the pancreatic parenchymal tissue. Autodigestion of the pancreas occurs as a result ([Fig. 62-2](#)). In *acute* pancreatitis, four major pathophysiologic processes occur: lipolysis, proteolysis, necrosis of blood vessels, and inflammation.

The hallmark of pancreatic necrosis is enzymatic fat necrosis of the endocrine and exocrine cells of the pancreas caused by the enzyme *lipase*. Fatty acids are released during this *lipolytic process* and combine with ionized calcium to form a soaplike product. The initial rapid lowering of serum calcium levels is not readily compensated for by the parathyroid gland. Because the body needs ionized calcium and cannot use bound calcium, hypocalcemia occurs.

Proteolysis involves the splitting of proteins by hydrolysis of the peptide bonds, resulting in the formation of smaller polypeptides. Proteolytic activity may lead to thrombosis and gangrene of the pancreas. Pancreatic destruction may be localized and confined to one area or may involve the entire organ.

Elastase is activated by trypsin and causes elastic fibers of the blood vessels and ducts to dissolve. The *necrosis of blood vessels* results in bleeding, ranging from minor bleeding to massive hemorrhage of pancreatic tissue. Another pancreatic

FIG. 62-2 The process of autodigestion in acute pancreatitis.

enzyme, kallikrein, causes the release of vasoactive peptides, bradykinin, and a plasma kinin known as *kallidin*. These substances contribute to vasodilation and increased vascular permeability, further compounding the hemorrhagic process. This massive destruction of blood vessels by necrosis may lead to generalized hemorrhage with blood escaping into the retroperitoneal tissues. *The patient with hemorrhagic pancreatitis is critically ill, and extensive pancreatic destruction and shock may lead to death. The majority of deaths in patients with acute pancreatitis result from irreversible shock.*

The *inflammatory stage* occurs when leukocytes cluster around the hemorrhagic and necrotic areas of the pancreas. A secondary bacterial process may lead to suppuration (pus formation) of the pancreatic parenchyma or the formation of an abscess. (See discussion of Pancreatic Abscess on p. 1328.) Mild infected lesions may be absorbed. When infected lesions are severe, calcification and fibrosis occur. If the infected fluid becomes walled off by fibrous tissue, a pancreatic pseudocyst is formed. (See discussion of **Pancreatic Pseudocyst** on p. 1329.)

Complications of Acute Pancreatitis

Acute pancreatitis may result in severe, life-threatening complications (Table 62-3). Jaundice occurs from swelling of the head of the pancreas, which slows bile flow through the common bile duct. The bile duct may also be compressed by calculi (stones) or a pancreatic pseudocyst. The resulting total bile flow obstruction causes severe jaundice. Intermittent hyperglycemia occurs from the release of glucagon, as well as the decreased release of insulin due to damage to the pancreatic islet cells. Total destruction of the pancreas may occur, leading to type 1 diabetes.

Left lung pleural effusions frequently develop in the patient with acute pancreatitis. Amylase effusions probably occur when exudate containing pancreatic enzymes passes from the peritoneal cavity into the pleural cavity via the transdiaphragmatic lymph channels. *Atelectasis and pneumonia may occur also, especially in older patients.*

Multi-system organ failure is caused by necrotizing hemorrhagic pancreatitis (NHP). The patient is at risk for acute respiratory distress syndrome (ARDS). This severe form of pulmonary edema is caused by disruption of the alveolar-capillary membrane and is a serious complication of acute pancreatitis. (See Chapter 34 for a discussion of ARDS.) In acute pancreatitis, pulmonary failure accounts for more than half of all deaths that occur in the first week of the disease.

Coagulation defects are another major potential complication and may result in death. Complex physiologic changes in the pancreas cause the release of necrotic tissue and enzymes into the bloodstream, resulting in altered

coagulation. Disseminated intravascular coagulation (DIC) involves hypercoagulation of the blood, with consumption of clotting factors and the development of microthrombi.

Shock in acute pancreatitis results from peripheral vasodilation from the released vasoactive substances and the retroperitoneal loss of protein-rich fluid from proteolytic digestion. Hypovolemia may result in decreased renal perfusion and acute renal failure. Paralytic (adynamic) ileus results from peritoneal irritation and seepage of pancreatic enzymes into the abdominal cavity.

Etiology and Genetic Risk

In many cases, the cause of pancreatitis is not known, but many factors can injure the pancreas. The most common cause is biliary tract disease, with gallstones accounting for almost half of the cases of obstructive pancreatitis. Acute pancreatitis may occur as a result of trauma from surgical manipulation after biliary tract, pancreatic, gastric, and duodenal procedures, such as cholecystectomy, the Whipple procedure, and partial gastrectomy. The trauma may also occur as a complication of the diagnostic procedure *endoscopic retrograde cholangiopancreatography (ERCP)*, although this rarely occurs.

Other causative factors include:

- Trauma: external (blunt trauma, stab wounds, gunshot wounds [GSWs])
- Pancreatic obstruction: tumors, cysts, or abscesses; abnormal organ structure
- Metabolic disturbances: hyperlipidemia, hyperparathyroidism, or hypercalcemia
- Renal disturbances: failure or transplantation
- Familial, inherited pancreatitis
- Penetrating gastric or duodenal ulcers, resulting in peritonitis
- Viral infections, such as coxsackievirus B infection
- Alcoholism
- Toxicities of drugs, including opiates, sulfonamides, thiazides, steroids, and oral contraceptives (less common)

Incidence/Prevalence

Pancreatic “attacks” are especially common during holidays and vacations when alcohol consumption may be high, especially in men. Women are affected most often after cholelithiasis and biliary tract problems. They are also most at risk for pancreatitis within several months after childbirth.

Death occurs in a small percentage of patients with acute pancreatitis, but with early diagnosis and treatment, mortality can be reduced. It occurs at a higher rate in *older adults* and in patients with postoperative pancreatitis. The prognosis for recovery is usually good for pancreatitis associated with biliary tract disease and poor if pancreatitis accompanies alcoholism.

TABLE 62-3 POTENTIAL COMPLICATIONS OF ACUTE PANCREATITIS

• Pancreatic infection (causes septic shock) • Hemorrhage (necrotizing hemorrhagic pancreatitis [NHP]) • Acute kidney failure • Paralytic ileus • Hypovolemic shock • Pleural effusion	• Acute respiratory distress syndrome (ARDS) • Atelectasis • Pneumonia • Multi-organ system failure • Disseminated intravascular coagulation (DIC) • Type 2 diabetes mellitus
---	--

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Most often, the patient reports severe and constant abdominal pain. Conduct the interview *after pain is controlled*. Ask whether the abdominal pain occurs when drinking alcohol or

eating a high-fat meal. Obtain information about alcohol usage, including the amount of alcohol consumed during what period of time (i.e., years of consumption, how much usually consumed over a particular period). Question the patient about a family or personal history of alcoholism, pancreatitis, trauma, or biliary tract disease. Ask whether any abdominal surgical interventions, such as cholecystectomy, or diagnostic procedures, such as ERCP, have been performed recently.

Ask about other medical problems known to cause pancreatitis, including peptic ulcer disease, renal failure, vascular disorders, hyperparathyroidism, and hyperlipidemia. Inquire about recent viral infections. Ask the patient or family member to list all prescription and over-the-counter (OTC) drugs taken recently, including nutritional and herbal supplements.

Physical Assessment/Clinical Manifestations

The diagnosis of pancreatitis is made based on the clinical presentation combined with the results of diagnostic studies—both laboratory and imaging assessments. Clinical manifestations of acute pancreatitis vary widely and depend on the severity of the inflammation. Typically, a patient is diagnosed after presenting with severe abdominal pain in the mid-epigastric area or left upper quadrant. Assess the intensity and quality of pain. The patient often states that the pain had a sudden onset and radiates to the back, left flank, or left shoulder. The pain is described as intense, **boring** (feeling that it is going through the body), and continuous and is worsened by lying in the supine position. Often the patient finds relief by assuming the fetal position (with the knees drawn up to the chest and the spine flexed) or by sitting upright and bending forward. He or she may report weight loss resulting from nausea and vomiting. Ask a nursing assistant or technician to weigh the patient.

When performing an abdominal assessment, inspect for:

- Generalized jaundice
- Gray-blue discoloration of the abdomen and periumbilical area
- Gray-blue discoloration of the flanks, caused by pancreatic enzyme leakage to cutaneous tissue from the peritoneal cavity

Listen for bowel sounds; absent or decreased bowel sounds usually indicate paralytic (adynamic) ileus. On light palpation, note abdominal tenderness, rigidity, and guarding as a result of peritonitis. A palpable mass may be found if a pancreatic pseudocyst is present. Pancreatic ascites creates a dull sound on percussion.

Monitor and record vital signs frequently to assess for elevated temperature, tachycardia, and decreased blood

pressure, or delegate and supervise this activity. Respiratory problems, such as left lung pleural effusions, atelectasis, and pneumonia, are common in patients with acute pancreatitis. Auscultate the lung fields for adventitious sounds or diminished breath sounds, and observe for dyspnea or orthopnea.

Psychosocial Assessment

If excessive alcohol is a causative factor, tactfully explore the patient's alcohol intake history. Provide patient privacy and establish a trusting relationship. Discuss the intake of alcohol and the reasons for overindulging. Ask him or her when increased drinking episodes occur and, in particular, whether binges occur during holidays, vacations, or weekends or revolve around particular activities, such as television viewing. Question the patient about any recent traumatic or stressful event that may have contributed to increased alcohol consumption, such as the death of a family member or a job loss.

Laboratory Assessment

Diagnostic laboratory abnormalities are typical in patients with acute pancreatitis (Table 62-4). A variety of pancreatic and nonpancreatic disorders can cause increased serum amylase levels. In patients with pancreatitis, *amylase* levels usually increase within 12 to 24 hours and remain elevated for 2 to 3 days. Persistent elevations may be an indicator of pancreatic abscess or pseudocyst (Pagana & Pagana, 2010).

Lipase also helps determine the presence of acute pancreatitis. Serum levels may rise later than amylase and remain elevated for up to 2 weeks. Because these levels stay elevated for such a long time, the health care provider may find this test useful in diagnosing patients who are not examined until several days after the initial onset of symptoms. An increase in lipase and amylase in the urine is also expected (Pagana & Pagana, 2010).

If pancreatitis is accompanied by biliary dysfunction (biliary pancreatitis), serum *bilirubin* and *alkaline phosphatase* levels are usually elevated. A sensitive indicator of biliary

TABLE 62-4 CAUSES OF DIAGNOSTIC LABORATORY ABNORMALITIES IN ACUTE PANCREATITIS

ABNORMAL FINDING	CAUSE
Cardinal Diagnostic Tests	
Increased <i>serum amylase</i>	Pancreatic cell injury
Elevated <i>serum lipase</i>	Pancreatic cell injury
Elevated <i>serum trypsin</i>	Pancreatic cell injury
Elevated <i>serum elastase</i>	Pancreatic cell injury
Other Diagnostic Tests	
Elevated serum glucose	Pancreatic cell injury, resulting in impaired carbohydrate metabolism; decreased insulin release
Decreased serum calcium and magnesium	Fatty acids combined with calcium; seen in fat necrosis
Elevated bilirubin	Hepatobiliary obstructive process
Elevated alanine aminotransferase	Hepatobiliary involvement
Elevated leukocyte count	Inflammatory response

! NURSING SAFETY PRIORITY

Critical Rescue

For the patient with acute pancreatitis, monitor for significant changes in vital signs that may indicate the life-threatening complication of shock. Hypotension and tachycardia may result from pancreatic hemorrhage, excessive fluid volume shifting, or the toxic effects of abdominal sepsis from enzyme damage. Observe the patient for changes in behavior and level of consciousness (LOC) that may be related to alcohol withdrawal, hypoxia, or impending sepsis with shock.

obstruction in acute pancreatitis is serum *alanine aminotransferase (ALT)*. A threefold or greater rise in concentration indicates that the diagnosis of acute biliary pancreatitis is valid. Elevated *white blood cell (WBC) count and differential*, *erythrocyte sedimentation rate (ESR)*, and serum *glucose* levels are also common in acute pancreatitis. The levels often correlate with disease severity.

Decreased serum *calcium* and *magnesium* levels are seen with fat necrosis. Calcium levels may fall and remain decreased for 7 to 10 days. Those that consistently remain below 8 mg/dL are associated with a poor prognosis. Other tests include the basic metabolic panel (BMP), complete blood count (CBC), triglycerides, serum total protein, and albumin. The blood urea nitrogen (BUN), serum glucose, and triglycerides are usually elevated. Hemoconcentration is common as a result of third-space fluid loss. Leukocytosis (elevated WBCs) and thrombocytopenia (decreased platelets) are common (Holcomb, 2007). Albumin levels are decreased because cytokines (e.g., tumor necrosis factor [TNF]) released as part of the inflammatory response allow it to move from the bloodstream into the extravascular space. The presence of C-reactive protein suggests pancreatic inflammation and necrosis.

Imaging Assessment

Abdominal ultrasound is the most sensitive test to diagnose causes of pancreatitis like gallstones and can be performed at the bedside. However, it is not helpful in viewing the pancreas because of overlying bowel gas. Therefore *contrast-enhanced computed tomography (CT)* provides a more reliable image and diagnosis of acute pancreatitis. This noninvasive technique may also be used to rule out pancreatic pseudocyst or ductal calculi.

An abdominal x-ray may also reveal gallstones. A chest x-ray may show elevation of the left side of the diaphragm or pleural effusion. Pancreatic stones are best diagnosed through ERCP.

ANALYSIS

The priority problems for patients with acute pancreatitis are:

1. Acute Pain related to pancreatic inflammation and enzyme leakage
2. Inadequate nutrition related to the inability to ingest food and absorb nutrients

PLANNING AND IMPLEMENTATION

Managing Acute Pain

Planning: Expected Outcomes. The patient with acute pancreatitis is expected to state that he or she has a decrease in or absence of abdominal pain, as evidenced by a pain intensity scale measurement.

Interventions. The priorities for patient care are to provide supportive care by relieving symptoms, to decrease inflammation, and to anticipate or treat complications. As for any patient, continually assess for and support the ABCs (*airway, breathing, and circulation*). In collaboration with the respiratory therapist, if available, provide oxygen and other respiratory support as needed. The collaborative plan of care depends on the severity of the illness.

Abdominal pain is the most common symptom of pancreatitis. The main focus of nursing care is aimed at controlling pain by interventions that decrease GI tract activity, thus decreasing pancreatic stimulation. Pain assessment to measure

the effectiveness of these interventions is an essential part of nursing care.

Nonsurgical Management. Mild pancreatitis requires hydration with IV fluids, pain control, and drug therapy. The health care team initially attempts to relieve pain with non-surgical interventions, which include fasting and rest, drug therapy, and comfort measures. If the patient has a life-threatening complication or requires frequent assessment, he or she is admitted to a critical care unit for invasive hemodynamic monitoring.

To rest the pancreas and reduce pancreatic enzyme secretion, withhold food and fluids during the acute period. The health care provider prescribes IV isotonic fluid administration to maintain hydration. IV replacement of calcium and magnesium may also be needed. Measure and document intake and output. Some patients have an indwelling urinary catheter to obtain accurate measurements.

Nasogastric drainage and suction are reserved for more severely ill patients who have continuous vomiting or biliary obstruction. Gastric decompression using a nasogastric tube (NGT) prevents gastric juices from flowing into the duodenum.

! NURSING SAFETY PRIORITY

Action Alert

Because paralytic (adynamic) ileus is a common complication of acute pancreatitis, prolonged nasogastric intubation may be necessary. Assess frequently for the return of peristalsis by asking the patient if he or she has passed flatus or had a stool. The return of bowel sounds is not reliable as an indicator of peristalsis return.

To decrease pain, the primary drug class used is opioid. Other drugs may also be prescribed. Pain management for acute pancreatitis typically begins with the administration of opioids by patient-controlled analgesia (PCA). Drugs such as morphine or hydromorphone (Dilaudid) are typically used because meperidine (Demerol) can cause seizures, especially in older adults. Other options that have been used successfully to manage acute pain include IV or transdermal fentanyl and epidural analgesia.

In mild pancreatitis, the pain usually subsides in 2 to 3 days. However, with severe acute pancreatitis, the abdominal pain and tenderness may persist for up to 2 weeks. The dosages and intervals of drug administration are individualized according to the severity of the disease and the symptoms.

Histamine receptor antagonists (e.g., ranitidine [Zantac]) and proton pump inhibitors (e.g., omeprazole [Prilosec]) help decrease gastric acid secretion. Antibiotics may be used, but they are indicated primarily for patients with acute necrotizing pancreatitis. Common drugs used include cefuroxime (Zinacef) and ceftazidime (Ceptaz).

Helping the patient assume a side-lying position (with the legs drawn up to the chest) may decrease the abdominal pain of pancreatitis. Sitting with the knees flexed toward the chest is also helpful.

If the patient is NPO or has an NGT, remind assistive nursing personnel to implement frequent oral hygiene measures to keep mucous membranes moist and free of inflammation or crusting. Because of the drying effect of drugs and the absence of oral fluids, the mouth and oral cavity may be

extremely dry, resulting in considerable discomfort and possibly parotitis (inflammation of the parotid [salivary] glands).

! NURSING SAFETY PRIORITY

Action Alert

For the patient with acute pancreatitis, monitor his or her respiratory status every 8 hours or more often as needed, and provide oxygen to promote comfort in breathing. Respiratory complications such as pleural effusions increase patient discomfort. Fluid overload can be detected by assessing for weight gain, listening for crackles, and observing for dyspnea. Carefully monitor for signs of respiratory failure.

Observe for signs and symptoms of hypocalcemia by assessing for Chvostek's and Trousseau's signs. These tests cause muscle spasms after stimulating the associated nerves. [Chapter 13](#) discusses assessment and interventions for patients with hypocalcemia in more detail.

Lowering the patient's anxiety level may also substantially reduce pain. Explain all procedures and other aspects of patient care thoroughly. Provide reassurance, offer diversional activities such as music and reading material, and encourage visitors to direct attention away from the pain.

If pancreatitis was caused by gallstones, an ERCP with a **sphincterotomy** (opening of the sphincter of Oddi) may be performed on an urgent or emergent basis. If this procedure is not successful, surgery is required. ERCP is described in detail in [Chapter 55](#).

Surgical Management. Surgical intervention for acute pancreatitis is usually not indicated. However, if an ERCP is not successful in removing gallstones, a laparoscopic cholecystectomy may be performed as described on p. 1319 in the discussion of Surgical Management in the Cholecystitis section.

Complications of pancreatitis, such as pancreatic pseudocyst and abscess, may also require surgical intervention. Laparoscopy (minimally invasive surgery [MIS]) may be done to drain an abscess or pseudocyst. For patients who are high surgical risks, pseudocysts or abscesses can be treated by percutaneous drainage under CT guidance.

Promoting Nutrition

Planning: Expected Outcomes. The patient with acute pancreatitis is expected to have adequate nutrition to meet his or her metabolic needs.

Interventions. The patient is maintained on NPO status in the early stages of pancreatitis. Antiemetics for nausea and vomiting are prescribed as needed. Patients who have severe pancreatitis and are unable to eat for 24 to 48 hours after illness onset may begin jejunal tube feeding unless paralytic ileus is present. *Early* nutritional intervention enhances immune system functioning and may prevent complications and worsening inflammation. Enteral feeding is preferred over total parenteral nutrition (TPN) because it causes fewer episodes of glucose elevation and other complications associated with TPN. Be sure that the patient is weighed every day. Collaborate with the health care provider, dietitian, and pharmacist to plan and implement the most appropriate nutritional intervention. [Chapter 63](#) describes collaborative care of patients receiving enteral feeding and TPN.

When food is tolerated during the healing phase, the health care provider prescribes small, frequent, moderate- to high-carbohydrate, high-protein, low-fat meals. Foods should

be bland with little spice. GI stimulants such as caffeine-containing foods (tea, coffee, cola, and chocolate), as well as alcohol, should be avoided. Monitor the patient beginning to resume oral food intake for nausea, vomiting, and diarrhea. *If any of these symptoms occur, notify the health care provider immediately.*

To boost caloric intake, commercial liquid nutritional preparations supplement the diet. The health care provider may also prescribe fat-soluble and other vitamin and mineral replacement supplements. Glutamine, omega-3 fatty acids, fiber, antioxidants, and/or nucleotides may be added to the patient's nutrition plan.

Community-Based Care

Home care preparation is individualized for each patient's circumstances. Some patients may be severely weakened from their acute illness and need to confine activity to one floor, limiting stair climbing and other strenuous activities until they regain their strength. Collaborate with the case manager to plan the best place for the patient to recover and resources that may be needed.

Education needs to be started early in the hospitalization period—as soon as the acute episodes of pain have subsided. Assess the patient's and family's knowledge of the disease.

The desired outcomes for discharge planning and education are to avoid further episodes of pancreatitis and prevent progression to a chronic disease. If the patient abuses alcohol, instruct him or her to abstain from drinking to prevent further pain attacks and extension of inflammation and pancreatic insufficiency. Tell the patient that if alcohol is consumed, acute pain will return and further autodigestion of the pancreas may lead to chronic pancreatitis.

Teach the patient to notify the health care provider after discharge to home if acute abdominal pain or biliary tract disease (as evidenced by jaundice, clay-colored stools, or darkened urine) occurs. These signs and symptoms are possible indicators of complications or disease progression.

Patients with acute pancreatitis may require several visits by a home care nurse if the hospital course was complicated. In these cases, home care may be needed for wound care and assistance with ADLs. The patient requires medical follow-up

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice; Teamwork and Collaboration; Informatics

A 78-year-old man is admitted from home to the medical unit with acute pancreatitis secondary to a history of gallstones, hypertension, osteoarthritis, and type 2 diabetes mellitus. He has lost 20 pounds (9.0 kg) in the past 2 months and reports severe boring-like abdominal pain, fatigue, and weakness. On physical assessment, he has decreased bowel sounds in all quadrants, crackles in the bases of his lungs, and signs of dehydration. Vital signs are: T, 100° F; P, 110; R, 36; and BP, 102/58.

1. What is the priority for this patient's care at this time? What current evidence supports your answer? Where would you look for current evidence that would help you answer this question? (Be specific in your answer.)
2. What laboratory findings would you expect him to have? Why?
3. With whom should you collaborate to meet the desired outcomes for his care?
4. What community support and health teaching is he going to require when he is discharged?

with the primary care physician or nurse practitioner to monitor the disease process. For those with alcoholism, provide information about groups such as Alcoholics Anonymous (AA). Family members may attend support groups such as Al-Anon and Alateen.

EVALUATION: OUTCOMES

Evaluate the care of the patient with acute pancreatitis based on the identified priority patient problems. The expected outcomes include that the patient will:

- Have control of abdominal pain, as indicated by self-report
- Have adequate nutrients available to meet metabolic needs

CHRONIC PANCREATITIS

Pathophysiology

Chronic pancreatitis is a progressive, destructive disease of the pancreas that has remissions and exacerbations (“flare-ups”). Inflammation and fibrosis of the tissue contribute to pancreatic insufficiency and diminished function of the organ.

Chronic pancreatitis can be classified into several categories. *Alcoholism* is the primary risk factor for **chronic calcifying pancreatitis (CCP)**, the most common type. In the early stages of the disease, pancreatic secretions precipitate as insoluble proteins that plug the pancreatic ducts and flow of pancreatic juices. As the protein plugs become more widespread, the cellular lining of the ducts changes and ulcerates. This inflammatory process causes fibrosis of the pancreatic tissue. Intraductal calcification and marked pancreatic tissue destruction (necrosis) develop in the late stages. The organ becomes hard and firm as a result of cell atrophy and pancreatic insufficiency.

Chronic calcifying pancreatitis is found predominantly in men, but the incidence in women is increasing. In women, chronic pancreatitis occurs more commonly among those with biliary tract disease (cholecystitis and cholelithiasis).

Chronic obstructive pancreatitis develops from inflammation, spasm, and obstruction of the sphincter of Oddi, often from cholelithiasis (gallstones). Inflammatory and sclerotic lesions occur in the head of the pancreas and around the ducts, causing an obstruction and backflow of pancreatic secretions. (See *Complications of Acute Pancreatitis*, p. 1322.)

Autoimmune pancreatitis is a chronic inflammatory process in which immunoglobulins invade the pancreas. Other organs may also be infiltrated, including the lungs and liver. Whereas other types of chronic pancreatitis may predispose the patient to pancreatic cancer, there is no evidence that autoimmune pancreatitis is a risk factor (Novotny et al., 2010).

Idiopathic and **hereditary chronic pancreatitis** may be associated with *SPINK1* and *CFTR* gene mutations (Midha et al., 2010). The protein encoded by the *SPINK1* gene is a trypsin inhibitor. The *CFTR* gene is associated with cystic fibrosis. Research on these gene mutations can help develop targeted drug therapy for treatment of these diseases.

Pancreatic insufficiency in any type of chronic pancreatitis causes loss of *exocrine* function. Most patients with chronic pancreatitis have decreased pancreatic secretions and bicarbonate. Pancreatic enzyme secretion must be greatly reduced to produce steatorrhea resulting from severe malabsorption

of fats. These characteristic stools are pale, bulky, and frothy and have an offensive odor. The action of colonic bacteria on unabsorbed lipids and proteins is responsible for the extremely foul odor. On inspection of the stools, the fat content is visible. In severe chronic pancreatitis, stool fat output may be more than 40 g/day.

Fat malabsorption also contributes to weight loss and muscle wasting (a decrease in muscle mass) and leads to general debilitation. Protein malabsorption results in a “starvation” edema of the feet, legs, and hands caused by decreased levels of circulating albumin.

The loss of pancreatic *endocrine* function is responsible for the development of diabetes mellitus in patients with chronic pancreatic insufficiency. (See *Chapter 67* for a complete discussion of diabetes mellitus.)

The patient with chronic pancreatitis may have pulmonary complications, such as pleuritic pain, pleural effusions, and pulmonary infiltrates. Pancreatic ascites may decrease diaphragmatic excursion and lung expansion, resulting in impaired ventilation. In the ill patient with chronic pancreatitis, acute respiratory distress syndrome (ARDS) may develop.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Many of the clinical manifestations of chronic pancreatitis differ from those of an acute inflammation. Abdominal pain is the major clinical manifestation for most types of pancreatitis (*Chart 62-2*). For those with chronic pancreatitis, pain is typically describes as a continuous burning or gnawing dullness with periods of acute exacerbation (flare-ups). The pain is very intense and relentless. The frequency of acute exacerbations may increase as the pancreatic fibrosis develops.

Perform an abdominal assessment. Abdominal tenderness is less intense in patients with chronic pancreatitis than in those with acute pancreatitis. A mass may be palpated in the left upper quadrant, which may suggest a pancreatic pseudocyst or abscess. Massive pancreatic ascites may be present, producing dullness on abdominal percussion. Because respiratory complications can occur, auscultate the lung fields for adventitious sounds or decreased aeration and observe for dyspnea or orthopnea.

CHART 62-2 KEY FEATURES

Chronic Pancreatitis

- Intense abdominal pain (major clinical manifestation) that is continuous and burning or gnawing
- Abdominal tenderness
- Ascites
- Possible left upper quadrant mass (if pseudocyst or abscess is present)
- Respiratory compromise manifested by adventitious or diminished breath sounds, dyspnea, or orthopnea
- Steatorrhea; clay-colored stools
- Weight loss
- Jaundice
- Dark urine
- Polyuria, polydipsia, polyphagia (diabetes mellitus)

Ask the patient to collect a random stool specimen if able, or ask him or her to describe the stools. The specimen may show **steatorrhea** (foul-smelling fatty stools that may increase in volume as pancreatic insufficiency progresses and lipase production decreases). Assess for unintentional weight loss, muscle wasting, jaundice, dark urine, and the manifestations of diabetes mellitus, such as polyuria (increased urinary output), polydipsia (excessive thirst), and polyphagia (increased appetite).

Diagnosis is based on the patient's clinical manifestations and laboratory and imaging assessment. Endoscopic retrograde cholangiopancreatography (ERCP) is done to visualize the pancreatic and common bile ducts. Imaging studies such as computed tomography (CT) scanning, contrast-enhanced magnetic resonance imaging (MRI), abdominal ultrasound (US), and endoscopic ultrasound (EUS) are also useful in making the diagnosis. In chronic pancreatitis, laboratory findings include normal or moderately elevated serum amylase and lipase levels. Obstruction of the intrahepatic bile duct can cause elevated serum bilirubin and alkaline phosphatase levels. Intermittent elevations in serum glucose levels are common and can be detected by blood glucose monitoring, both fasting and non-fasting.

INTERVENTIONS

The focus of caring for the patient with chronic pancreatitis is to manage pain, assist in maintaining a sufficient nutritional intake, and prevent recurrence.

Nonsurgical Management

Nonsurgical interventions include primarily drug and nutrition therapy. The major intervention for the pain of chronic pancreatitis is drug therapy. Medicate the patient as prescribed according to the assessment of the intensity of pain. Evaluate the effectiveness of the drug intervention. Opioid analgesia is most frequently used initially, but dependency may occur. Non-opioid analgesics may be tried to relieve pain. (See [Chapter 5](#) for other interventions for chronic pain.)

Pancreatic-enzyme replacement therapy (PERT) is the standard of care to prevent malnutrition, malabsorption, and excessive weight loss ([Chart 62-3](#)). Pancrelipase is usually prescribed in capsule or tablet form and contains varying amounts of amylase, lipase, and protease. Pancrelipase delayed-release capsules (Creon) or enteric tablets should not be crushed or chewed.

! NURSING SAFETY PRIORITY

Drug Alert

Teach the patient who is taking pancreatic-enzyme replacement therapy to take these drugs with meals and snacks and a glass of water. Instruct patients who have difficulty swallowing either to cover the capsules with applesauce or, if needed, open the capsules and spread their contents over applesauce, mashed fruit, or rice cereal. Enzyme preparations should not be mixed with foods containing proteins because the enzymatic action dissolves the food into a watery substance. Be sure that patients drink a full glass of water after taking the drug to ensure that none of the enzymes remain in the mouth. Advise patients to wipe their lips with a wet towel to prevent the skin irritation and breakdown that residual enzymes can cause.

The dosage of pancreatic enzymes depends on the severity of the malabsorption. Record the number and consistency of

CHART 62-3 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Enzyme Replacement for the Patient with Chronic Pancreatitis

- Take pancreatic enzymes with meals and snacks and follow with a glass of water.
- Administer enzymes after antacid or H₂ blockers. (Decreased pH inactivates drug.)
- Swallow the tablets or capsules without chewing to minimize oral irritation and to allow the drug to be released slowly.
- If you cannot swallow the capsule, pierce the gelatin casing and place contents in applesauce.
- Do not mix enzyme preparations in protein-containing foods.
- Wipe your lips after taking enzymes to avoid skin irritation.
- Do not crush enteric-coated preparations.
- Follow up on all scheduled laboratory testing. (Pancrelipase can cause an increase in uric acid levels.)

stools per day to monitor the effectiveness of enzyme therapy. If pancreatic enzyme treatment is effective, the stools should become less frequent and less fatty.

If the patient has diabetes, the health care provider prescribes insulin or oral hypoglycemic agents for glucose control. Patients maintained on total parenteral nutrition (TPN) are particularly susceptible to elevated glucose levels and may require regular insulin additives to the solution. Closely monitor blood glucose so that hyperglycemia is controlled. Check finger-stick blood glucose (FSBG) or sugar (FSBS) levels every 2 to 4 hours. [Chapter 63](#) describes in detail the care associated with TPN.

The health care provider may also prescribe drug therapy to decrease gastric acid. Gastric acid destroys the lipase needed to break down fats. Controlling the acidity of the stomach with H₂ blockers or proton pump inhibitors or neutralizing stomach acid with oral sodium bicarbonate may enhance the effectiveness of PERT.

Protein and fat malabsorption result in significant weight loss and decreased muscle mass in the patient with chronic pancreatitis. Therefore the nutritional interventions for acute pancreatitis are also used for chronic pancreatitis. The patient often limits food intake to avoid increased pain. For this reason, nutrition maintenance is often difficult to achieve. Patients receive either total parenteral nutrition (TPN) or total enteral nutrition (TEN), including vitamin and mineral replacement.

Collaborate with the dietitian to teach the patient about long-term dietary management. He or she needs an increased number of calories, up to 4000 to 6000 calories/day, to maintain weight. Those foods high in carbohydrates and protein also assist in the healing process. Foods high in fat are avoided because they cause or increase diarrhea. Teach all patients to avoid alcohol. Alcohol-cessation programs may be recommended.

Surgical Management

Surgery is not a primary intervention for the treatment of chronic pancreatitis. However, it may be indicated for ongoing abdominal pain, incapacitating relapses of pain, or complications such as abscesses and pseudocysts.

The underlying pathologic changes determine the procedure indicated. Using laparoscopy, the surgeon incises and

drains an abscess or pseudocyst. Laparoscopic cholecystectomy or choledochotomy (incision of the common bile duct) may be indicated if biliary tract disease is an underlying cause of pancreatitis. If the pancreatic duct sphincter is fibrotic, the surgeon performs a sphincterotomy (incision of the sphincter) to enlarge it. Endoscopic sphincterotomy may be used for patients who are poor surgical candidates.

In some cases, laparoscopic distal pancreatectomy may be appropriate for resection of the distal pancreas or pancreas head. Endoscopic pancreatic necrosectomy and natural orifice transluminal endoscopic surgery (NOTES) are becoming more common for removing necrosed pancreatic tissue. Both procedures are performed through the GI wall without a visible skin incision. The NOTES procedure is discussed in Surgical Management on p. 1319 in the Cholecystitis section.

In a few cases, pancreas transplantation may be done. However, this procedure is performed most often for patients with severe, uncontrolled diabetes. [Chapter 67](#) discusses pancreas transplantation.

Community-Based Care

Collaborate with the hospital-based case manager (CM) or discharge planner about home care or follow-up in another setting. A community-based CM may continue to follow the patient after hospital discharge. If the patient is discharged to home, the activity area should be limited to one floor until he or she regains strength and can increase activity. Teach patients and families that toilet facilities must be easily accessible because of chronic steatorrhea and frequent defecation. If they are not easily accessible, a bedside commode is obtained for the home.

Because there is no known cure for chronic pancreatitis, patient and family education is aimed at preventing acute episodes of the disease, providing long-term care, and promoting health maintenance ([Chart 62-4](#)). Teach the patient to avoid known irritating substances, such as caffeinated beverages (stimulates the GI system) and alcohol. Collaborate with the dietitian in diet teaching, which focuses on eating bland, low-fat, frequent meals and avoiding rich, fatty foods. Stress the importance of adhering to the nutritional recommendations. Written instructions are essential, with consideration of personal and cultural food preferences.

CHART 62-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Prevention of Exacerbations of Chronic Pancreatitis

- Avoid things that make your symptoms worse, such as drinking caffeinated beverages.
- Avoid alcohol ingestion; refer to self-help group for assistance.
- Avoid nicotine.
- Eat bland, low-fat, high-protein, moderate-carbohydrate meals; avoid gastric stimulants, such as spices.
- Eat small meals and snacks high in calories.
- Take the pancreatic enzymes that have been prescribed for you with meals.
- Rest frequently; restrict your activity to one floor until you regain your strength.

Remind the patient and family members or significant others of the importance of adhering to pancreatic enzyme replacement. The patient must take the prescribed enzymes with meals and snacks to aid in the digestion of food and promote the absorption of fats and proteins. Teach the patient to take the enzymes before or at the beginning of the meal. Instruct him or her to report any increase in abdominal distention, cramping, and foul-smelling, frothy, fatty stools to the health care provider so that these supplements may be increased as needed. Remind the patient to report any skin breakdown so that therapeutic interventions to promote skin integrity can be started. Abdominal fistulas are common and present a difficult challenge because pancreatic secretions irritate the skin.

The frequency of defecation (whether continent or incontinent) poses challenging skin care problems. Instruct the patient to keep the skin dry and free of the abrasive fatty stools, which damage the skin. The skin should be cleaned thoroughly after each stool and a moisture barrier applied to prevent breakdown and maintain skin integrity. Many products on the market actively repel stool from the skin.

If the patient develops diabetes mellitus as a result of chronic pancreatitis, management of elevated glucose levels after discharge from the hospital may require oral antidiabetic agents or insulin injections. If this is the case, collaborate with the certified diabetic educator (CDE) to provide in-depth teaching concerning diabetes, its signs and symptoms, medical management, drug therapy, nutrition therapy, blood glucose monitoring, and general care.

Chronic illnesses are devastating for families. The high costs of medical insurance, medical treatment, and drug therapy cause serious financial problems. Often the patient with chronic pancreatitis is unable to work. Collaborate with the CM about ways to assist the patient with resources for financial help.

The patient may require several home visits by nurses, depending on the severity of the chronic health problems and home maintenance and support needs. The nurse assesses the patient for pain management, adherence to the nutritional plan and alcohol abstinence, the effectiveness of pancreatic enzyme therapy, and psychosocial adaptation to a chronic illness. Refer him or her and the family to a counselor or a self-help group, such as Alcoholics Anonymous (www.aa.org) and Al-Anon (www.al-anon.org), if appropriate.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The physician assistant prescribes pancreatic enzyme replacement capsules for a client with chronic pancreatitis. What health teaching will the nurse provide?

- "Take the enzymes after meals to be most effective."
- "Swallow the capsule whole or with applesauce."
- "Drink a full glass of milk after taking the drug."
- "Crush the capsules and tablets and mix with juice."

PANCREATIC ABSCESS

Pancreatic abscesses are the most serious complication of acute necrotizing pancreatitis. If untreated, they are always fatal. After surgery, the recurrence rate is high. The abscesses form from collections of purulent liquefaction of the necrotic pancreas.

Pancreatic abscesses occur after severe acute pancreatitis, episodes of chronic pancreatitis, or gallbladder surgery. The development of either a single abscess or multiple abscesses results from extensive inflammatory necrosis of the pancreas that is readily invaded by infectious organisms, such as enteric bacteria and *Candida*. They can erode through the retroperitoneum into the bowel mesentery, the mediastinum, the pleural space, or the pelvis.

Patients with pancreatic abscesses often appear more seriously ill than those with pseudocysts. Clinical manifestations are similar. However, the temperature in patients with abscesses may spike to as high as 104° F (40° C). Blood cultures are helpful in revealing the infective organism. Pleural effusions commonly accompany these abscesses if they enter the pleural space. Ultrasonography and contrast-enhanced computed tomography (CT) cannot differentiate between pancreatic pseudocysts and abscesses.

Drainage via the percutaneous method or laparoscopy should be performed as soon as possible to prevent sepsis. Antibiotic treatment alone does not resolve the abscess. Death rates remain high even after surgical drainage. Many patients require multiple drainage procedures for repeated abscesses.

PANCREATIC PSEUDOCYST

Pathophysiology

Pancreatic pseudocysts, or false cysts, are so named because, unlike true cysts, they do not have an epithelial lining. They are encapsulated, saclike structures that form on or surround the pancreas. The pseudocyst wall is inflamed, vascular, and fibrotic. It may contain up to several liters of straw-colored or dark brown viscous fluid, the enzymatic exudate of the pancreas (McCance et al., 2010). Risk factors for pseudocysts are acute pancreatitis, abdominal trauma, and chronic pancreatitis.

PATIENT-CENTERED COLLABORATIVE CARE

A pseudocyst can be palpated as an epigastric mass in about half of all cases. The primary presenting symptom is epigastric pain radiating to the back. Other common clinical manifestations include abdominal fullness, nausea, vomiting, and jaundice. Pseudocysts are diagnosed and their growth and resolution monitored by serial pancreatic diagnostic testing. Complications of pseudocyst formation include:

- Hemorrhage
- Infection
- Obstruction of the bowel, biliary tract, or splenic vein
- Abscess
- Fistula formation
- Pancreatic ascites

Pseudocysts may spontaneously resolve, or they may rupture and produce hemorrhage. Surgical intervention is necessary if the pseudocyst does not resolve within 6 to 8 weeks or if complications develop. Possible surgeries include:

- Percutaneous drainage using a needle, usually under CT scan guidance
- Endoscopic-assisted drainage using an endoscope to locate the pseudocyst
- Surgical drainage of the pseudocyst into the stomach or jejunum

To provide external drainage, the surgeon inserts a sump drainage tube to remove pancreatic secretions and exudate. Pancreatic fistulas are common after surgery, and skin breakdown from corrosive pancreatic enzymes in patients who have external drainage presents a major nursing care challenge.

PANCREATIC CANCER

Pathophysiology

Cancer of the pancreas is a leading cause of cancer deaths each year in the United States. It is difficult to diagnose early because the pancreas is hidden and surrounded by other organs. Treatment has limited results, and 5-year survival rates are low (American Cancer Society [ACS], 2010).

Pancreatic tumors usually originate from epithelial cells of the pancreatic ductal system. If the tumor is discovered in the early stages, the tumor cells may be localized within the glandular organ. However, this is highly unlikely. Most often, the tumor is discovered in the late stages of development and may be a well-defined mass or is diffusely spread throughout the pancreas.

The tumor may be a primary cancer, or it may result from metastasis from cancers of the lung, breast, thyroid, kidney, or skin. Primary tumors are generally adenocarcinomas and grow in well-differentiated glandular patterns. They grow rapidly and spread to surrounding organs (stomach, duodenum, gallbladder, and intestine) by direct extension and invasion of lymphatic and vascular systems. This highly metastatic lesion may eventually invade the lung, peritoneum, liver, spleen, and lymph nodes.

Clinical manifestations depend on the site of origin or metastasis. The head of the pancreas is the most common site. The tumors are usually small lesions with poorly defined margins. Jaundice results from tumor compression and obstruction of the common bile duct and from gallbladder dilation, causing the organ to enlarge.

Cancers of the body and tail of the pancreas are usually large and invade the entire tail and body. These tumors may be palpable abdominal masses, especially in the thin patient. Through metastatic spread via the splenic vein, metastasis to the liver may cause **hepatomegaly** (enlargement of the liver up to two to three times its normal size). Cancers of the body and tail spread more extensively than do pancreatic head carcinomas, with invasion of the retroperitoneum, vertebral column, spleen, adrenal glands, colon, or stomach. Regardless of where it originates, it spreads rapidly through the lymphatic and venous systems to other organs.

Venous thromboembolism is a common complication of pancreatic cancer. Necrotic products of the pancreatic tumor are believed to have thromboplastic properties resulting in the blood's hypercoagulable state. In addition, the patient is at high risk because of decreased mobility and extensive surgical manipulation.

GENETIC/GENOMIC CONSIDERATIONS

A small number of those with pancreatic cancer have an inherited risk. Mutations in certain oncogenes have been identified. Mutations have also been revealed in tumor suppressor genes, such as *p16* and *BRCA2*—the same mutation that makes some women susceptible to breast and ovarian cancer. Genes responsible for hereditary non-polyposis colorectal cancer can also increase a person's risk for pancreatic cancer (ACS, 2010).

The exact cause of pancreatic cancer is unknown. High-risk populations are those in their sixth to eighth decades of life and those with a personal history of smoking.

Other risk factors associated with the disease include:

- Diabetes mellitus
- Chronic pancreatitis
- Cirrhosis
- High intake of red meat, especially processed meat like bacon
- Long-term exposure to chemicals such as gasoline and pesticides
- Obesity

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Pancreatic cancer often presents in a slow and vague manner. The presenting symptoms depend somewhat on the location of the tumor. The first sign may be jaundice, which suggests late, advanced disease (Chart 62-5). Jaundice occurs because the gallbladder and liver are commonly involved. As the tumor spreads, the green-gold skin color associated with obstructive jaundice progressively worsens. Ask the patient whether the color of the stool and urine has changed. As a result of the obstructive process, the stool is clay colored and the urine is dark and frothy. Inspect the skin for dryness and scratch marks, indicating pruritus from jaundice caused by bile salt collection. Assess the sclerae for icterus (yellowing) and the mucous membranes for signs of jaundice.

The enlarged gallbladder and liver may be palpable. In advanced cases of pancreatic carcinoma, the tumor may be felt as a firm, fixed mass in the left upper abdominal quadrant or epigastric region.

The most common concern is fatigue, which is described as a diminished energy level and an increased need for rest relative to the level of activity. The patient notices an inability to perform usual physical or intellectual activities.

Question the patient about abdominal pain, which is usually described as a vague, constant dullness in the upper abdomen and nonspecific in nature. Pain also indicates advanced stages of the disease and may be related to eating or activity. Ask whether the patient has pain in other areas of the body. Referred back pain may be caused by pressure on the nerve plexus. Some patients have leg or calf pain with swelling and redness as a result of deep vein thrombosis or thrombophlebitis.

CHART 62-5 KEY FEATURES

Pancreatic Cancer

- | | |
|---|--|
| • Jaundice | • Glucose intolerance |
| • Clay- (light) colored stools | • Splenomegaly (enlarged spleen) |
| • Dark urine | • Flatulence |
| • Abdominal pain: usually vague, dull, or nonspecific that radiates into the back | • Gastrointestinal bleeding |
| • Weight loss | • Ascites (abdominal fluid) |
| • Anorexia | • Leg or calf pain (from thrombophlebitis) |
| • Nausea or vomiting | • Weakness and fatigue |

Weigh the patient to determine the extent of weight loss and whether it has occurred rapidly. Ask about food intake and intolerances. Anorexia accompanied by early satiety, nausea, flatulence (gas), and vomiting are common. GI bleeding may develop from esophageal or gastric varices caused by the tumor pressing on the portal vein. A new diagnosis of diabetes is found in some patients.

In addition to the focused history, perform a general abdominal assessment. In particular, observe for distention and swelling, which may be **ascites** (abdominal fluid). Percussion over the ascitic abdomen elicits dullness, seen in the advanced stages of the disease process.

No specific blood tests diagnose pancreatic cancer. Serum amylase and lipase levels, as well as alkaline phosphatase and bilirubin levels, are increased. The degree of elevation depends on the acuteness or chronicity of the pancreatic and biliary damage. Elevated carcinoembryonic antigen (CEA) levels occur in most patients with pancreatic cancer. This test may provide early information about the presence of tumor cells. Other tumor markers such as CA 19-9 and CA 242 have been found to be useful serologic tests for monitoring a proven diagnosis and for continuing surveillance for potential spread or recurrence (Pagana & Pagana, 2010).

Abdominal ultrasound and contrast-enhanced computed tomography (CT) are the most commonly used imaging techniques for confirming a tumor and can differentiate the tumor from a cyst. Endoscopic ultrasonography can also be performed to sample tissue for diagnosis and provide information on tumor type and size (Riehl, 2007). Contrast harmonic echo-endoscopic ultrasound increases the accuracy of diagnosing solid pancreatic masses (Fusaroli et al., 2010).

Endoscopic retrograde cholangiopancreatography (ERCP) also provides visual diagnostic data. An alternative to ERCP is a percutaneous transhepatic biliary cholangiogram with placement of a percutaneous transhepatic biliary drain (PTBD). This drain decompresses the blocked biliary system by draining bile, either internally, externally, or both. Aspiration of pancreatic ascitic fluid by abdominal paracentesis may reveal cancer cells and elevated amylase levels.

INTERVENTIONS

Management of the patient with pancreatic cancer is geared toward preventing tumor spread and decreasing pain. These measures are not curative, only palliative. The cancers are often metastatic and recur despite treatment.

Nonsurgical Management

As in other types of cancer, chemotherapy or radiation is used to relieve pain by shrinking the tumor. It may be used before, after, or instead of surgery. *Chemotherapy* has had limited success in increasing survival time. In most cases, combining agents has been more successful than single-agent chemotherapy. 5-Fluorouracil (5-FU), a commonly used drug, may be given alone or with gemcitabine (Gemzar) for locally advanced, or unresectable, pancreatic cancers. Gemcitabine may also be given with capecitabine (Xeloda), docetaxel (Taxotere), and/or erlotinib (Tarceva), a targeted agent for unresectable or metastatic tumors. Some patients receive three or four drugs and have had more tumor shrinkage as a result. Observe for adverse drug effects, such as fatigue, rash, anorexia, and diarrhea.

Other targeted therapies being investigated include growth factor inhibitors, anti-angiogenesis factors, and kinase inhibitors (also known as *tyrosine kinase inhibitors*). Kinase inhibitors are a newer group of drugs that focus on cancer cells with little or no effect on healthy cells. Chapter 24 describes general nursing interventions associated with chemotherapy.

To control pain, the patient takes high doses of opioid analgesics (usually morphine) as prescribed and uses other comfort measures before the pain escalates and peaks. Because of the poor prognosis, drug dependency is not a consideration. Chapter 5 describes in detail the care of the patient with chronic cancer pain.

Intensive external beam *radiation* therapy to the pancreas may offer pain relief by shrinking tumor cells, alleviating obstruction, and improving food absorption. It does not improve survival rates. Implantation of radioactive iodine (^{125}I) seeds, in combination with systemic or intra-arterial administration of floxuridine (FUDR), has also been used. The patient may experience discomfort during and after the radiation treatments. Chapter 24 describes radiation therapy in more detail.

For patients experiencing biliary obstruction who are high surgical risks, **biliary stents** placed percutaneously (through the skin) can ensure patency to relieve pain. These stents are devices made of plastic materials that keep the ducts of the biliary system open. Using another approach, self-expandable stents may be inserted endoscopically to relieve obstruction.

Surgical Management

Complete surgical resection of the pancreatic tumor offers the patient with pancreatic cancer the only effective treatment, but it is done only in patients with small tumors. *Partial pancreatectomy* is the preferred surgery for tumors smaller than 3 centimeters in diameter (Halls & Ward-Smith, 2007). Recent technologic advances have expanded the role of **minimally invasive surgery (MIS)** via laparoscopy in the staging, palliation, and removal of pancreatic cancers. The procedure selected depends on the purpose of the surgery and stage of the disease. For example, if the patient has a biliary obstruction, a laparoscopic procedure to relieve the obstruction is performed. This procedure diverts bile drainage into the jejunum.

For larger tumors, the surgeon may perform either a *radical pancreatectomy* or the *Whipple procedure (pancreaticoduodenectomy)*. These procedures have traditionally been done using an open surgical approach. Because of new advances in laparoscopic technology using a hand-assist device, this method is beginning to replace the conventional method. Some surgeons are not yet trained in how to perform this technique. Therefore the traditional open surgical approach remains the most common method of performing these surgeries.

Preoperative Care. The patient with pancreatic cancer may be a poor surgical risk because of malnutrition and debilitation. Specific care depends on the type of surgical approach being used.

Often, in the late stages of pancreatic cancer or before the Whipple procedure, the physician inserts a small catheter into the jejunum (**jejunostomy**) so that enteral feedings may be given. This feeding method is preferred to prevent reflux and to facilitate absorption. Feedings are started in low concentrations and volumes and are gradually increased as tolerated.

Provide feedings using a pump to maintain a constant volume, and assess for diarrhea frequency to determine tolerance. Chapter 63 provides additional information about enteral feeding.

For optimal nutrition, TPN may be necessary in addition to tube feedings or as a single measure to provide nutrition. When central venous access is required, a peripherally inserted central catheter (PICC) or other type of IV catheter may be necessary. Meticulous IV line care is an important nursing measure to prevent catheter sepsis. Sterile dressing changes and site observation are extremely important (see Chapter 15). Additional nursing care measures for the patient receiving TPN are given in Chapter 63. Monitor nutrition indicators such as serum prealbumin and albumin.

For the laparoscopic procedure, no bowel preparation is needed. However, either approach requires that the patient have nothing by mouth (NPO) for at least 6 to 8 hours before surgery. Surgeon preference and agency policy determine the preferred protocol for preoperative preparation.

Operative Procedures. The **Whipple procedure (radical pancreaticoduodenectomy)** involves extensive surgical manipulation and is used most often to treat cancer of the head of the pancreas. The procedure entails removal of the proximal head of the pancreas, the duodenum, a portion of the jejunum, the stomach (partial or total **gastrectomy**), and the gallbladder, with anastomosis of the pancreatic duct (**pancreaticojejunostomy**), the common bile duct (**choledochojejunostomy**), and the stomach (**gastrojejunostomy**) to the jejunum (Fig. 62-3). In addition, the surgeon may remove the spleen (**splenectomy**).

Postoperative Care. In addition to routine postoperative care measures, the patient who has undergone an open radical pancreaticoduodenectomy requires intensive nursing care

FIG. 62-3 The three anastomoses that constitute the Whipple procedure: choledochojejunostomy, pancreaticojejunostomy, and gastrojejunostomy.

TABLE 62-5 POTENTIAL COMPLICATIONS OF THE WHIPPLE PROCEDURE

Cardiovascular Complications • Hemorrhage at anastomosis sites with hypovolemia • Myocardial infarction • Heart failure • Thrombophlebitis	Gastrointestinal Complications • Adynamic (paralytic) ileus • Gastric retention • Gastric ulceration • Bowel obstruction from peritonitis • Acute pancreatitis • Hepatic failure • Thrombosis to mesentery
Pulmonary Complications • Atelectasis • Pneumonia • Pulmonary embolism • Acute respiratory distress syndrome • Pulmonary edema	Wound Complications • Infection • Dehiscence • Fistulas: pancreatic, gastric, and biliary
	Metabolic Complications • Unstable diabetes mellitus • Renal failure

and is usually admitted to a surgical critical care unit. Observe for multiple potential complications of the open Whipple procedure as listed in Table 62-5.

The primary benefit of MIS is the patient's fast postoperative recovery and less pain than with traditional open procedures. The patient having the laparoscopic Whipple surgery or radical pancreatectomy is also less at risk for severe complications. For patients having one of these procedures, observe for and implement preventive measures for these surgical complications:

- Diabetes (Check blood glucose often.)
- Hemorrhage (Monitor pulse, blood pressure, skin color, and mental status [e.g., LOC].)
- Wound infection (Monitor temperature, and assess wounds for redness and induration [hardness].)
- Bowel obstruction (Check bowel sounds and stools.)
- Intra-abdominal abscess (Monitor temperature and patient's report of severe pain.)

Immediately after surgery, the patient is NPO and usually has a nasogastric tube (NGT) to decompress the stomach. Monitor GI drainage and tube patency. In open surgical approaches, biliary drainage tubes are placed during surgery to remove drainage and secretions from the area and to prevent stress on the anastomosis sites. Assess the tubes and drainage devices for tension or kinking, and maintain them in a dependent position.

Monitor the drainage for color, consistency, and amount. The drainage should be serosanguineous. The appearance of clear, colorless, bile-tinged drainage or frank blood with an increase in output may indicate disruption or leakage of an anastomosis site. Most of the disruptions of the site occur within 7 to 10 days after surgery. Hemorrhage can occur as an early or late complication.

Place the patient in the semi-Fowler's position to reduce tension on the suture line and anastomosis site as well as to optimize lung expansion. Stress can be decreased by maintaining NGT drainage at a low or high intermittent suction level to keep the remaining stomach (if a partial gastrectomy

is done) or the jejunum (if a total gastrectomy is done) free of excessive fluid buildup and pressure. The NGT also reduces stimulation of the remaining pancreatic tissue.

The development of a fistula (an abnormal passageway) is the most common and most serious postoperative complication. Biliary, pancreatic, or gastric fistulas result from partial or total breakdown of an anastomosis site. The secretions that drain from the fistula contain bile, pancreatic enzymes, or gastric secretions, depending on which site is ruptured. These secretions, particularly pancreatic fluid, are corrosive and irritating to the skin, and internal leakage causes chemical peritonitis. Peritonitis (inflammation and infection of the peritoneum causing boardlike abdominal rigidity) requires treatment with multiple antibiotics. If you suspect any postoperative complications resulting from MIS or open surgical approaches, call the surgeon immediately and provide assessment findings that support your concerns.

Because the open Whipple procedure is extensive and can take many hours to complete, maintaining fluid and electrolyte balance can be difficult. Patients often have significant intraoperative blood loss and postoperative bleeding. The intestine is exposed to air for long periods, and fluid evaporates. Significant losses of fluid and electrolytes occur from the NGT and other drainage tubes. In addition, these patients may be malnourished and have low serum levels of protein and albumin, which maintain colloid osmotic pressure within the circulating system. Reduction in the serum osmotic pressure makes the patient likely to develop third spacing of body fluids, with fluid moving from the vascular to the interstitial space, resulting in shock. These problems are less likely to occur when MIS is used. Therefore, when possible, the trained surgeon prefers to perform laparoscopic Whipple procedures to shorten operating time and prevent the many complications that can occur.

Closely monitor vital signs for decreased blood pressure and increased heart rate, decreased vascular pressures with a pulmonary artery catheter (Swan-Ganz catheter) (in ICU setting), and decreased urine output to detect early signs of hypovolemia and prevent shock. Be alert for pitting edema of the extremities, dependent edema in the sacrum and back, and an intake that far exceeds output. Maintain sequential compression devices to prevent deep vein thrombosis.

Maintenance of prescribed IV isotonic fluid replacement with colloid replacements is important. Monitor hemoglobin and hematocrit values to assess for blood loss and the need for blood transfusions. Review electrolyte values for decreased serum levels of sodium, potassium, chloride, and calcium. IV fluid concentrations must be altered to correct these electrolyte imbalances. The physician prescribes replacement of electrolytes as needed.

Immediately after the Whipple procedure, the patient may have hyperglycemia or hypoglycemia as a result of stress and surgical manipulation of the pancreas. Most of the endocrine cells (responsible for insulin and glucagon secretion) are located in the body and tail of the pancreas. In some patients, up to half of the gland remains and diabetes does not develop. However, a large number of patients are diabetic before surgery. For patients having a radical pancreatectomy, administer insulin as prescribed because the entire pancreas is removed. Monitor glucose levels frequently during the early postoperative period, and administer insulin injections as prescribed.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client has had an open Whipple procedure for pancreatic cancer. Which nursing interventions are appropriate for this client in the postoperative period? **Select all that apply.**

- A. Maintain IV fluids, and monitor for fluid imbalance.
- B. Assess for signs and symptoms of deep vein thrombosis.
- C. Connect the nasogastric tube to high intermittent suction.
- D. Start pancreatic enzyme replacements as soon as possible.
- E. Check finger-stick blood glucose levels regularly.
- F. Tell the client to lie flat to protect the incision.

Community-Based Care

The patient with pancreatic cancer is usually followed by a case manager (CM), both in the hospital and in the home or other community-based setting. Collaborate with the CM to ensure that the patient receives cost-effective treatment and that his or her needs are met.

Home Care Management

The stage of progression of pancreatic cancer and available home care resources determine whether the patient can be discharged to home or whether additional care is needed in a skilled nursing facility or with a hospice provider. Home care preparations depend on the patient's physical and activity limitations and should be tailored to his or her needs. Coordinate care with the patient, family, or whoever will be providing care after discharge from the hospital—home care provider, hospice care provider, or extended-care provider.

The patient and family need compassionate emotional support to deal with issues related to this illness. The diagnosis of pancreatic cancer can frighten and overwhelm the patient and family. Assist family members in looking

realistically and objectively at the amount of physical care required. Tell family members that their own physical and emotional health are at risk during this stressful period and that supportive counseling may be needed. If the family does not have a religious affiliation or a spiritual leader (e.g., a minister or a rabbi) to provide support, suggest alternative counseling options. Refer patients and families to the certified hospital chaplain if desired. It is appropriate for the nurse to make the initial contact or appointment according to the patient's or family's wishes.

Teaching for Self-Management

When the patient is discharged to home, many interventions are palliative and aimed at managing symptoms such as pain. In many cases, the diagnosis of pancreatic cancer is made a few months before death occurs. The patient needs time to adjust to the diagnosis, which is usually made too late for cure or prolonged survival. Help the patient identify what needs to be done to prepare for death, including end-of-life care. For example, he or she may want to write a will or see family members and friends whom he or she has not seen recently. The patient needs to make known to family members or others his or her specific requests for the funeral or memorial service. These actions help prepare for death in a dignified manner. [Chapter 9](#) discusses in detail anticipatory grieving and preparation for death, as well as symptom management during the end of life.

Health Care Resources

Regular home care nursing and assistive nursing personnel visits may be scheduled to assist the patient and family by providing physical, psychological, and supportive care. Supply information about local hospice care (see [Chapter 9](#)) and cancer support groups.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate digestion and nutrition as a result of gallbladder and pancreatic disorders?

- Report of intense abdominal pain
- Report of nausea, especially after food
- Report of anorexia
- Vomiting
- Jaundice
- Report of weight loss
- Dark urine
- Clay-colored stools

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate digestion and nutrition as a result of gallbladder and pancreatic disorders?

Perform and interpret physical assessment, including:

- Take vital signs to assess for hypovolemia and fever.
- Assess respiratory status, including breath sounds.
- Conduct a complete pain assessment if possible.
- Weigh the patient.

- Check laboratory values, especially enzyme levels like amylase and lipase, liver function studies, and CBC. Assess vomitus for quality and amount.

Respond by:

- Keeping the patient's head of the bed elevated and knees flexed
- Providing pain management by comfort measures and analgesia
- Providing oxygen if patient is having dyspnea or adventitious breath sounds
- Reassuring the patient who may be concerned about possible cancer

On what should you REFLECT?

- Observe patient for improvement in signs and symptoms, including pain control.
- Think about what could have caused the health problem.
- Think about what else you could do to help the patient meet desired outcomes.
- Plan health teaching for patient discharge.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- When caring for a patient with a T-tube, do not place the drainage bag higher than the tube insertion site.
- Recognize that acute pain relief is the first priority for patients with acute pancreatitis.
- Be aware that patients with biliary and pancreatic disorders are at high risk for biliary obstruction, a serious and painful complication.

Health Promotion and Maintenance

- Recognize that obese, middle-aged women are most likely to have gallbladder disease.
- Teach patients to avoid losing weight too quickly and to keep weight under control to help prevent gallbladder disease.
- Instruct patients about ways to prevent exacerbations of chronic pancreatitis as outlined in [Chart 62-4](#).

Psychosocial Integrity

- Provide pain relief measures for patients with acute pancreatitis to reduce anxiety.
- Refer patients with pancreatitis who use excessive alcohol to community resources such as Alcoholics Anonymous.

- Refer patients with pancreatic cancer for support services such as spiritual leaders and counselors.
- Help prepare the pancreatic cancer patient and family for the death and dying process.

Physiological Integrity

- Be aware that autodigestion of the pancreas causes severe pain in patients with acute pancreatitis (see [Fig. 62-2](#)).
- Monitor serum laboratory values, especially amylase and lipase (both elevated), in patients with pancreatitis (see [Table 62-4](#)).
- Assess for common clinical manifestations of cholecystitis as listed in [Chart 62-1](#).
- For patients with acute pancreatitis, provide pain management including opioid analgesia.
- Assess for common clinical manifestations of chronic pancreatitis as listed in [Chart 62-2](#).
- Teach patients about enzyme replacement therapy as described in [Chart 62-3](#).
- Assess patients with presenting clinical manifestations of pancreatic cancer as described in [Chart 62-5](#).
- Observe for and implement interventions to prevent life-threatening complications of the Whipple procedure as outlined in [Table 62-5](#).

Care of Patients with Malnutrition and Obesity

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Collaborate with members of the health care team when providing care for patients with malnutrition or obesity.
2. Protect bariatric patients from injury.
3. Select appropriate activities to delegate to unlicensed assistive personnel to promote a patient's nutrition.

Health Promotion and Maintenance

4. Provide care that meets the special nutrition needs of older adults.
5. Teach overweight and obese patients the importance of lifestyle changes to promote health.
6. Perform a nutrition screening for all patients to determine if they are at high risk for nutritional health problems.
7. Identify the key recommendations from the *Dietary Guidelines for Americans, 2010* document.

Psychosocial Integrity

8. Assess patient responses to being obese.

Physiological Integrity

9. Interpret findings of a nutrition screening and assessment.

10. Calculate body mass index (BMI), and interpret findings.
11. Describe the risk factors for malnutrition, especially for older adults.
12. Explain why serum visceral protein levels indicate change in nutritional status.
13. Identify the role of nutritional supplements in restoring or maintaining nutrition.
14. Describe complications of total enteral nutrition (TEN).
15. Explain how to prevent complications of total parenteral nutrition (TPN).
16. Explain how to maintain enteral tube patency.
17. Describe evidence-based practices to prevent aspiration for patients with nasoenteric tubes.
18. Explain the medical complications associated with obesity.
19. Identify the role of drug therapy in the management of obesity.
20. Prioritize nursing care for patients having bariatric surgery.
21. Develop a discharge teaching plan for patients having bariatric surgery.

Carbohydrates, protein, and fat are nutrients in food that supply the body with energy. In healthy people, most of this energy undergoes digestion and is absorbed from the GI tract. Food energy is used to maintain body temperature, respiration, cardiac output, muscle function, protein

synthesis, and the storage and metabolism of food sources. Therefore proper *nutrition* plays a major role in promoting and maintaining health.

Energy balance refers to the relationship between energy used and energy stored. Weight loss occurs when energy

TABLE 63-1 EXAMPLES OF 2010 DIETARY GUIDELINES FOR AMERICANS

- Control total calorie intake to manage body weight.
- Consume less than 300 mg per day of dietary cholesterol.
- Increase intake of fat-free or low-fat milk and milk products, such as milk, yogurt, cheese, or fortified soy products.
- Choose a variety of protein foods, which include seafood, lean meat and poultry, eggs, beans and peas, soy products, and unsalted nuts and seeds.
- Reduce the intake of calories from solid fats and added sugars.
- Reduce daily sodium intake to less than 2300 mg and further reduce intake to 1500 mg among persons who are 51 years or older and those of any age who are African American or have hypertension, diabetes, or chronic kidney disease.
- Limit the consumption of foods that contain refined grains, especially refined grains that contain solid fats, added sugars, and sodium.
- Increase vegetable and fruit intake.

Source: Dietary Guidelines for Americans Council. (2010). Retrieved March 31, 2011, from www.cnpp.usda.gov/Publications/DietaryGuidelines/2010/DGAC/Report/A-ExecSummary.pdf.

used is more than intake. If food intake is more than energy used, weight is gained. Body proteins are used for energy when calorie intake is insufficient. The body attempts to meet its calorie requirements even if it is at the expense of protein needs.

NUTRITION STANDARDS FOR HEALTH PROMOTION AND MAINTENANCE

The role of nutrition in disease has been a subject of interest for many years. The current focus is on health promotion and the prevention of disease by healthy eating and exercise. In the United States, the [Dietary Guidelines for Americans](#) are revised by the U.S. Department of Agriculture (USDA) and the U.S. Department of Health and Human Services (DHHS) every 5 years. The most recent guidelines (2010) emphasize the need to include preferences of specific racial/ethnic groups, vegetarians, and other populations when selecting foods to maintain a healthful diet that is balanced with moderation and variety. If alcohol is consumed, it should be limited to one drink per day for women and two drinks for men ([USDA, 2010](#)). Examples of other guidelines are listed in [Table 63-1](#).

The USDA also recently designed a picture to remind people about the good foods to increase and the foods that should be reduced in the daily diet. [Fig. 63-1](#) illustrates the USDA's MyPlate to show that half of each meal should consist of fruits and vegetables. When grains are consumed, half of them should be whole grains rather than refined grain products.

An increasing number of people are adopting a variety of vegetarian diet patterns for health, environmental, or moral reasons. In general, vegetarians are leaner than those who consume meat. The [lacto-vegetarian](#) eats milk, cheese, and dairy foods but avoids meat, fish, poultry, and eggs. The [lacto-ovo-vegetarian](#) includes eggs in his or her diet. The [vegan](#) eats only foods of plant origin. Some people among these groups eat fish as well. Vegans can develop anemia as a result of vitamin B₁₂ deficiency. Therefore they should include a daily source of vitamin B₁₂ in their diets, such as a fortified

FIG. 63-1 The U.S. Department of Agriculture MyPlate.

breakfast cereal, fortified soy beverage, or meat substitute. All vegetarians should ensure that they get adequate amounts of calcium, iron, zinc, and vitamins D and B₁₂. Well-planned vegetarian diets can provide adequate nutrition. The [National Agriculture Library \(2008\)](#) publishes a Vegetarian Nutrition Resource List that provides credible resources regarding vegetarian health.

CULTURAL AWARENESS

Many people have specific food preferences based on their ethnicity or race. For example, for people of Hispanic descent, tortillas, beans, and rice may be desired over pasta, risotto, and potatoes. *Never assume that a person's racial or ethnic background means that he or she eats only foods associated with his or her primary ethnicity.* Health teaching about nutrition should incorporate any cultural preferences (also see [Chapter 4](#)).

Some people have food allergies or intolerances. For instance, lactose intolerance (lactose is found in milk and milk products) is a common problem that occurs in a number of ethnic groups. It is found more often in Mexican Americans and black people as well as in some American Indian groups, Asian Americans, and Ashkenazi Jews. A small percentage of white people, particularly those of Mediterranean descent (e.g., Greek, Italian), are also lactose intolerant. The cause of [lactose intolerance](#) is an inadequate amount of the lactase enzyme, which converts lactose into absorbable glucose. Patients may benefit from learning more about the management of lactose intolerance from resources provided by organizations such as the American Dietetic Association.

CONSIDERATIONS FOR OLDER ADULTS

The USDA recommends that older adults drink eight glasses of water a day and eat plenty of fiber to prevent or manage constipation. It also suggests daily calcium and vitamins D and B₁₂ supplements and a reduction in sodium and cholesterol-containing foods.

One of the most recent publications from Health Canada on nutrition is the Canada Food Guide. Compared with previous documents, it includes more culturally diverse foods, information on *trans* fats, customized individual recommendations, and exercise guidelines. Several booklets can be purchased to help people select the best foods and nutrients from the new Guide, such as *Eating Well with Canada's Food Guide*. In addition, Canada has published a separate booklet to address the special needs of some of its indigenous people. The *Eating Well with Canada's Food Guide—First Nations*,

Inuit, and Métis includes berries, wild plants, and wild game to reflect the values and traditions for aboriginal people living in Canada (Health Canada, 2007).

NUTRITIONAL ASSESSMENT

Malnutrition (also called *undernutrition*) and obesity are common nutritional health problems. These problems lead to deficits that cause many comorbidities and complications, including death.

Nutritional status reflects the balance between nutrient requirements and intake. Common factors that affect these requirements include age, gender, disease, infection, and psychological stress. Nutrient intake is influenced by eating behavior, economic factors, emotional stability, disease, drug therapy, and cultural factors.

Evaluation of nutritional status is an important part of total patient assessment and includes:

- Review of the nutritional history
- Food and fluid intake record
- Laboratory data
- Food-drug interactions
- Health history and physical assessment
- Anthropometric measurements
- Psychosocial assessment

Monitor the nutritional status of a patient during hospitalization as an important part of your initial assessment. Collaborate with the interdisciplinary health care team to identify patients at risk for nutritional problems.

Initial Nutritional Screening

Not every patient needs a complete nutritional assessment, but it is important to identify those at risk for problems through screening. An initial screening provides an inexpensive, quick way of determining which patients need more extensive nutritional assessment by the health care team. *The Joint Commission Patient Care Standards require that a nutritional screening occur within 24 hours of the patient's hospital admission. If indicated, an in-depth nutritional assessment should be performed.* When patients are in the hospital more than a week, nutritional assessment should be part of the daily plan of care.

The initial **nutritional screening** includes inspection, measured height and weight, weight history, usual eating habits, ability to chew and swallow, and any recent changes in appetite or food intake. Examples of questions that help identify patients at risk for nutritional problems are part of the history and physical assessment (Chart 63-1).

The Mini Nutritional Assessment (MNA), a two-part tool that has been tested worldwide, provides a reliable, rapid assessment for patients in the community and in any health care setting. The *first* part (A-F) is a screening section that takes 3 minutes to complete and asks about food intake, mobility, and body mass index (BMI) (described on p. 1339). It also screens for weight loss, acute illness, and psychological health problems. If the patient scores 11 points or less, the *second* part (G-R) of the MNA is completed, for an additional 12 questions. The entire assessment takes less than 15 minutes (Fig. 63-2) (DiMaria-Ghalili & Guenter, 2008). A new MNA® Short Form can be used as a stand-alone tool to evaluate whether the older patient is well-nourished, at risk for malnutrition, or malnourished. The alternative is to take the

CHART 63-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Nutritional Screening Assessment

General

- Does the patient have any conditions that cause nutrient loss, such as malabsorption syndromes, draining abscesses, wounds, fistulas, or prolonged diarrhea?
- Does the patient have any conditions that increase the need for nutrients, such as fever, burn, injury, sepsis, or antineoplastic therapies?
- Has the patient been NPO for 3 days or more?
- Is the patient receiving a modified diet or a diet restricted in one or more nutrients?
- Is the patient being enterally or parenterally fed?
- Does the patient describe food allergies, lactose intolerance, or limited food preferences?
- Has the patient experienced a recent unexplained weight loss?
- Is the patient on drug therapy, either prescription, over-the-counter, or herbal/natural products?

Gastrointestinal

- Does the patient report nausea, indigestion, vomiting, diarrhea, or constipation?
- Does the patient exhibit glossitis (tongue inflammation), stomatitis (oral inflammation), or esophagitis?
- Does the patient have difficulty chewing or swallowing?
- Does the patient have a partial or total GI obstruction?
- What is the patient's state of dentition?

Cardiovascular

- Does the patient have ascites or edema?
- Is the patient able to perform ADLs?
- Does the patient have heart failure?

Genitourinary

- Is fluid intake about equal to fluid output?
- Does the patient have an ostomy?
- Is the patient hemodialyzed or peritoneally dialyzed?

Respiratory

- Is the patient receiving mechanical ventilatory support?
- Is the patient receiving oxygen via nasal prongs?
- Does the patient have chronic obstructive pulmonary disease (COPD) or asthma?

Integumentary

- Does the patient have abnormal nail or hair changes?
- Does the patient have rashes or dermatitis?
- Does the patient have dry or pale mucous membranes or decreased skin turgor?
- Does the patient have pressure areas on the sacrum, hips, heels, or ankles?

Extremities

- Does the patient have pedal edema?
- Does the patient have cachexia?

Modified with courtesy of Ross Products Division, Abbott Laboratories, Columbus, OH.

patient's calf circumference, which can be a reliable alternative if BMI is unavailable.

Anthropometric Measurements

Anthropometric measurements are noninvasive methods of evaluating nutritional status. These measurements include height and weight and assessment of body fat.

NESTLÉ NUTRITION SERVICES

Mini Nutritional Assessment (MNA)

Last name:	First name:	Sex:	Date:
Age:	Weight, kg:	Height, cm:	I.D. Number:

Complete the screen by filling in the boxes with the appropriate numbers.

Add the numbers for the screen. If score is 11 or less, continue with the assessment to gain a Malnutrition Indicator Score.

Screening

A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?

0 = severe loss of appetite

1 = moderate loss of appetite

2 = no loss of appetite

☐

B Weight loss during last 3 months

0 = weight loss greater than 3 kg (6.6 lbs)

1 = does not know

2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs)

3 = no weight loss

☐

C Mobility

0 = bed or chair bound

1 = able to get out of bed/chair but does not go out

2 = goes out

☐

D Has suffered psychological stress or acute disease in the past 3 months

0 = yes 2 = no

☐

E Neuropsychological problems

0 = severe dementia or depression

1 = mild dementia

2 = no psychological problems

☐

F Body Mass Index (BMI) (weight in kg) / (height in m)²

0 = BMI less than 19

1 = BMI 19 to less than 21

2 = BMI 21 to less than 23

3 = BMI 23 or greater

☐

Screening score (subtotal max. 14 points)

12 points or greater Normal – not at risk – no need to complete assessment

11 points or below Possible malnutrition – continue assessment

Assessment

G Lives independently (not in a nursing home or hospital)

0 = no 1 = yes

☐

H Takes more than 3 prescription drugs per day

0 = yes 1 = no

☐

I Pressure sores or skin ulcers

0 = yes 1 = no

☐

J How many full meals does the patient eat daily?

0 = 1 meal

1 = 2 meals

2 = 3 meals

☐

K Selected consumption markers for protein intake

• At least one serving of dairy products

(milk, cheese, yogurt) per day? yes ☐ no ☐

• Two or more servings of legumes or eggs per week? yes ☐ no ☐

• Meat, fish or poultry every day yes ☐ no ☐

0.0 = if 0 or 1 yes

0.5 = if 2 yes

1.0 = if 3 yes

☐ . ☐

L Consumes two or more servings of fruits or vegetables per day?

0 = no 1 = yes

☐

M How much fluid (water, juice, coffee, tea, milk...) is consumed per day?

0.0 = less than 3 cups

0.5 = 3 to 5 cups

1.0 = more than 5 cups

☐ . ☐

N Mode of feeding

0 = unable to eat without assistance

1 = self-fed with some difficulty

2 = self-fed without any problem

☐

O Self view of nutritional status

0 = views self as being malnourished

1 = is uncertain of nutritional state

2 = views self as having no nutritional problem

☐

P In comparison with other people of the same age, how does the patient consider his/her health status?

0.0 = not as good

0.5 = does not know

1.0 = as good

2.0 = better

☐ . ☐

Q Mid-arm circumference (MAC) in cm

0.0 = MAC less than 21

0.5 = MAC 21 to 22

1.0 = MAC 22 or greater

☐ . ☐

R Calf circumference (CC) in cm

0 = CC less than 31

1 = CC 31 or greater

☐

Assessment (max. 16 points)

☐ ☐ . ☐

Screening score

☐ ☐

Total Assessment (max. 30 points)

☐ ☐ . ☐

Malnutrition Indicator Score

17 to 23.5 points at risk of malnutrition

☐

Less than 17 points malnourished

☐

FIG. 63-2 The Mini Nutritional Assessment (MNA).

Obtain a current *height and weight* to provide a baseline. Be sure to obtain accurate measurements because patients tend to overestimate height and underestimate weight. Measurements taken days or weeks later may indicate an early change in nutritional status. *You may delegate this activity to unlicensed assistive personnel (UAP) under your supervision.*

Patients should be measured and weighed while wearing minimal clothing and no shoes. Determine the height in inches or centimeters using the measuring stick of a weight scale if the patient can stand. He or she should stand erect and look straight ahead, with the heels together and the arms at the sides. For patients who cannot stand or those who cannot stand erect (e.g., some older adults), use a sliding-blade **knee height caliper**, if available. This device uses the distance between the patient's patella and heel to estimate height. It is especially useful for patients who have knee or hip contractures.

UAP weigh ambulatory patients with an upright balance-beam scale. Non-ambulatory patients can be weighed with a movable wheelchair balance-beam scale or a bed scale.

! NURSING SAFETY PRIORITY

Action Alert

Be sure that the manufacturer calibrates weight scales twice yearly for accurate readings. For daily or sequential weights, obtain the weight at the same time each day, if possible, preferably before breakfast. Conditions such as congestive heart failure and renal disease cause weight gain; dehydration and conditions such as cancer cause weight loss. Weight is the most reliable indicator of fluid gain or loss, so accurate weights are essential!

Normal weights for adult men and women are available from several reference standards, including the revised Metropolitan Life tables. Some health care professionals prefer these tables because they consider body-build differences by gender and body frame size.

Changes in body weight can be expressed by three different formulas:

1. Weight as a percentage of ideal body weight (IBW):

$$\%IBW = \frac{\text{Current weight}}{\text{Ideal body weight}} \times 100$$

2. Current weight as a percentage of usual body weight (UBW):

$$\%UBW = \frac{\text{Current weight}}{\text{Usual body weight}} \times 100$$

3. Change in weight:

$$\text{Weight change} = \frac{\text{Usual weight} - \text{Current weight}}{\text{Usual weight}} \times 100$$

An unintentional weight loss of 10% over a 6-month period at any time significantly affects nutritional status and should be evaluated. Depending on the patient's needs, weights may need to be taken daily, several times a week, or weekly for monitoring status and the effectiveness of nutritional support.

In the health care setting, *assessment of body fat* is usually calculated by the dietitian. For people who participate in a structured exercise program in the community, this assessment is typically performed by a fitness trainer or physical therapist.

The **body mass index (BMI)** is a measure of nutritional status that does not depend on frame size. It indirectly estimates total fat stores within the body by the relationship of weight to height. *Therefore an accurate height is as important as an accurate weight.*

A simple calculation for estimating BMI can be programmed into handheld computers or calculators using one of these two formulas:

$$BMI = \frac{\text{Weight (lb)}}{\text{Height (in inches)}^2} \times 703$$

$$BMI = \frac{\text{Weight (kg)}}{\text{Height (in meters)}^2}$$

BMI can also be determined using a table that is linked with height and weight. The least risk for malnutrition is associated with scores between 18.5 and 25. BMIs above and below these values are associated with increased health risks ([Centers for Disease Control and Prevention \[CDC\], 2009](#)).

CONSIDERATIONS FOR OLDER ADULTS

Body weight and BMI usually increase throughout adulthood until about 60 years of age. As people get older, they become less hungry and eat less, even if they are healthy. Older adults should have a BMI between 23 and 27 ([DiMaria-Ghalili & Amella, 2005](#)).

The average daily energy intake expended by this group tends to be more than the average energy intake. This physiologic change has been called the "anorexia of aging" ([Conte et al., 2009](#)). Many older adults are underweight, leading to undernutrition and increased risk for illness.

? NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

An older adult is admitted to the hospital with pressure ulcers and septicemia. His height is 5 feet, 10 inches (1.78 meters), and he weighs 342 pounds (155 kg). His current body mass index (BMI) is _____. (Your answer should be rounded to the nearest tenth.)

Skinfold measurements estimate body fat and can be measured by either the nurse or the dietitian. The *triceps and subscapular* skinfolds are most commonly measured using a special caliper. Both are compared with standard measurements and recorded as percentiles.

The *midarm circumference (MAC)* and *calf circumference (CC)* can be obtained to measure muscle mass and subcutaneous fat. These measurements are needed if the Mini Nutritional Assessment tool is used. To measure MAC, place a flexible tape around the upper arm at the midpoint, taking care to hold the tape firmly but gently to avoid compressing the tissue. This measurement is usually recorded in centimeters. The midarm muscle mass (MAMM) measures the amount of muscle in the body and is a sensitive indicator of protein reserves. It can be computed from the MAC and the

triceps skinfold measure. The CC is obtained using a similar procedure on the calf.

MALNUTRITION

Pathophysiology

Protein-energy malnutrition (PEM), also known as **protein-calorie malnutrition (PCM)**, may present in three forms: marasmus, kwashiorkor, and marasmic-kwashiorkor. **Marasmus** is generally a calorie malnutrition in which body fat and protein are wasted. Serum proteins are often preserved. **Kwashiorkor** is a lack of protein quantity and quality in the presence of adequate calories. Body weight is more normal, and serum proteins are low. **Marasmic-kwashiorkor** is a combined protein and energy malnutrition. This problem often presents clinically when metabolic stress is imposed on a chronically starved patient. The outcome of unrecognized or untreated PEM is often dysfunction or disability and increased morbidity and mortality.

Malnutrition (also called *undernutrition*) is a multinutrient problem because foods that are good sources of calories and protein are also good sources of other nutrients. In the malnourished patient, protein catabolism exceeds protein intake and synthesis, resulting in negative nitrogen balance, weight loss, decreased muscle mass, and weakness.

The function of the liver, heart, lungs, GI tract, and immune system decreases in the patient with malnutrition. A decrease in serum proteins (**hypoproteinemia**) occurs as protein synthesis in the liver decreases. Vital capacity is also reduced as a result of respiratory muscle atrophy. Cardiac output diminishes. Malabsorption occurs because of atrophy of GI mucosa and the loss of intestinal villi.

Other common complications of severe malnutrition in adults include:

- Leanness and **cachexia** (muscle wasting with prolonged malnutrition)
- Decreased activity tolerance
- Lethargy
- Intolerance to cold
- Edema
- Dry, flaking skin and various types of dermatitis
- Poor wound healing
- Possible death
- Infection, particularly postoperative infection and sepsis

Malnutrition results from inadequate nutrient intake, increased nutrient losses, and increased nutrient requirements. Inadequate nutrient intake can be linked to poverty, lack of education, substance abuse, decreased appetite, and a decline in functional ability to eat independently, particularly in older adults. Infectious diseases, such as tuberculosis and human immune deficiency virus (HIV) infection, can also cause PEM. Diseases that produce diarrhea and infections leading to anorexia result in negative calorie and protein balance. Anorexia then leads to poor food intake. Vomiting causes decreased intestinal absorption with increased nutrient losses. Medical treatments such as chemotherapy can also cause malnutrition. In addition, catabolic processes, such as that caused by prolonged immobility, increase nutrient requirements and metabolic losses.

Inadequate nutrient intake can result also when a person is admitted to the hospital or long-term care facility. For

example, decreased staffing may not allow time for patients who need to be fed, especially older adults, who may eat slowly. Many diagnostic tests, surgery, trauma, and unexpected medical complications require a period of NPO or cause **anorexia** (loss of appetite).

CULTURAL AWARENESS

In some cases, malnutrition results when the provided meals are different from what the patient usually eats. Be sure to identify specific food preferences that the patient can eat and enjoy that are in keeping with his or her cultural practices.

CONSIDERATIONS FOR OLDER ADULTS

Older adults in the community or in any health care setting are most at risk for poor nutrition, especially PEM. Risk factors include physiologic changes of aging, environmental factors, and health problems. Chart 63-2 lists some of these major factors. Chapter 3 discusses nutrition for older adults in more detail.

Acute PEM may develop in patients who were adequately nourished before hospitalization but experience starvation while in a catabolic state from infection, stress, or injury. **Chronic** PEM can occur in those who have cancer, end-stage kidney or liver disease, or chronic neurologic disease.

Eating disorders, such as anorexia nervosa and bulimia nervosa seen most often in teens and young adults, also lead to malnutrition. **Anorexia nervosa** is a self-induced starvation resulting from a fear of fatness, even though the patient is underweight. **Bulimia nervosa** is characterized by episodes of binge eating in which the patient ingests a large amount of food in a short time. The binge eating is followed by some form of purging behavior, such as self-induced vomiting or excessive use of laxatives and diuretics. If not treated, death can result from starvation, infection, or suicide. Information about eating disorders can be found in textbooks on mental/behavioral health nursing.

CHART 63-2 NURSING FOCUS ON THE OLDER ADULT

Risk Assessment for Malnutrition

Assess for:

- Decreased appetite
- Weight loss
- Poor-fitting or no dentures/poor dental health
- Poor eyesight
- Dry mouth
- Limited income
- Lack of transportation
- Inability to prepare meals because of functional decline or fatigue
- Loneliness and/or depression
- Chronic constipation (e.g., in patients with Alzheimer's disease)
- Decreased meal enjoyment
- Chronic physical illness
- "Failure to thrive" (a combination of three of five symptoms, including weakness, slow walking speed, low physical activity, unintentional weight loss, exhaustion)
- Prescription and OTC drugs (including herbs, vitamins, and minerals)
- Acute or chronic pain

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Review the medical history to determine the possibility of increased metabolic needs or nutritional losses, chronic disease, trauma, recent surgery of the GI tract, drug and alcohol abuse, and recent significant weight loss. Each of these conditions can contribute to malnutrition. For older adults, explore mental status changes and note poor eyesight, diseases affecting major organs, constipation or incontinence, and slowed reactions. Review prescription and over-the-counter (OTC) drugs, including vitamin, mineral, herbal, and other nutritional supplements.

For patients who live independently in the community, the nurse may assess their performance of instrumental activities of daily living (IADLs). Functional status can best be evaluated for institutionalized patients by assessing their ADL performance. Poor nutrition is a major contributing factor to decreased functional ability.

In collaboration with the dietitian, obtain information about the patient's usual daily food intake, eating behaviors, change in appetite, and recent weight changes. If the patient is able to communicate, ask him or her to describe the usual foods eaten daily, cultural food preferences, and the times of meals and snacks. If available, ask the family these questions if the patient cannot communicate. If the patient cannot understand the questions due to language differences, locate an interpreter to assist with communication. The dietitian can more thoroughly analyze the diet, if necessary, based on your initial nutritional screening.

Ask about changes in eating habits as a result of illness, and document any change in appetite, taste, and weight loss. *A weight loss of 5% or more in 30 days, a weight loss of 10% in 6 months, or a weight that is below ideal may indicate malnutrition.*

! NURSING SAFETY PRIORITY

Action Alert

When assessing for malnutrition, assess for difficulty or pain in chewing or swallowing. *Unrecognized dysphagia is a common problem among nursing home residents and can cause malnutrition, dehydration, and aspiration pneumonia.* Ask the patient whether any foods are avoided and why. Ask UAP to report any choking while the patient eats. Record the occurrence of nausea, vomiting, heartburn, or any other symptoms of discomfort with eating.

Ask the patient about dental health problems, including the presence of dentures. Dentures or partial plates that do not fit well interfere with food intake. Dental caries (decay) or missing teeth may also cause discomfort while eating.

Physical Assessment/Clinical Manifestations

Assess for manifestations of various nutrient deficiencies (Table 63-2). Inspect the patient's hair, eyes, oral cavity, nails, and musculoskeletal and neurologic systems. Examine the condition of the skin, including any reddened or open areas. The previously described anthropometric measurements

TABLE 63-2 MANIFESTATIONS OF NUTRIENT DEFICIENCIES

SIGN/SYMPTOM	POTENTIAL NUTRIENT DEFICIENCY
Hair	
Alopecia	Zinc
Easy to remove	Protein
Lackluster hair	Protein
"Corkscrew" hair	Vitamin C
Decreased pigmentation	Protein
Eyes	
Xerosis of conjunctiva	Vitamin A
Corneal vascularization	Riboflavin
Keratomalacia	Vitamin A
Bitot's spots	Vitamin A
Gastrointestinal Tract	
Nausea, vomiting	Pyridoxine
Diarrhea	Zinc, niacin
Stomatitis	Pyridoxine, riboflavin, iron
Cheilosis	Pyridoxine, iron
Glossitis	Pyridoxine, zinc, niacin, folic acid, vitamin B ₁₂
Magenta tongue	Vitamin A, riboflavin
Swollen, bleeding gums	Vitamin C
Fissured tongue	Niacin
Hepatomegaly	Protein
Skin	
Dry and scaling	Vitamin A
Petechiae/ecchymoses	Vitamin C
Follicular hyperkeratosis	Vitamin A
Nasolabial seborrhea	Niacin
Bilateral dermatitis	Niacin
Extremities	
Subcutaneous fat loss	Calories
Muscle wastage	Calories, protein
Edema	Protein
Osteomalacia, bone pain, rickets	Vitamin D
Hematologic	
Anemia	Vitamin B ₁₂ , iron, folic acid, copper, vitamin E
Leukopenia, neutropenia	Copper
Low prothrombin time, prolonged clotting time	Vitamin K, manganese
Neurologic	
Disorientation	Niacin, thiamine
Confabulation	Thiamine
Neuropathy	Thiamine, pyridoxine, chromium
Paresthesia	Thiamine, pyridoxine, vitamin B ₁₂
Cardiovascular	
Congestive heart failure, cardiomegaly, tachycardia	Thiamine
Cardiomyopathy	Selenium
Cardiac dysrhythmias	Magnesium

may also be obtained. The nurse or UAP should monitor all food and fluid intake and note any mouth pain or difficulty in chewing or swallowing. A 3-day caloric intake may be collected and then calculated by the dietitian.

Psychosocial Assessment

The psychosocial history provides information about the patient's economic status, occupation, educational level, gender orientation, ethnicity/race, living and cooking arrangements, and mental status. Determine whether financial resources are adequate for providing the necessary food. If resources are inadequate, the social worker or case manager may refer the patient and family to available community services. [Chapter 3](#) discusses nutrition in older adults in more detail.

Laboratory Assessment

Laboratory tests supply objective data that can support subjective data and identify preclinical deficiencies. However, they must be carefully interpreted with regard to the total patient; an isolated value may yield an inaccurate conclusion.

A low *hemoglobin* level may indicate anemia, recent hemorrhage, or hemodilution caused by fluid retention. Hemoglobin may also be low secondary to conditions such as low serum albumin, infection, catabolism, or chronic disease. High levels may indicate hemoconcentration or dehydration, or they may be secondary to liver disease.

Low *hematocrit* levels may reflect anemia, hemorrhage, excessive fluid, renal disease, or cirrhosis. High hematocrit levels may indicate dehydration or hemoconcentration.

Serum albumin, thyroxine-binding prealbumin, and transferrin are measures of **visceral proteins**. Serum *albumin* is a plasma protein that reflects the nutritional status of the patient a few weeks before testing and is therefore not the most sensitive test. In addition, patients who are dehydrated often have high levels of albumin and those with fluid excess have a lowered value. The normal serum albumin level for men and women is 3.5 to 5.0 g/dL or 35 to 50 g/L (SI units) (Pagana & Pagana, 2010).

Thyroxine-binding **prealbumin (PAB)** is a plasma protein that provides a more sensitive indicator of nutritional deficiency because of its short half-life of 2 days. Depending on the laboratory test used, the normal PAB range is 15 to 36 mg/dL or 150 to 360 mg/L (SI units) (Pagana & Pagana, 2010). PAB can also assess improvement in nutritional status with refeeding; levels can increase by 1 mg/dL daily with adequate nutritional support.

Although not used as commonly, serum **transferrin**, an iron-transport protein, can be measured directly or calculated as an indirect measurement of total iron-binding capacity (TIBC). It has a short half-life of 8 to 10 days and therefore is also a more sensitive indicator of protein status than albumin.

Cholesterol levels normally range between 160 and 200 mg/dL in adult men and women. Values are typically low with malabsorption, liver disease, pernicious anemia, end-stage cancer, or sepsis. A cholesterol level below 160 mg/dL has been identified as a possible indicator of malnutrition. Cholesterol testing is discussed in more detail in [Chapter 35](#).

Total lymphocyte count (TLC) can be used to assess immune function. Malnutrition suppresses the immune system and

leaves the patient more likely to get an infection. When a patient is malnourished, the TLC is usually decreased to below 1500/mm³.

ANALYSIS

The priority problem for the patient with malnutrition is:

1. Inadequate nutrition to meet body needs related to inability to ingest or digest food or absorb nutrients.

PLANNING AND IMPLEMENTATION

Improving Nutrition

Planning: Expected Outcomes. The patient with malnutrition is expected to have nutrients available to meet his or her metabolic needs as evidenced by normal serum proteins and adequate hydration.

Interventions. The preferred route for nutritional intake is through the GI tract because it enhances the immune system and is safer, easier, less expensive, and more enjoyable.

Nutrition Management. The dietitian calculates the nutrients required daily and plans the patient's diet. In collaboration with the health care provider and dietitian, provide high-calorie, nutrient-rich foods (e.g., milkshakes, cheese, supplement drinks like Boost or Ensure). Assess the patient's food likes and dislikes. A feeding schedule of six small meals may be tolerated better than three large ones. A pureed or

NURSING SAFETY PRIORITY

Action Alert

Malnourished ill patients often need to be encouraged to eat. Instruct UAP who are feeding patients to keep food at the appropriate temperature and to provide mouth care before feeding. Assess for other needs, such as pain management, and provide interventions to make the patient comfortable. Pain can prevent patients from enjoying their meals. Remove bedpans, urinals, and emesis basins from sight. Provide a quiet environment, which is conducive to eating. Soft music may calm those with advanced dementia or delirium. Appropriate time should be taken so that the patient does not feel rushed through a meal.

CONSIDERATIONS FOR OLDER ADULTS

Some patients, especially older adults, may take a long time to eat even small quantities of food because they tend to be less hungry than younger adults. If available, suggest that family members bring in favorite or ethnic foods that the patient might be more likely to eat. Teach them about ways to encourage the patient to increase food intake. [Chart 63-3](#) describes additional interventions to promote nutritional intake in older adults.

Restorative feeding programs help nursing home residents who need special assistance. These residents often eat in a separate dining area so that time and attention can be given to them. Some nursing homes have designated food and nutrition nursing assistants and/or trained volunteers who are primarily responsible for promoting and maintaining nutrition and hydration. Delegate and supervise these UAPs during resident mealtime.

If the patient cannot take in enough nutrients in food, fortified **medical nutritional supplements (MNSs)** (e.g., Ensure, Sustacal, Carnation Instant Breakfast [also available as lactose-free supplement]) may be given, especially to older adults. Many commercial enteral products are available. For patients with medical diagnoses such as liver and renal disease or diabetes, special products that meet those needs are available.

dental soft diet may be easier for those who have problems chewing or are **edentulous** (toothless).

Nutritional supplements used in acute care, long-term care, and home care can be costly. In addition, patients may refuse them and the supplements are then wasted. In a classic study, Bender et al. (2000) found that a more successful alternative to having the MNS given by nursing assistant staff in the nursing home was to have the supplements delivered by nurses during their usual medication passes. In this study, the nurses gave 60 mL or more of the MNS at least four times a day with the residents' medications. As a result, the patients gained weight and had fewer pressure ulcers, thus making the program very cost-effective and providing positive clinical outcomes.

Nutritional supplements are supplied as liquid formulas, powders, soups, coffee, and puddings in a variety of flavors. They come in different degrees of sweetness and are also available as modular supplements that provide single nutrients. Examples of modular supplements are Polycose glucose polymers for carbohydrates and Resource Beneprotein for protein, both available in liquid and powder form.

CHART 63-3 NURSING FOCUS ON THE OLDER ADULT

Promoting Nutritional Intake

- Be sure patient is toileted and receives mouth care before mealtime.
- Make sure that patient has glasses and hearing aids in place, if appropriate, during meals.
- Be sure that bedpans, urinals, and emesis basins are removed from sight.
- Give analgesics to control pain and/or antiemetics for nausea at least 1 hour before mealtime.
- Remind unlicensed assistive personnel (UAP) to have patient sit in chair, if possible, at mealtime.
- If needed, open cartons and packages and cut up food at the patient's and/or family's request.
- Observe the patient during meals for food intake.
- Ask the patient about food likes and dislikes and ethnic food preferences.
- Encourage self-feeding, or feed the patient slowly; *delegate* this activity to UAP if desired.
- If feeding patient, sit at eye-level if culturally appropriate.
- Create an environment that is conducive to eating and socialization and relaxation, if possible.
- Decrease distractions, such as environmental noise from television, music, or other people.
- Provide adequate, nonglaring lighting.
- Keep patient away from offensive or medicinal odors.
- Keep eye contact with the patient during the meal if culturally appropriate.
- Serve snacks with activities, especially in long-term care settings; *delegate* this activity to UAP if desired.
- Document the percentage of food eaten at each meal and snack; *delegate* this activity to UAP if appropriate.
- Ensure that meals are visually appealing, appetizing, appropriately warm or cold, and properly prepared.
- Do not interrupt patients during mealtimes for nonurgent procedures or rounds.
- Assess for need for supplements between meals and at bedtime.
- Review the patient's drug profile, and discuss with the health care provider the use of drugs that might be suppressing appetite.
- If the patient is depressed, be sure that the depression is treated by the health care provider.

Carbohydrate modulars are useful only if additional calories are needed. Protein modulars are indicated when metabolic stress causes a need for higher protein intake.

The dietitian may ask the nursing staff to keep a food and fluid intake record for at least 3 consecutive days to help assess the patient's nutritional status. Delegate this activity to UAP under your supervision. UAP also weigh the patient daily, every 3 days, or once a week, depending on the health care setting and severity of malnutrition.

Drug Therapy. Multivitamins, zinc, and an iron preparation are often prescribed to treat or prevent anemia. Monitor the patient's hemoglobin and hematocrit levels. Drug therapy can affect nutritional status. For example, iron can cause constipation and zinc can cause nausea and vomiting.

If the patient still does not receive enough nutrition by mouth using the interventions just mentioned, request **specialized nutrition support (SNS)**. SNS consists of either total enteral nutrition (TEN) or total parenteral nutrition (TPN).

Total Enteral Nutrition. Patients often cannot meet the desired outcomes of nutritional therapy through their usual oral intake because of increased metabolic demands or a decreased ability to eat. Therefore TEN using enteral tube feeding may be necessary to supplement oral intake or to provide total nutritional support.

Patients likely to receive TEN can be divided into three groups:

- Those who can eat but cannot maintain adequate nutrition by oral intake of food alone
- Those who have permanent neuromuscular impairment and cannot swallow
- Those who do not have permanent neuromuscular impairment but are critically ill and cannot eat because of their condition

Patients in the first group are often older adults or patients receiving cancer treatment who cannot meet their calorie and protein needs. In some cases, this artificial nutrition and hydration may not be desired. For example, some patients have advance directives stating that they do not want to be kept alive by artificial nutrition and hydration if certain conditions exist. *However, legal and ethical questions arise when patients are not able to make their wishes known!*

For many years it was believed that withholding food and fluids would cause discomfort. Terminally or chronically ill patients who do not eat and drink may not suffer. In fact, they may be more comfortable if food and fluids are withheld. *The decision to feed is complex, and there is no clear right or wrong answer. To compound this legal and ethical dilemma, medical complications (e.g., aspiration, pressure ulcers) are common in older adults who are tube-fed.*

Decisions about these dilemmas are aided by the advice of interdisciplinary ethics committees in health care facilities. When clinicians are making decisions about the desirability of tube feedings in these cases, the focus should be on achieving consensus by:

- Reviewing what is known about tube feedings, especially their risks and benefits
- Reviewing the medical facts about the patient
- Investigating any available evidence that would help understand the patient's wishes
- Obtaining the opinions of all stakeholders in the situation
- Delaying any action until consensus is achieved

Those in the second group of patients likely to receive TEN usually have permanent swallowing problems and require some type of feeding tube for delivery of the enteral product on a long-term basis. Examples of conditions that can cause permanent swallowing problems are strokes, severe head trauma, and advanced multiple sclerosis. Patients in the third group receive enteral nutrition for as long as their illness lasts. The feeding is discontinued when the patient's condition improves and he or she can eat again. TEN is contraindicated for patients in states of significant hemodynamic compromise, such as those with diffuse peritonitis, severe acute or chronic pancreatitis, intestinal obstruction, intractable vomiting or diarrhea, and paralytic ileus (Bankhead et al., 2009).

Many commercially prepared enteral products are available. A therapeutic combination of carbohydrates, fat, vitamins, minerals, and trace elements is available in liquid form. Differences among products allow the dietitian to select the right formula for each patient. A prescription from the health care provider is required for enteral nutrition, but the dietitian usually makes the recommendation and computes the amount and type of product needed for each patient.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

An older client admitted to the hospital from the nursing home refuses to eat anything on her meal tray. What instructions will the nurse give to the nursing assistant who is attempting to feed the client? **Select all that apply.**

- A. "Feed her the soft food because she has no teeth."
- B. "Place the fork in her hand and leave the room."
- C. "Sit at her level so that she can feel more comfortable."
- D. "Take your time feeding her and don't rush her."
- E. "Offer her the Ensure supplement instead of feeding her."
- F. "Ask the client what foods she likes and dislikes."

Methods of Administering Total Enteral Nutrition. TEN is administered as "tube feedings" through one of the available GI tubes, either through a nasenteric or enterostomal tube. It can be used in the patient's home or any health care setting.

A **nasenteric tube (NET)** is any feeding tube inserted nasally and then advanced into the GI tract, such as a Keofeed, Entriplex, or Dobhoff tube. Commonly used NETs include the **nasogastric (NG) tube** and the smaller (small-bore) **nasoduodenal tube (NDT)** (Fig. 63-3, A). A nasojejunal tube (NJT) is also available but is used less often than the other NETs.

The NDTs are used for delivering *short-term* enteral feedings (usually less than 4 weeks) because they are easy to use and are safer for the patient at risk for aspiration *if the tip of the tube is placed below the pyloric sphincter of the stomach and into the duodenum*. Small-bore polyurethane or silicone tubes from 8 to 12 Fr external diameter are preferred. The smaller tubes are more comfortable and are less likely to cause complications such as nasal irritation, sinusitis, tissue erosion, and pulmonary compromise.

Enterostomal feeding tubes are used for patients who need *long-term* enteral feeding. The most common types are gastrostomies and jejunostomies. The surgeon directly accesses the GI tract using various surgical, endoscopic, and laparoscopic techniques.

A **gastrostomy** is a stoma created from the abdominal wall into the stomach, through which a short feeding tube is inserted by the surgeon. It may require a small abdominal incision or may be placed endoscopically. This tube is called a **percutaneous endoscopic gastrostomy (PEG)** or dual-access gastrostomy-jejunostomy (PEG/J) tube. The PEG does not require general anesthesia for placement and is more secure and more durable than traditional gastrostomies. An alternative to either device is the **low-profile gastrostomy device (LPGD)** (Fig. 63-3, B and C). The LPGD is available

FIG. 63-3 Feeding tubes used for total enteral nutrition. **A**, Nasoduodenal tube. **B** and **C**, Gastrostomy tubes.

with a firm or balloon-style internal bumper or retention disk. An anti-reflux valve keeps GI contents from leaking onto the skin. This device is less irritating to the skin, longer lasting, and more cosmetically pleasing. It also allows greater patient independence. However, skin-level devices do not allow easy access for checking **residuals** (the amount of feeding that remains in the stomach).

Jejunostomies are used less often than gastrostomies. A **jejunostomy** is used for long-term feedings when it is desirable to bypass the stomach, such as with gastric disease, upper GI obstruction, and abnormal gastric or duodenal emptying.

Tube feedings are administered by bolus feeding, continuous feeding, and cyclic feeding. **Bolus feeding** is an intermittent feeding of a specified amount of enteral product at set intervals during a 24-hour period, typically every 4 hours. This method can be accomplished manually or by infusion through a mechanical pump or controller device. Another method of tube feeding is continuous enteral feeding. **Continuous feeding** is similar to IV therapy in that small amounts are continuously infused (by gravity drip or by a pump or controller device) over a specified time. The most commonly seen method, **cyclic feeding**, is the same as continuous feeding except the infusion is stopped for a specified time in each 24-hour period, usually 6 hours or longer (“down time”). Down time typically occurs in the morning to allow bathing, treatments, and other activities.

Infusion rates for cyclic feedings (and to some extent for intermittent bolus feeding) vary with the total amount of solution to be infused, the specific composition of the product, and the response of the patient to the feeding. The health care provider and dietitian usually decide the type, rate, and method of tube feeding, as well as the amount of additional water (“free water”) needed. If the patient can swallow small amounts of food, he or she may also eat orally while the tube is in place.

The nurse is responsible for the care and maintenance of the feeding tube and the enteral feeding. **Chart 63-4** lists best practices for the patient receiving TEN.

Complications of Total Enteral Nutrition. The nursing priority for care is patient safety, including preventing, assessing, and managing complications associated with tube feeding. Some complications of therapy result from the type of tube used to administer the feeding, and others result from the enteral product itself. The most common problem is the development of a clogged tube. Use the tips in **Chart 63-5** to maintain tube patency.

Patients receiving TEN are at risk for several other complications, including refeeding syndrome, tube misplacement and dislodgement, abdominal distention and nausea/vomiting, and fluid and electrolyte imbalance, often associated with diarrhea. These problems can be prevented if the patient is carefully monitored and complications are detected early.

Refeeding Syndrome. **Refeeding syndrome** is a life-threatening metabolic complication that can occur when nutrition is restarted for a patient who is in a *starvation* state. When a patient is starved for nutrition, the body breaks down fat and protein, rather than carbohydrates, for energy. Protein catabolism leads to muscle and cell loss, often in major organs like the heart, liver, and lungs. The body’s cells lose valuable electrolytes, including potassium and phosphate, into the

plasma. Insulin secretion decreases in response to these changes. When *refeeding* begins, insulin production resumes and the cells take up glucose and electrolytes from the bloodstream, thus depleting serum levels.

! NURSING SAFETY PRIORITY

Critical Rescue

The electrolyte shift of refeeding syndrome can cause cardiovascular, respiratory, and neurologic problems, primarily as a result of hypophosphatemia (Mehanna et al., 2008). Observe for clinical manifestations of this electrolyte imbalance, including shallow respirations, weakness, acute confusion, seizures, and increased bleeding tendency. Report and document your findings immediately. More information on fluid and electrolyte imbalance can be found in Chapter 13.

CHART 63-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Tube Feeding Care and Maintenance

- If nasogastric or nasoduodenal feeding is prescribed, use a soft, flexible, small-bore feeding tube (smaller than 12 Fr). *The initial placement of the tube should be confirmed by x-ray study.* Secure the tube with tape or a commercial attachment device after applying a skin protectant; change the tape regularly.
- Check tube placement by x-ray study when the correct position of the tube is in question; *an x-ray study is the most reliable method.*
- If a gastrostomy or jejunostomy tube is used, assess the insertion site for signs of infection or excoriation (e.g., excessive redness, drainage). Rotate the tube 360 degrees each day, and check for in-and-out play of about $\frac{1}{4}$ inch (0.6 cm). If the tube cannot be moved, notify the health care provider immediately because the retention disk may be embedded in the tissue. Cover the site with a dry, sterile dressing, and change the dressing at least once a day.
- Check and record the residual volume every 4 to 6 hours, or per facility policy, by aspirating stomach contents into a syringe. If residual feeding is obtained, check with the health care provider for the appropriate intervention (usually to slow or stop the feeding for a time) or use the American Society of Parenteral and Enteral Nutrition (ASPEN) best practice recommendations.
- Check the feeding pump to ensure proper mechanical operation.
- Ensure that the enteral product is infused at the prescribed rate (mL/hr).
- Change the feeding bag and tubing every 24 to 48 hours; label the bag with the date and time of the change with your initials. Use an irrigation set for no more than 24 hours.
- For continuous or cyclic feeding, add only 4 hours of product to the bag at a time to prevent bacterial growth. *A closed system is preferred, and each set should be used no longer than 24 hours.*
- Wear clean gloves when changing or opening the feeding system or adding product; wipe the lid of the formula can with clean gauze; wear sterile gloves for critically ill or immunocompromised patients.
- Label open cans with date and time opened; cover, and keep refrigerated. Discard any unused open cans after 24 hours.
- *Do not use blue (or any color) food dye in formula because it does not assess aspiration and can cause serious complications.*
- To prevent aspiration, keep the head of the bed elevated at least 30 degrees during the feeding and for at least 1 hour after the feeding for bolus feeding; continuously maintain semi-Fowler’s position for patients receiving cyclic or continuous feeding.
- Monitor laboratory values, especially blood urea nitrogen (BUN), serum electrolytes, hematocrit, prealbumin, and glucose.
- Monitor for complications of tube feeding, especially diarrhea.
- Monitor and carefully record the patient’s weight and intake and output as requested by the physician or dietitian.

CHART 63-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Maintaining a Patent Feeding Tube

- Flush the tube with 20 to 30 mL of water (or the amount prescribed by the health care provider or dietitian):
 - At least every 4 hours during a continuous tube feeding
 - Before and after each intermittent tube feeding
 - Before and after drug administration (use warm water)
 - After checking residual volume
- If the tube becomes clogged, use 30 mL of water for flushing, applying gentle pressure with a 50-mL piston syringe.
- Avoid the use of carbonated beverage, except for existing clogs *when water is not effective*. Do not use cranberry juice.
- Whenever possible, use liquid medications instead of crushed tablets unless liquid forms cause diarrhea; make sure that the drug is compatible with the feeding solution.
- Do not mix drugs with the feeding product before giving. Crush tablets as finely as possible, and dissolve in warm water. (*Check to see which tablets are safe to crush. For example, do not crush slow-acting [SA] or slow-release [SR] drugs.*)
- Consider use of automatic flush feeding pump such as Flexiflo or Kangaroo.

Refeeding syndrome can be prevented if patients are carefully assessed and managed for nutritional needs. Interventions to supplement or replace nutrition should be implemented early before the patient is in a starvation state.

Tube Misplacement and Dislodgement. A less common but more serious complication is misplacement or dislodgement of the tube, *which can cause aspiration and possible death*. Lung intubation occurs in up to 27% of enteral tubes placed in hospitalized patients (Elpern et al., 2007). *Immediately remove any tube that you suspect is dislodged!* The Joint Commission's National Patient Safety Goals and the Centers for Medicare and Medicaid require all health care facilities to establish and implement procedures and systems to prevent patient harm from medical complications.

Several techniques should be used to confirm proper placement to prevent harm and to keep the patient safe. *An x-ray is the most accurate confirmation method and should always be done upon initial tube insertion.* After the initial placement is confirmed, check the placement before each intermittent feeding or at least every 4 to 8 hours during feeding. Also check placement before each drug administration.

The traditional auscultatory method for checking tube placement may not be reliable, especially for patients with small-bore tubes. In this method, the nurse instills 20 to 30 mL of air into the tube ("insufflation") while listening over the epigastric area (stomach) with a stethoscope. *The resulting whooshing sound does not guarantee correct tube placement!*

Although some patients have respiratory distress if the tube is misplaced into the lungs, some do not. Therefore better methods for patient safety are being researched. Several safer procedures have been recommended for checking tube placement *after the initial placement has been confirmed by x-ray*. These methods include:

- Testing aspirated contents for pH, bilirubin, trypsin, or pepsin
- Assessing for carbon dioxide using capnometry

Some hospitals and nursing homes support testing the *pH of GI contents* at the bedside. To perform this procedure, aspirate

a sample of the GI content, observe its color, and test its pH. When aspirating fluid, wait at least 1 hour after drug administration and then flush the tube with 20 mL of air to clear it. Collect the aspirate, and test it with pH paper. The pH of gastric fluid ranges from 0 to 4.0. If the tube has moved down into the intestines, the pH will be between 7.0 and 8.0. If the tube is in the lungs, the pH will be greater than 6.0. The pH may also be as high as 6 if the patient takes certain drugs, such as H₂ blockers (e.g., ranitidine [Zantac] and famotidine [Pepcid]). Because these drugs affect pH, bilirubin testing or capnometry may be more reliable and valid methods for predicting tube location.

A newer method that has been researched is the use of *capnometry* to determine if carbon dioxide is emitted from the tube (Elpern et al., 2007). A device to measure the presence of the gas is attached to the end of the tube after placement. The test is positive for carbon dioxide if the tube is placed into the lungs, rather than the stomach. *The tube should be immediately removed if the gas is detected.*

! NURSING SAFETY PRIORITY

Action Alert

If enteral tubes are misplaced or become dislodged, the patient is likely to aspirate. Aspiration pneumonia is a common, life-threatening complication associated with TEN, especially for older adults. Observe for increasing temperature and pulse, as well as for other signs of dehydration such as dry mucous membranes and decreased urinary output. Auscultate lungs every 4 to 8 hours to check for diminishing breath sounds, especially in lower lobes. Patients may become short of breath and report chest discomfort. A chest x-ray confirms this diagnosis, and treatment with antibiotics is started.

Abdominal Distention and Nausea/Vomiting. Abdominal distention, nausea, and vomiting during tube feeding are often caused by overfeeding. To *prevent* overfeeding, check gastric residual volumes every 4 to 6 hours, depending on facility policy and the needs of the patient. The American Society of Parenteral and Enteral Nutrition (ASPEN) recommends holding a feeding if the gastric residual volumes are more than 200 mL on two consecutive assessments. In some facilities, feedings are temporarily held if the gastric residual is 100 mL or more, depending on the patient. After a period of rest, the feeding can be restarted at a lower flow rate.

A problem with frequent residual assessments is that the formula may clog the tube during aspiration, even if flushed with water. If the patient's residual volumes have been low or zero and he or she has no abdominal distention, nausea, or vomiting, consider discontinuing these assessments, depending on facility policy.

Fluid and Electrolyte Imbalances. *Patients receiving enteral nutrition therapy are at an increased risk for fluid imbalances.* They are often older or debilitated and may also have cardiac or renal problems. Fluid imbalances associated with enteral nutrition are usually related to the body's response to increased serum osmolarity, but *fluid overload* from too much tube feeding can also occur.

Osmolarity is the amount or concentration of particles dissolved in solution. This concentration exerts a specific osmotic pressure within the solution. Normal osmolarity of extracellular fluid (ECF) ranges between 270 and 300 mOsm. Enteral feeding products range in osmolarity from isotonic (about 300 mOsm) to extremely hypertonic (600 mOsm).

Electrolytes (including sodium) contribute to this hypertonicity, but more of the osmolarity is determined by the concentration of proteins and sugar molecules in the enteral product. Even when the product is isotonic, the ECF can become hyperosmolar unless some hypotonic fluids are also administered to the patient. This situation is most likely to develop in patients who are unconscious, unable to respond to the thirst reflex, on fluid restrictions, or receiving hyperosmotic enteral preparations.

Because increased plasma osmolarity is largely a result of extra glucose and proteins (which tend to remain in the plasma rather than move to interstitial spaces), the plasma osmotic pressure (water-pulling pressure) is increased. In this situation, intracellular and interstitial water move into and expand the plasma volume. This volume expansion results in an increased renal excretion of water (in patients with normal renal function) and leads to osmotic *dehydration*. If patients do *not* have normal renal and cardiac function, expansion of the plasma volume can lead to circulatory overload and pulmonary edema, especially in older adults. Assess for signs and symptoms of circulatory overload, such as peripheral edema, sudden weight gain, crackles, dyspnea, increased blood pressure, and bounding pulse. Collaborate with the dietitian and health care provider to plan the correct amount of fluid to be provided.

Excessive *diarrhea* may develop when hyperosmolar enteral preparations are delivered quickly. This situation can also lead to *dehydration* through excessive water loss. Collaborate with the health care provider and dietitian for recommendations to prevent diarrhea. The dietitian usually changes the feeding to a more iso-osmolar formula. Most of these formulas can be started full strength but slowly at 15 to 20 mL/hr. The rate is gradually increased as the patient tolerates and as the expected nutritional outcome is achieved.

If diarrhea continues, especially if it has a very foul odor, the patient should be evaluated for *Clostridium difficile* or other infectious organisms. Contamination can occur because of repeated and often faulty handling of the feeding solution and system. *Wear clean gloves when changing systems and adding product. Sterile gloves may help prevent infection in critically ill or immunocompromised patients. A closed feeding system is preferred over an open one because the chance of contamination is lessened* (see [Chart 63-4](#)). Tubes with ports also minimize contamination by eliminating the need to open the feeding system to administer drugs.

In some cases, diarrhea may be the result of multiple liquid medications, such as elixirs and suspensions that have a very high osmolarity. Examples include acetaminophen (Tylenol), furosemide (Lasix), and phenytoin (Dilantin). Patients receiving multiple liquid drugs should be evaluated by the health care provider to determine whether their drug regimen can be changed to prevent diarrhea. Diluting these liquids may also be an option.

Depending on the patient's state of health, some electrolyte imbalances can be avoided. This is achieved by the use of enteral preparations containing lower concentrations of the electrolytes that the patient cannot handle well. For example, renal patients with high potassium levels receive a special formula that is used for this imbalance.

The two most common electrolyte imbalances associated with enteral nutrition therapy are hyperkalemia and hyponatremia. Both of these conditions may be related to

hyperglycemia-induced hyperosmolarity of the plasma and the resultant osmotic diuresis. Fluid and electrolyte imbalances are discussed in detail in [Chapter 13](#).

Parenteral Nutrition. When a patient cannot effectively use the GI tract for nutrition, either partial or total parenteral nutrition therapy may maintain or improve his or her nutritional status. This form of IV therapy differs from standard IV therapy in that any or all nutrients (carbohydrates, proteins, fats, vitamins, minerals, and trace elements) can be given. One liter of IV fluid containing 5% dextrose, which is often used as standard therapy, provides only 170 kcal. A hospitalized patient typically receives 3 to 4 L a day, for a total number of calories ranging between 500 and 700 a day. This calorie intake is not sufficient when the patient requires IV therapy for a prolonged period and cannot eat an adequate diet or has increased calorie needs for tissue repair and building.

Partial Parenteral Nutrition. Partial, or peripheral, parenteral nutrition (PPN) is usually given through a cannula or catheter in a large distal vein of the arm or through a peripherally inserted central catheter (PICC line). (See [Chapter 15](#) for care of patients with PICC lines.) This nutritional alternative is used for some patients who can eat but are not able to take in enough nutrients to meet their needs. The patient must have adequate peripheral vein access and be able to tolerate large volumes of fluid to have PPN. Two types of solutions are commonly used in various combinations for PPN: IV fat (lipid) emulsions (IVFEs) and amino acid–dextrose solutions. IVFEs are usually given using a piggyback method.

! NURSING SAFETY PRIORITY

Critical Rescue

For patients receiving fat emulsions, monitor for manifestations of fat overload syndrome, especially in those who are critically ill. These manifestations include fever, increased triglycerides, clotting problems, and multi-system organ failure. Discontinue the IVFE infusion and report any of these changes to the health care provider immediately if this complication is suspected.

Most IVFEs (20% fat emulsion) are isotonic, but the tonicity of commercially prepared amino acid–dextrose solutions ranges from 300 mOsm to nearly 900 mOsm for PPN. Amino acid–dextrose solutions are considered more stable than IVFEs and therefore additives (e.g., vitamins, minerals, electrolytes, trace elements) tend to be mixed with them. These solutions must be delivered through an in-line filter and are administered by an infusion pump for an accurate and constant delivery rate.

Some PPN products are a *mixture* of lipids (10% or 20% fat emulsion) and an amino acid–dextrose (usually 10%) solution. This mixture of three types of nutrients is referred to as a 3:1, *total nutrient admixture (TNA)*, or *triple-mix solution*.

Total Parenteral Nutrition. When the patient requires intensive nutritional support for an extended time, the health care provider prescribes centrally administered **total parenteral nutrition (TPN)**. TPN is delivered through access to central veins, usually through a PICC line or the subclavian or internal jugular veins. Central venous catheters and associated nursing care are described in detail in [Chapter 15](#).

Total parenteral nutrition solutions contain higher concentrations of dextrose and proteins, usually in the form of synthetic amino acids or protein hydrolysates (3% to 5%). These solutions are hyperosmotic (three to six times the osmolality of normal blood). The base solutions are available as commercially prepared solutions. The hospital or community pharmacist adds components (specific electrolytes, minerals, trace elements, and insulin) according to the patient's nutritional needs. This therapy provides needed calories and spares body proteins from catabolism for energy requirements.

The TPN solutions are administered with an infusion pump. The osmolality of the fluid and the concentrations of the specific components make controlled delivery essential.

Patients receiving parenteral nutrition fluids are at risk for a wide variety of serious and potentially life-threatening complications. Complications may result from the solutions or from the peripheral or central venous catheter. The following discussion is limited to the complications that involve fluid or electrolyte balance. Complications of IV cannulas and central venous catheters are discussed in [Chapter 15](#), including infection and sepsis.

Patients receiving parenteral nutrition therapy are at high risk for fluid imbalance. Not only is fluid delivered directly into the venous system, but also the extreme hyperosmolality of the solutions stimulates fluid shifts between body fluid compartments. The hyperosmolality is caused by their amino acid and dextrose concentrations. Increased dextrose causes hyperglycemia (increased blood glucose). As a result, some of the dextrose moves into the interstitial and intracellular spaces, where it is metabolized. However, dextrose remains in the plasma volume when the solutions are administered too rapidly, without enough insulin coverage, or in the presence of hyponatremia and hypokalemia. The result is a shift of water from the interstitial and intracellular spaces into the plasma. Expansion of the plasma volume together with hyperglycemia can cause osmotic diuresis and lead to serious dehydration and hypovolemic shock. If the patient also has cardiac or renal dysfunction, he or she may develop fluid overload, congestive heart failure, and pulmonary edema. Monitor the infusion rate of the parenteral fluid, and give insulin as prescribed.

Monitor for these complications by taking daily weights and by recording accurate intake and output while the patient is receiving parenteral nutrition. Serum glucose and electrolyte values are also monitored ([Chart 63-6](#)). Report any major changes or abnormalities to the health care provider, and document all assessments and interventions.

Patients receiving TPN are at an increased risk for many different electrolyte imbalances, depending on the composition of the solution and whether a fluid imbalance occurs. The health care provider usually requests frequent determinations of serum electrolyte levels to detect these imbalances. The risk for metabolic and electrolyte complications is reduced when the rate of administration is carefully controlled and patients are closely monitored for response to treatment. Potassium and sodium imbalances are common, especially when insulin is also administered as part of the therapy. Calcium imbalances, particularly hypercalcemia, are associated with TPN, although immobility may play more of a role than the actual therapy in developing this imbalance.

CHART 63-6 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care and Maintenance of Total Parenteral Nutrition

- Check each bag of total parenteral nutrition (TPN) solution for accuracy by comparing it with the physician's or pharmacist's prescription.
- Monitor the IV pump for accuracy in delivering the prescribed hourly rate.
- If the TPN solution is temporarily unavailable, give 10% dextrose/water (D/W) or 20% D/W until the TPN solution can be obtained.
- If the TPN administration is not on time ("behind"), do not attempt to "catch up" by increasing the rate.
- Monitor the patient's weight daily or according to facility protocol.
- Monitor serum electrolytes and glucose daily or per facility protocol. (Many facilities require finger-stick blood sugars [FSBSs] every 4 hours, especially if the patient is receiving insulin. Urine testing for ketones may also be requested.)
- Monitor for, report, and document complications, including fluid and electrolyte imbalances.
- Monitor and carefully record the patient's intake and output.
- Assess the patient's IV site for signs of infection or infiltration (see [Chapter 15](#)).
- Change the IV tubing every 24 hours or per facility protocol.
- Change the dressing around the IV site every 48 to 72 hours or per facility protocol.
- Before administering TPN, have a second nurse check the prescription and solution to prevent patient harm.

Community-Based Care

Malnourished patients can be cared for in a variety of settings, including the acute care hospital, transitional care unit, nursing home, or their own home. Malnutrition is often diagnosed when the patient is admitted to the acute care hospital or shortly after hospitalization if complications such as poor wound healing or sepsis occur. If the patient is severely compromised, he or she may require admission to a traditional nursing home for either transitional or long-term care. If adequate home support is available, he or she may be discharged to home in the care of a family member or other caregiver. Home care nurses may be needed to monitor and direct the care.

Home Care Management

The malnourished patient needs a variety of resources at home to continue aggressive nutrition support. If he or she can consume food by the oral route, the case manager or other discharge planner determines whether financial resources are available for the necessary nutrition supplements. If the hospital provides ambulatory nutrition counseling services, the patient is scheduled for follow-up after discharge for assessment of weight gain.

Teaching for Self-Management

The dietitian teaches the malnourished patient and family about high-calorie, high-protein diet and nutritional supplements. In collaboration with the pharmacist, review specific parenteral solutions with the patient and family or significant others.

Reinforce the importance of adhering to the prescribed diet, and review any drugs the patient may be taking. If using

an iron preparation, teach the importance of taking the drug immediately before or during meals. Caution the patient that iron tends to cause constipation. For the older adult already susceptible to constipation, emphasize the importance of measures for prevention, including adequate fiber intake, adequate fluids, and exercise.

Some patients are discharged to home with enteral or parenteral nutrition. Teach the family or other caregiver how to continue these therapies. Remind caregivers to consider the psychosocial aspects of these alternative methods for nutrition. For example, the caregiver can bring the enteral product and napkin to the patient on a decorative tray to make the feeding experience more elegant and “normal.” Moving the feeding equipment out of view of the patient when it is not in use is also helpful.

Health Care Resources

The malnourished patient discharged to home on enteral or parenteral nutrition support needs the specialized services of a home nutrition therapy team. This team generally consists of the physician, nurse, dietitian, pharmacist, and case manager or social worker. Several commercial companies supply these services to patients at home in addition to the feeding supplies and formulas and health teaching.

EVALUATION: OUTCOMES

Evaluate the care of the malnourished patient based on the identified priority patient problem. The primary expected outcome is that he or she has available nutrients to meet the metabolic demands for maintaining weight and total protein and has adequate hydration.

OBESITY

Pathophysiology

Obesity, like cancer, is not just one disease but, instead, many conditions with varying causes. The terms *obesity* and *overweight* are often used interchangeably, but they refer to different health problems. **Overweight** is an increase in body weight for height compared with a reference standard, or up to 10% greater than ideal body weight (IBW). However, this weight may not reflect excess body fat. It is possible for well-developed athletes to appear overweight because of increased muscle (lean) mass, in which the proportion of muscle to fat is greater than average.

Obesity refers to an excess amount of body fat when compared with lean body mass. The normal amount of body fat in *men* is between 15% and 20% of body weight. For *women*, the normal amount is 18% to 32%. An obese person weighs at least 20% above the upper limit of the normal range for ideal body weight. **Morbid obesity**, also called *extreme obesity*, refers to a weight that has a severely negative effect on health—usually more than 100% above IBW.

More than 72 million Americans are obese (Clancy, 2010), and another third of Americans are overweight. About 10% or more of adults are morbidly obese. *This problem is the second leading cause of preventable deaths in the United States, second only to smoking, and has become a national crisis. Obesity across the life span is considered an epidemic in the United States and Canada. Worldwide, it is recognized as a major global health problem, costing billions of dollars for health care and lost productivity.*

The pathophysiology of obesity is very complex. A number of chemicals in the body, including hormones known as *adipokines*, work together to affect appetite and fat metabolism:

- **Leptin**: a hormone released by fat cells and possibly by gastric cells; it also acts on the hypothalamus to control appetite
- **Adiponectin**: an anti-inflammatory and insulin sensitizing hormone
- **Resistin**: a hormone produced by fat cells that creates resistance to insulin activity
- **Inflammatory cytokines**: such as inflammatory interleukins and tumor necrosis factor- α
- **Apolipoprotein E**: one of several regulators of lipoprotein metabolism
- **Cholecystokinin**: a hormone that stimulates digestive juices and may work with leptin to increase or decrease appetite
- **Ghrelin**: the “hunger hormone” that is secreted in the stomach; increases in a fasting state and decreases after a meal

Some adipokines are neuropeptides, including orexins and anorexins, which play a role in body weight. **Orexins** are appetite stimulants; examples are ghrelin secreted by the stomach and peptide YY from the intestines. **Anorexins** decrease appetite and include leptin and insulin (McCance et al., 2010). Increased circulating plasma levels of orexins are associated with the development of obesity. However, in some people, high levels of leptin may not be effective in suppressing appetite—a condition known as *leptin resistance*. In this case, overeating and excessive weight gain can result. Hyperleptinemia also stimulates the autonomic nervous system and contributes to blood vessel inflammation and ventricular hypertrophy. These actions may help explain why obese patients are most at risk for hypertension, atherosclerosis, and heart disease (Kulie et al., 2011). Obesity is also associated with insulin resistance, which predisposes obese patients to type 2 diabetes mellitus (see Chapter 67).

Obesity is determined by weight compared with height, BMI, and waist circumference. To establish the percentage of IBW, the *height and weight* of the patient are compared with the midpoint of the desirable weight using an accepted reference standard. The *body mass index (BMI)*, as described previously, is a measure of heaviness and is only an indirect indicator of body fat. It reflects the combined effects of body build, proportions, lean body mass, and body fat. However, BMI has substantial correlations with fat mass for adult men and women and has been validated as a risk factor for cardiovascular disease. A BMI of 25 to 29.9 indicates that a person is overweight. A BMI of 30 or more indicates obesity. *People who are morbidly obese have a BMI of greater than 40 and are at a major risk for life-threatening health problems.*

The distribution of excess body fat rather than the degree of obesity has been used to predict increased health risks. For example, the waist circumference (WC) is a stronger predictor of coronary artery disease (CAD) than is the BMI. A WC greater than 35 inches (89 cm) in women, and a WC greater than 40 inches (102 cm) in men indicate central obesity (National Institute of Diabetes and Digestive and Kidney Diseases, 2008). Central obesity is a major risk factor for CAD, stroke, type 2 diabetes, some cancers (e.g., colon, breast), sleep apnea, and early death.

TABLE 63-3 COMMON COMPLICATIONS OF OBESITY

- Type 2 diabetes mellitus - Hypertension Hyperlipidemia (increased serum lipids) - Coronary artery disease (CAD) - Stroke - Peripheral artery disease (PAD) - Metabolic syndrome - Obstructive sleep apnea	- Obesity hypoventilation syndrome - Depression and other mental health/behavioral health problems - Urinary incontinence Cholelithiasis (gallstones) - Gout - Chronic back pain - Early osteoarthritis - Decreased wound healing
---	---

The waist-to-hip ratio (WHR) is also a predictor of CAD. This measure differentiates peripheral lower body obesity from central obesity. A WHR of 0.95 or greater in men (0.8 or greater in women) indicates android obesity with excess fat at the waist and abdomen.

Complications of Obesity

The major complications of obesity affect primarily the cardiovascular and respiratory systems. However, excess weight can also cause degeneration of the musculoskeletal system, especially the joints (osteoarthritis). Obese people are also more susceptible to infections and infectious diseases than are thinner people and tend to heal more slowly. [Table 63-3](#) lists some of the most common complications of obesity.

Etiology and Genetic Risk

The causes of obesity involve complex interrelationships of many environmental, genetic, and behavioral factors. A number of causes of both human and animal obesity have been identified.

One of the most common causes of being overweight or obese is eating *high-fat and high-cholesterol diets*. Obesity is associated with diet when it contains a significant amount of *saturated fat*, which increases low-density lipoproteins (LDL-C). *Trans fatty acids* (TFAs), saturated fats, and cholesterol are linked to obesity and CAD ([American Heart Association, 2010](#)). By contrast, monounsaturated and polyunsaturated fats are healthy fats.

TFA is made when food manufacturers add hydrogen to vegetable oil, a process known as *hydrogenation*. This process increases the food's shelf life and flavor. Large amounts of TFA can be found in vegetable shortening, commercial baked goods, snack foods, and French fries. Food labels in the United States and Canada include amounts of total fat, subtypes of fat, and cholesterol content per serving.

Physical inactivity has been identified as another cause of overweight and obesity. The major barriers to increasing physical activity include a lack of time or decreased mobility associated with prolonged illness. Regular exercise is associated with lower death rates for adults of any age. It also increases lean muscle, decreases body fat, aids in weight control, and enhances psychological well-being. Regular exercise can also decrease the risk for falling in older adults (see [Chapter 3](#)).

Although some people think that regular exercise has to include joining a fitness program or exercising for long periods, simple forms of exercise like walking 20 minutes

provide the same type of benefit. Older adults can engage in this type of exercise. It does not cost money (like joining a program) and provides health benefits such as strengthening joints and improving cardiovascular health.

Another cause of obesity is *drug therapy*. Some prescribed drugs contribute to weight gain when they are taken on a long-term basis. Examples include:

- Corticosteroids
- Estrogens and certain progestins
- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Antihypertensives
- Antidepressants and other psychoactive drugs
- Antiepileptic drugs
- Certain oral antidiabetic agents

GENETIC/GENOMIC CONSIDERATIONS

Familial and genetic factors seem to play a very important role in obesity. When both parents are overweight, about 80% of their children will be overweight. If neither parent is overweight, fewer than 10% of the children will be overweight. In studies of identical twins, nonidentical twins, and parent-sibling relationships, about 50% of the difference in body fatness is transmitted to children and about 50% of this amount is genetically controlled (McCance et al., 2010).

Genetic composition may predispose some people, but not others, to obesity. Leptin, the hormone encoded by the *ob* gene, appears to send a message to the brain that the body has stored enough fat. This message serves as a signal to stop eating. In some obese people, other gene mutations have been identified, including an abnormality of the melanocortin-4 receptor that inhibits appetite in families with a history of obesity.

A small number of obese people have disorders of the neuroendocrine system. Examples include injury to the hypothalamus, Cushing's disease, polycystic ovary failure, hypogonadism, and growth hormone deficiency.

Health Promotion and Maintenance

Obesity is a major public health problem and is associated with many complications, including death. As a result of this increasing problem, the *Healthy People 2010* agenda addressed the need to reduce the proportion of children, adolescents, and adults who are obese. The new *Healthy People 2020 objectives for Nutrition and Weight Status* include specific population targets related to obesity and healthy nutritional habits ([Table 63-4](#)). In collaboration with the dietitian, teach the importance of weight management and exercise to improve health. Even a 5% weight loss can drastically decrease the risk for coronary artery disease (CAD) and diabetes mellitus.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

In addition to taking a complete history regarding present and past health problems, collect this information about the patient in collaboration with the dietitian:

- Economic status
- Usual food intake
- Eating behavior
- Cultural background
- Attitude toward food

TABLE 63-4 MEETING HEALTHY PEOPLE 2020 SAMPLE OBJECTIVES AND TARGETS: NUTRITION AND WEIGHT STATUS

- Reduce the proportion of adults who are obese (by 10%).
- Increase the proportion of adults who are at a healthy weight (by 10%).
- Increase the proportion of physician visits made by adult patients that include counseling about nutrition or diet (by 15.2%).
- Increase the proportion of primary care physicians who regularly assess body mass index (BMI) in their adult patients (by 10%).
- Increase the contribution of total vegetables to the diets of the population aged 2 years and older (to 1.1 cups per 1000 calories).
- Increase the contribution of fruits to the diets of the population aged 2 years and older (to 0.9 cups per 1000 calories).
- Reduce consumption of saturated fat in the population aged 2 years and older (by 9.5%).

- Appetite
- Chronic diseases
- Drugs (prescribed and OTC, including herbal preparations)
- Physical activity/functional ability
- Family history of obesity
- Developmental level

A nutritional history usually includes a 24-hour recall of food intake and the frequency with which foods are consumed. The adequacy of the diet can be evaluated by comparing the amount and types of foods consumed daily with the established standards. The dietitian then provides a more detailed analysis of nutritional intake.

Physical Assessment/Clinical Manifestations

Obtain an accurate height and weight. The dietitian calculates the percentage of ideal body weight (% IBW) and the body mass index (BMI). He or she may also:

- Measure the waist circumference
- Calculate the waist-to-hip ratio
- Determine arm and calf circumferences

Examine the skin of the obese patient for reddened or open areas. Lift skinfold areas, such as pendulous breasts and abdominal aprons (**panniculus**), to observe for *Candida* (yeast) (a condition called *intertrigo*) or other infections or lesions. Infection of the panniculus is referred to as **panniculitis**.

Psychosocial Assessment

Obtain a psychosocial history to determine the patient's circumstances and emotional factors that might prevent successful therapy or that might be worsened by therapy. Interview the patient to determine his or her perception of current weight and weight reduction. Some patients do not view weight as a problem, which affects treatment and outcome. Ask the patient questions about his or her health beliefs related to being overweight, such as:

- What does food mean to you?
- Do you want to lose weight?
- What prevents you from losing weight?
- What do you think will motivate you to lose weight?
- How do you think you might benefit from losing weight?

Many patients report that they have tried multiple diets to lose weight but either the diets have not worked or they regained the weight they had initially lost. People who attempt restrictive diets become easy targets for the billion-dollar weight-loss industry, yet most dieters regain lost weight. This problem can be even more concerning for the older adult who loses weight and then regains it. Recent studies have shown that this cycle may contribute to loss of lean muscle mass, especially in older men (Lee et al., 2010).

The results of dieting and other efforts can lead to a sense of failure and lowered self-esteem, which often stimulates more overeating. Many overweight and obese people eat in response to environmental and emotional stressors rather than because they are hungry. Ask patients to identify their perceived stressors and what triggers their need for food.

Lifestyle changes are difficult without adequate family and community support. Assess useful coping strategies and support systems that the patient can use during treatment for obesity.

Explore the patient's history to assess:

- Attempts at weight-reduction diets and outcomes
- Effects of obesity on lifestyle
- Effects of obesity on social interactions
- Mental health/behavioral health problems, such as depression
- Effects of obesity on intimate relationships, especially sexuality

Obese men often experience erectile dysfunction (ED), which can cause or worsen depression. Women often experience changes in their menstrual cycles and may have problems getting pregnant.

INTERVENTIONS

Weight is lost only when energy used is greater than intake. Weight loss may be accomplished by nutritional modification with or without the aid of drugs and in combination with a regular exercise program. Patients who may be candidates for surgical treatment include those who have:

- Repeated failure of nonsurgical interventions
- A BMI equal to or greater than 40
- Weight more than 100% above IBW (i.e., morbidly obese)

Nonsurgical Management

Various nutritional approaches and drug therapy have attempted to help obese patients achieve permanent weight loss.

Diet Programs. Diets for helping people lose weight include fasting, very-low-calorie diets, balanced and unbalanced low-energy diets, and novelty diets.

Short-term fasting programs have not been successful in treating morbidly obese patients, and prolonged fasting does not produce permanent benefits. Most patients regain the weight that was lost by this method. In addition, the risks associated with fasting (e.g., severe ketosis) require close medical supervision.

Very-low-calorie diets generally provide 200 to 800 calories/day. Two types of these diets are the *protein-sparing modified fast* and the *liquid formula diet*. The protein-sparing modified fast provides protein of high biologic value (1.5 g/kg of desirable body weight daily) within a limited number of calories. The diet produces rapid weight loss while preserving lean

body mass. The liquid formula diet provides between 33 and 70 g of protein daily.

Both diets require an initial cardiac evaluation, supervision by an interdisciplinary health care team with monitoring by a physician, nutrition counseling by a dietitian, and supplementation with vitamins and minerals. These diets are only one part of a weight-reduction program. Patients who are on these diets should receive nutrition education, psychological counseling, exercise, and behavior therapy. Comparable weight losses have been achieved with both diets, but again, most patients regain the weight they lost.

Nutritionally *balanced diets* generally provide about 1200 calories/day with a conventional distribution of carbohydrate, protein, and fat. Vitamin and mineral supplements may be necessary if energy intakes fall below 1200 calories for women and 1800 calories for men. This diet provides conventional foods that are economical and easy to obtain. Thus the outcome of weight loss is facilitated, and it is hoped that loss is maintained. For example, Weight Watchers is an organization that provides education about nutritionally balanced diets based on a point system. They offer on-site weekly group support meetings or the option of an online community.

Unbalanced low-energy diets, such as the low-carbohydrate diet (e.g., Atkins or South Beach diet), restrict one or more nutrients. Protein and vegetables are encouraged, but certain carbohydrates and high-fat foods are not. Although they remain controversial in the medical community, these diets are extremely popular. Scientific outcome data have been conflicting.

Novelty diets, such as the grapefruit diet, the Cookie diet, and the Hollywood diet, are often nutritionally *inadequate*. This type of diet implies that a certain food or liquid increases metabolic rate or accelerates the oxidation of body fat. Weight loss is achieved because energy is restricted by food choice, but patients do not sustain weight loss after stopping the diet.

Nutrition Therapy. Nutritional recommendations for each patient should be developed through close interaction among the patient, family, physician, nurse, and dietitian. The diet should meet the patient's needs, habits, and lifestyle and should be realistic.

The dietitian develops a diet plan and instructs the patient. At a minimum, the diet should:

- Have a scientific rationale
- Be nutritionally adequate for all nutrients
- Have a low risk-benefit ratio
- Be practical and conducive to long-term success

Calorie estimates are easily calculated. Resting metabolic rate is determined using a gender-specific formula that incorporates the appropriate activity factor. This figure reflects the total calories needed daily for maintaining current weight. To encourage a weight loss of 1 pound (2.2 kg) a week, the dietitian subtracts 500 calories each day. To encourage a weight loss of 2 pounds (4.4 kg) a week, 1000 calories each day are subtracted. The amount of weight lost varies with the patient's food intake, level of physical activity, and water losses. A reasonable expected outcome of 5% to 10% loss of body weight has been shown to improve glycemic control and reduce cholesterol and blood pressure. These benefits continue if the weight loss is sustained.

Exercise Program. A major intervention to manage obesity is to increase the type and amount of daily exercise to burn calories along with change in eating habits. For most

people, adding exercise to a nutritional intervention produces more weight loss than just dieting alone. More of the weight lost is fat, which preserves lean body mass. An increase in exercise can reduce the waist circumference and the waist-to-hip ratio.

Teach patients that increasing and maintaining physical activity levels are important in maintaining weight loss. Many overweight or obese patients are so unfit that it may take several months of conditioning before they can exercise sufficiently to lose weight.

The physical therapist or exercise physiologist or assistant first obtains a clinical exercise and health history. It is important to determine the patient's current exercise pattern, if any, and exercise habits over a lifetime. Teach about the importance of an exercise component in a weight-loss program. The patient's desire to participate in an exercise program and his or her preferred types of exercise are also identified.

The health care provider may evaluate the patient by an exercise stress test. Not all patients need one, but those with chronic disease may need the results to assist with an individual exercise plan. Patients are counseled about unusual signs and symptoms during exercise (e.g., chest pain) and what to do if they occur. The physical therapist or exercise physiologist first emphasizes the importance of exercising consistently and then stresses its duration, intensity, and frequency.

A minimum-level workout should be developed so that consistency can be achieved. The expected outcome is to maintain a lifetime of increased physical activity. The patient is likely to be less fatigued and discouraged with a low-intensity, short-duration program. Encourage sedentary (physically inactive) patients to increase their activity by walking 30 to 40 minutes at least 5 days each week. The activity may be performed all at once or divided over the course of the day. Remind the patient to exercise only under the supervision of the physician. All members of the interdisciplinary team should encourage and support any increase in physical activity. Structured national programs with support staff, such as Curves, may be helpful for some patients. The staff typically offer diet counseling as well as cardiovascular and muscle-toning activities.

Drug Therapy. A BMI of 30 or a BMI of 27 with comorbidities is one indicator for the use of drug therapy. **Anorectic drugs** suppress appetite, which reduces food intake and, over time, may result in weight loss. The Food and Drug Administration in the United States has pulled several drugs off the market and not approved other drugs due to concerns about cardiovascular complications associated with long-term use. The only *prescription* drug still available for the *long-term* treatment of obesity is orlistat (Xenical).

Orlistat inhibits lipase and leads to partial hydrolysis of triglycerides. Because fats are only partially digested and absorbed, calorie intake is decreased. The usual dosage is 120 mg three times daily. Most patients taking this drug have GI symptoms that include loose stools, abdominal cramps, and nausea unless they reduce their fat intake to less than 30% of their food intake each day. Therefore it should be used with caution and limited to adults between 18 and 75 years of age. Treatment is usually not extended beyond 12 months. A lower-dose 60-mg orlistat tablet (Alli) is the only *over-the-counter* weight loss aid product that has received FDA approval for long-term use.

Other sympathomimetic drugs suppress appetite for *short-term* use along with a structured weight-management and exercise program. These drugs act on the central nervous system, including suppressing the appetite center in the hypothalamus. Examples include phentermine (Adipex-P), diethylpropion (Tenuate, Tenuate Dospan), and phendimetrazine (Bontril).

! NURSING SAFETY PRIORITY

Drug Alert

Patients with hypertension, heart disease, and hyperthyroidism should not take anorectic drugs because they may worsen their symptoms. These drugs are not prescribed for any patient taking psychoactive agents because they cause similar side effects. Teach patients who are candidates for sympathomimetic drugs about side effects, which include:

- Palpitations
- Diarrhea or constipation
- Restlessness
- Insomnia
- Dry mouth
- Blurred vision (especially Bontril)
- Change in sex drive or activity
- Anxiety

Behavioral Management. Behavioral management of obesity helps the patient change daily eating habits to lose weight. This ongoing process should produce a change in behavior. Self-monitoring techniques include keeping a record of foods eaten (food diary), exercise patterns, and emotional and situational factors. Stimulus control involves controlling the external cues that promote overeating. Reinforcement techniques are used to self-reward the behavior change. Cognitive restructuring involves modifying negative beliefs by learning positive coping self-statements. Counseling by health care professionals must continue before, during, and after treatment. The 12-step program offered by Overeaters Anonymous (www.oa.org) has helped many people lose weight, especially those who are compulsive eaters.

Complementary and Alternative Therapies. Many complementary and alternative therapies have been tested and used for obesity. These modalities aim to suppress appetite and therefore limit food intake to lose weight:

- Acupuncture
- Acupressure
- Ayurvedic (a combination of holistic approaches)
- Hypnosis

Descriptions of most of these methods can be found in [Chapter 2](#).

Surgical Management

At any weight, some patients seek to improve their appearance by having a variety of cosmetic procedures to reduce the amount of adipose tissue in selected areas of the body. A typical example of this type of surgery is **liposuction**, which can be done in a physician's office or ambulatory surgery center. Although the patient's appearance improves, if weight gain continues, the fatty tissue will return. This procedure is not a solution for people who are morbidly obese.

Morbidly obese people who do not respond to traditional interventions may be considered for a major surgical

procedure aimed at producing permanent weight loss. Patients with a body mass index (BMI) of 40 or greater or a BMI of 35 or greater along with additional risk factors are considered for surgery. Surgery has been perceived as a last resort to address weight issues, but it *is the only method that has a long-term impact on morbid obesity*.

Bariatrics is a branch of medicine that manages obesity and its related diseases. Surgical procedures include these three types: gastric restrictive, malabsorption, or both. *Restrictive* surgeries decrease the volume capacity of the stomach to limit the amount of food that can be eaten at one time. As the name implies, *malabsorption* procedures interfere with the absorption of food and nutrients from the GI tract.

Every year, more than 100,000 people in the United States have these procedures, and that number is rapidly increasing. The surgeon may use a conventional open approach or minimally invasive surgery (MIS). Most patients have MIS by having either the laparoscopic adjustable gastric band (LAGB) or the laparoscopic sleeve gastrectomy (LSG). Both procedures are classified as restrictive surgeries (Kaser & Kukla, 2009). The decision of whether the patient is a candidate for the MIS is based on weight, body build, history of abdominal surgery, and co-existing medical complications. With any surgical approach, patients must agree to modify their lifestyle and follow stringent protocols to lose weight and keep the weight off. After bariatric surgery, many patients no longer have complications of obesity, such as diabetes mellitus, hypertension, depression, or sleep apnea.

Preoperative Care. Preoperative care is similar to that for any patient undergoing abdominal surgery or laparoscopy (see [Chapter 16](#)). However, obese patients are at increased surgical risks of pulmonary and thromboembolic complications, as well as death. Some surgeons require limited weight loss before bariatric surgery to decrease these complications. Patients also have a thorough psychological assessment and testing to detect depression, substance abuse, or other mental health/behavioral health problem that could interfere with their success after surgery. Additional assessments to evaluate cognitive ability, coping skills, development, motivation, expectations, and support systems are also performed. Patients who are not alert and oriented or do not have sufficient strength and mobility are not considered for bariatric surgery. *The primary role of the nurse is to reinforce health teaching in preparation for surgery.* Most bariatric surgical centers provide education sessions for groups of patients who plan to have a bariatric procedure.

Operative Procedures. *Gastric restriction* surgeries allow for normal digestion without the risk for nutritional deficiencies. In the LAGB procedure, the surgeon places an adjustable band to create a small proximal stomach pouch through a laparoscope (Fig. 63-4, A). The band may or may not be inflatable. For example, the REALIZE® band requires that saline be injected into a balloon to control the tightness of the band. This type of procedure is considered to be restrictive; malabsorption complications do not usually occur (Pettit, 2009). For the LSG, the surgeon removes the portion of the stomach where ghrelin, the “hunger hormone,” is secreted. Restrictive surgeries are the easiest to perform and can be reversed. However, weight lost is often regained after a period of time. By contrast, patients having the malabsorption procedures maintain 60% to 70% of their weight loss even after 20 years.

FIG. 63-4 Bariatric surgical procedures. **A**, Adjustable banded gastroplasty. **B**, Roux-en-Y gastric bypass (RNYGB).

The most common *malabsorption surgery* performed in the United States is the *Roux-en-Y gastric bypass (RNYGB)*, which is often done as a robotic surgical procedure. Other procedures less commonly done are the biliopancreatic diversion (rarely done) and the duodenal switch. All of these procedures result in quicker weight loss, but they are more invasive with a higher risk for postoperative complications. In RNYGB, most commonly just called a **gastric bypass**, gastric resection is combined with malabsorption surgery. The patient's stomach, duodenum, and part of the jejunum are bypassed so that fewer calories can be absorbed (see Fig. 63-4, B).

Postoperative Care. Postoperative care depends on the type of surgery—the conventional open approach or the minimally invasive technique. Although many patients have MIS, they are considered as having major abdominal surgery along with all its risks and are cared for accordingly. These patients may require less than 24 hours in the hospital; some may need 1 to 2 days. Patients with open procedures may need several days to recover.

Patients having one of the MIS procedures have less pain, scarring, and blood loss. They typically have a faster recovery time and a faster return to daily activities.

The priority for immediate care of postoperative bariatric surgery patients is airway management. Patients with short and thick necks often have compromised airways and need aggressive respiratory support, possibly mechanical ventilation in the critical care unit.

All patients experience some degree of pain, but it is usually less severe when MIS is done. Patients may use patient-controlled analgesia (PCA) with morphine for up to the first 24 hours. All patients receive oral opioid analgesic agents as prescribed after the PCA is discontinued. Liquid forms of drug therapy are preferred. Acute pain management is discussed in detail in [Chapter 5](#).

Care of the bariatric surgical patient is similar to that of any patient having abdominal or laparoscopic surgery. A *major focus is patient and staff safety*. Special bariatric equipment and accommodations, including an extra-wide bed and additional personnel for moving the patient, are needed for both the surgical suite and postoperative care units. Weight-rated beds must be wide enough to allow the patient to turn. Bed rails should not be touching the body because they can cause pressure areas. Pressure between skinfolds, as well as tubes and catheters, can also cause skin breakdown. Monitor the skin in these areas, and keep it clean and dry.

NURSING SAFETY PRIORITY

Action Alert

Some patients who have bariatric surgery have a nasogastric (NG) tube put in place, especially after open surgical procedures. In gastroplasty procedures, the NG tube drains both the proximal pouch and the distal stomach. Closely monitor the tube for patency. Never reposition the tube, because its movement can disrupt the suture line! The NG tube is removed on the second day if the patient is passing flatus.

Clear liquids are introduced slowly if the patient can tolerate water, and 1-ounce cups are used for each serving. Pureed foods, juice, and soups thinned with broth, water, or milk are added to the diet 24 to 48 hours after clear liquids are tolerated. Typically, the patient can increase the volume to 1 ounce over 5 minutes or until satisfied, but the diet is limited to liquids or pureed foods for 6 weeks. The patient then progresses to regular food, with an emphasis on nutrient-dense foods. Nausea, vomiting, or discomfort occurs if too much liquid is ingested.

NURSING SAFETY PRIORITY

Critical Rescue

Anastomotic leaks are the most common serious complication and cause of death after gastric bypass surgery. Monitor for manifestations of this life-threatening problem, including increasing back, shoulder, or abdominal pain; restlessness; and unexplained tachycardia and oliguria (scant urine). Report any of these findings to the surgeon immediately!

In addition to the postoperative complications typically associated with abdominal and laparoscopic surgeries, bariatric patients have special needs and risks. Implement these measures to prevent complications:

- Apply an abdominal binder to prevent wound dehiscence for open surgical procedures.

- Place the patient in semi-Fowler's position or use bi-level or continuous positive airway pressure (BiPAP or CPAP) ventilation at night to improve breathing and decrease risk for sleep apnea or other pulmonary complications, such as pneumonia and atelectasis.
- Monitor oxygen saturation; provide oxygen at 2 L/min as prescribed.
- Apply sequential compression stockings and administer prophylactic anticoagulant (usually heparin) therapy as prescribed to help prevent thromboembolic complications, including pulmonary embolism (PE).
- Observe skin areas and folds for redness, excoriation, or breakdown to treat these problems early.
- Use absorbent padding between folds to prevent pressure areas and skin breakdown; make sure that tubes and catheters are not causing pressure as well.
- Remove urinary catheter within 24 hours after surgery to prevent urinary tract infection.
- Assist the patient out of bed on the day of surgery; encourage and assist with turning every 2 hours using an appropriate weight-bearing overhead trapeze. Collaborate with the physical or occupational therapist if needed for transfers or ambulation assistive devices, such as walkers.
- Ambulate patient as soon as possible to prevent post-operative complications, such as deep vein thrombosis and pulmonary embolus.
- Measure and record abdominal girth daily, as requested.
- In collaboration with the dietitian, provide six small feedings and plenty of fluids to prevent dehydration.
- Observe for signs and symptoms of **dumping syndrome** (caused by food entering the small intestine instead of the stomach) after *gastric bypass*, such as tachycardia, nausea, diarrhea, and abdominal cramping.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice; Teamwork and Collaboration; Informatics

A 34-year-old morbidly obese man had a laparoscopic adjustable gastric band procedure yesterday afternoon as part of a long-term plan for weight loss. He tells you that he is afraid he is going to die. He also tells you that he is scared that his two young children, ages 2 and 5, will become "fat like me." As he talks with you, his respiratory rate increases to over 40 breaths per minute. He is having diaphoresis and places his hand on his chest as he speaks.

1. What patient problems do you think he is having at this time? What data support your answer?
2. What health assessments will you perform at this time and why?
3. How will you respond to his problems at this time and why?
4. When he is ready for discharge, what health teaching will you provide related to the *Healthy People 2020* and *2010 Dietary Guidelines for Americans*? Find the complete evidence-based documents on the Internet and develop a teaching plan for this patient.
5. With whom will you collaborate as you prepare for his discharge to home?

Community-Based Care

Obese patients are cared for in a variety of settings, including the acute care hospital and transitional care unit (particularly after surgery) or in their own home. Obesity is a chronic,

CHART 63-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Discharge Teaching for the Patient After Bariatric Surgery

Nutrition: Diet progression, nutrient (including vitamin and mineral) supplements, hydration guidelines

Drug therapy: Analgesics and antiemetic drugs, if needed; drugs for other health problems

Wound care: Clean procedure for open or laparoscopic wounds; cover during shower or bath

Activity level: Restrictions, such as avoiding lifting; activity progression; return to driving and work

Signs and symptoms to report: Fever; excessive nausea or vomiting; epigastric, back, or shoulder pain; red, hot, and/or draining wound(s); pain, redness, or swelling in legs; chest pain; difficulty breathing

Follow-up care: Health care provider office or clinic visits, support groups and other community resources, counseling for patient and family

Continuing education: Nutrition and exercise classes; follow-up visits with dietitian

lifelong problem. Diets, drug therapy, exercise, and behavior modification can produce short-term weight losses with reasonable safety. However, most patients who do lose weight often regain the weight. Treatment of obesity should focus on the long-term reduction of health risks and medical problems associated with obesity, improving quality of life, and promoting a health-oriented lifestyle. Interdisciplinary team members need to provide a nonjudgmental, supportive atmosphere that encourages the patient to:

- Increase physical activity
- Decrease fat intake and reliance on appetite-reducing drugs
- Establish a normal eating pattern in response to physiologic hunger
- Address psychological problems and concerns

Frequent, long-term ambulatory care follow-up coordinated by a case manager is essential for successful treatment.

Teach patients that bowel changes are common after surgery, including constipation. Vitamin and mineral supplements are often needed after surgery, especially vitamin D, B-complex vitamins, iron, and calcium.

The most important features of health teaching for any obese patient and family focus on health-related behavior patterns. In collaboration with the dietitian, counsel the patient on a healthful eating pattern. The physical therapist or exercise physiologist recommends an appropriate exercise program. A psychologist may recommend cognitive restructuring approaches that help alter dysfunctional eating patterns. For patients who have surgery, additional discharge teaching is needed. [Chart 63-7](#) lists the important areas that should be reviewed.

Bariatric surgery results in a major lifestyle change and a variety of emotions. During weight loss, the patient may become depressed or anxious. Some experience a "hibernation phase" for about a month after surgery because of physical and emotional adjustments. Patients are usually followed closely by the surgeon and dietitian for several years.

Encourage them to keep all appointments and to adhere to the community-based treatment plan to ensure success. Plastic surgery, such as **panniculectomy** (removal of the abdominal apron, or **panniculus**), may be performed after weight is stabilized, usually in about 18 to 24 months.

Provide the patient with a list of available community resources, such as Overeaters Anonymous (www.oa.org) and the American Obesity Association (www.obesity.org). For surgical patients, the American Society for Metabolic and Bariatric Surgery (www.asmb.org) may be helpful.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate nutrition as a result of malnutrition or obesity?

Malnutrition

- Weight below ideal body weight or report of unexplained weight loss of 10 pounds in 6 months
- Dry, flaky skin
- Brittle nails and hair
- Leanness
- Activity intolerance
- Report of lethargy or fatigue
- Weakness
- Complications, such as infections, pressure ulcers, poor healing

Obesity

- Weight at least 20% above ideal
- Excessive fat
- Shortness of breath during activity or at rest
- Slowed movement
- Change in gait or limping
- Complications, such as type 2 diabetes mellitus, hypertension, depression

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate nutrition as a result of malnutrition or obesity?

Perform and interpret assessments, including:

- Take and record height and weight.
- Calculate BMI based on height and weight.
- Check laboratory values for hematocrit and hemoglobin and visceral proteins.

- Take complete medical history to determine associated complications and cause of nutritional problem.
- Assess impact of nutritional status on daily life, including ADLs.
- Assess coping mechanisms, especially for patients who are morbidly obese.

Respond by:

- Teaching patients about their need for a healthy nutritional state
- Teaching patients how to either lose or gain weight, depending on their specific problem (e.g., nutritional supplements for malnutrition; restrictive diet and exercise for obesity)
- Teaching patients to weigh frequently
- Monitoring changes in serum visceral proteins (especially prealbumin) as an indicator of improved nutrition for malnourished patients
- Initiating total enteral or total parenteral nutrition as prescribed for malnutrition
- Informing morbidly obese patients about bariatric surgery options

On what should you REFLECT?

- Monitor patient for indicators of improved nutrition (e.g., increased prealbumin and weight for malnutrition; weight loss and decreased fat for obesity).
- Think about what may have caused these nutritional problems and how they can be prevented.
- Think about what else you can do to improve nutritional health of patients you care for.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Ensure that feeding tube placement is verified by x-ray; check placement every 4 to 8 hours by aspirating gastric contents and assessing pH for nasogastric tubes.
- Place patients receiving tube feeding in a semi-Fowler's position at all times to prevent aspiration; check residual contents every 4 hours or as designated per facility policy.

- Use gloves when changing feeding system tubing or adding product; use sterile gloves when working with critically ill or immunocompromised patients.
- Use a feeding pump when the patient receives continuous or cyclic tube feeding.
- Collaborate with the interdisciplinary health care team, especially the dietitian, health care provider, and case manager, when caring for patients with malnutrition or obesity.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Be sure that bariatric furniture and equipment are available for the obese patient in the hospital or other health care setting; avoid pressure on skinfold areas.

Health Promotion and Maintenance

- Perform nutritional screening for all patients to determine if they are at risk (see [Charts 63-1 and 63-2](#)).
- For patients receiving enteral or parenteral nutrition at home, teach family members or other caregivers how to provide nutrition while avoiding complications.
- Teach patients who are undernourished to eat high-protein, high-calorie foods and nutritional supplements.
- Instruct obese patients about the importance of health care provider–approved exercise for weight reduction.

Psychosocial Integrity

- Be aware that some obese patients may not view their weight as a problem and are therefore unlikely to be part of a weight-reduction plan.
- Recognize that obesity can cause depression or anxiety, low self-esteem, and a disturbed body image.
- Be aware of legal and ethical issues related to tube-feeding older adults with chronic or terminal illness.

Physiological Integrity

- Review serum prealbumin, hemoglobin, and hematocrit levels to identify patients at nutritional risk.
- Older patients are at increased risk for malnutrition (see [Chart 63-2](#)).
- Assess patients with severe malnutrition for common complications, such as edema; lethargy; and dry, flaking skin.
- Implement interventions to promote nutritional intake in older adults as specified in [Chart 63-3](#).
- Provide nursing interventions for managing total enteral nutrition as listed in [Chart 63-4](#).

- Maintain feeding tube patency for patients receiving total enteral nutrition as described in [Chart 63-5](#).
- Provide care for patients receiving total parenteral nutrition as specified in [Chart 63-6](#).
- Recognize that many people are following low-carbohydrate rather than low-fat diets to lose weight.
- Recall that normal body mass index (BMI) for adults should be between 18.5 and 25; older adults should have a BMI between 23 and 27. A BMI of 27 to 30 indicates overweight, over 30 indicates obesity, and 40 and greater indicates morbid obesity.
- Recall that obesity causes early onset of many chronic illnesses, such as osteoarthritis, diabetes mellitus, hypertension, and coronary artery disease. Pulmonary problems, such as obstructive sleep apnea, delayed wound healing, and infections are also common.
- Remember that bariatric surgery includes gastric restriction procedures or gastric bypass; a panniculectomy may be performed to remove skinfolds once weight is stabilized.
- Be alert for signs and symptoms of anastomotic leak after bariatric surgery, including severe pain, restlessness, anxiety, and unexplained tachycardia.
- Provide postoperative care for patients having bariatric surgery to prevent complications such as wound dehiscence, respiratory distress, skin breakdown, and thromboembolic complications, such as pulmonary embolism. Observe for complications, such as dumping syndrome in patients who have a gastric bypass. Tachycardia, nausea, diarrhea, and abdominal cramping are common manifestations of dumping syndrome.
- Provide discharge teaching for patients having bariatric surgery as described in [Chart 63-7](#).

UNIT XIV

Problems of Regulation and Metabolism

Management of Patients with Problems of the Endocrine System

CHAPTER

Decision-Making Challenges
Audio Glossary

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Ensure that agency laboratory procedures for collecting and handling specimens for endocrine function studies are followed.

Health Promotion and Maintenance

2. Identify factors that place patients at risk for endocrine health problems.
3. Teach everyone about the dangers of misusing or abusing hormones or steroids.

Psychosocial Integrity

4. Encourage the patient to express concerns about a change in appearance, sexuality, or fertility.
5. Assess whether the patient has experienced recent changes in behavior or responses to stress.
6. Teach patients and family members about what to expect during tests and procedures to assess for endocrine problems.

Physiological Integrity

7. Describe the relationship between hormones and receptor sites.
8. Explain negative feedback as a control mechanism for hormone secretion.
9. Apply the principles of anatomy and physiology to understand the role of the endocrine system in homeostasis.
10. Identify adaptations in nursing assessment or interventions needed because of age-related changes in endocrine function.
11. Interpret laboratory test findings and clinical manifestations for patients with possible endocrine problems.

FIG. 64-1 The locations of various glands within the endocrine system.

The endocrine system is made up of glands in many tissues and organs in a variety of body areas (Fig. 64-1). The purpose of all endocrine glands is to secrete **hormones**, which are natural chemicals that exert their effects on specific tissues known as **target tissues**. Target tissues are usually located some distance from the endocrine gland, with no direct physical connection between the endocrine gland and its target tissue. For this reason, endocrine glands are called “ductless” glands and must use the blood to transport secreted hormones to the target tissues (McCance et al., 2010). Endocrine glands include:

- Hypothalamus (a neuroendocrine gland)
- Pituitary gland
- Adrenal glands
- Thyroid gland
- Islet cells of the pancreas
- Parathyroid glands
- Gonads

The endocrine system works with the nervous system to control overall body function, known as **neuroendocrine regulation**. Many interactions must occur between the endocrine system and all other body systems to ensure that each system maintains a constant normal balance (**homeostasis**) in response to environmental changes. For example, neuroendocrine control of body systems keeps the internal body temperature at or near 98.6° F (37° C), even when environmental temperatures vary. Other actions keep the serum sodium level between 136 and 145 mEq/L (mmol/L), regardless of whether a person eats 2 g or 12 g of sodium per day.

Table 64-1 lists hormones secreted by various endocrine glands. Hormones travel through the blood to all body areas but exert their actions only on target tissues. They recognize their target tissues and exert their actions by binding to recep-

TABLE 64-1 PRINCIPAL HORMONES OF THE ENDOCRINE GLANDS

GLAND	HORMONES
Hypothalamus	Corticotropin-releasing hormone (CRH) Thyrotropin-releasing hormone (TRH) Gonadotropin-releasing hormone (GnRH) Growth hormone–releasing hormone (GHRH) Growth hormone–inhibiting hormone (somatostatin GHIH) Prolactin-inhibiting hormone (PIH) Melanocyte-inhibiting hormone (MIH)
Anterior pituitary	Thyroid-stimulating hormone (TSH), also known as <i>thyrotropin</i> Adrenocorticotropic hormone (ACTH, corticotropin) Luteinizing hormone (LH), also known as <i>Leydig cell–stimulating hormone (LCSH)</i> Follicle-stimulating hormone (FSH) Prolactin (PRL) Growth hormone (GH) Melanocyte-stimulating hormone (MSH)
Posterior pituitary	Vasopressin (antidiuretic hormone [ADH]) Oxytocin
Thyroid	Triiodothyronine (T ₃) Thyroxine (T ₄) Calcitonin
Parathyroid	Parathyroid hormone (PTH)
Adrenal cortex	Glucocorticoids (cortisol) Mineralocorticoids (aldosterone)
Ovary	Estrogen Progesterone
Testes	Testosterone
Pancreas	Insulin Glucagon Somatostatin

tors on or within the target tissue cells. In general, each receptor site type is specific for only one hormone. Hormone-receptor actions work in a “lock and key” manner in that only the correct hormone (key) can bind to and activate the receptor site (lock) (Fig. 64-2). Binding a hormone to its receptor causes the target tissue to change its activity, producing specific responses.

Disorders of the endocrine system usually are related to:

- An excess of a specific hormone
- A deficiency of a specific hormone
- A receptor defect

ANATOMY AND PHYSIOLOGY REVIEW

The control of cellular function by any hormone depends on a series of reactions working through negative feedback control mechanisms. Hormone secretion usually depends on the need of the body for the final action of that hormone. When a body condition starts to move away from the normal range and a specific action or response is needed to correct this change, secretion of the hormone capable of starting the correcting action or response is stimulated until the need (demand) is met and the body condition returns to the normal range. As the correction occurs, hormone secretion decreases (and may halt). This type of control for hormone

synthesis is “**negative feedback**” because the hormone causes the *opposite* action of the initial condition change.

An example of a simple negative feedback hormone response is the control of insulin secretion. When blood glucose levels start to rise above normal, the hormone *insulin* is secreted. Insulin increases glucose uptake by the cells, causing a *decrease* in blood glucose levels. Thus the action of insulin (decreasing blood glucose levels) is the opposite of or

FIG. 64-2 “Lock and Key” hormone-receptor binding. *Hormone A* fits and binds to its receptors, causing a change in cell action. *Hormone B* does not fit or bind to receptors; no change in cell action results.

negative to the condition that stimulated insulin secretion (elevated blood glucose levels).

Some hormones have more complex interactions for negative feedback. These interactions involve a series of reactions in which more than one endocrine gland, as well as the final target tissues, is stimulated. In this situation, the first hormone in the series may have another endocrine gland as its target tissue. For this type of mechanism to maintain homeostasis, this series of interactions must occur:

- The central nervous system receives and reacts to various sensory inputs transmitted to the hypothalamus as stimuli.
- The hypothalamus responds to the stimuli with the production and release of either releasing or inhibiting factors, which are transported to the pituitary.
- In the pituitary gland, the releasing or inhibiting factors either stimulate or inhibit the release of specific hormones.
- The anterior pituitary hormones then control the secretion of hormones in other endocrine glands. These glands then secrete hormones into the blood that then act on their target organs or tissues, resulting in a change of at least one function.

An example of complex control is the interaction of the hypothalamus and the anterior pituitary with the adrenal cortex (Fig. 64-3). Low blood levels of cortisol from the adrenal cortex stimulate the secretion of corticotrophic-releasing hormone (CRH) in the hypothalamus. CRH stimulates the anterior pituitary gland to secrete adrenocorticotrophic hormone (ACTH). ACTH then triggers the release of cortisol from the adrenal cortex. The rising blood levels of cortisol

FIG. 64-3 Examples of positive and negative feedback control of hormone secretion. *ACTH*, Adrenocorticotrophic hormone; *CRH*, corticotrophic hormone.

inhibit CRH release from the hypothalamus. Without CRH, the anterior pituitary gland stops secretion of ACTH. In response, normal blood cortisol levels are maintained.

The normal blood level range of each hormone is well defined. Excesses or deficiencies of hormone secretion can lead to pathologic conditions.

Hypothalamus and Pituitary Glands

The hypothalamus is a small area of nerve and glandular tissue located beneath the thalamus in the brain. Nerve fibers connect the hypothalamus to the rest of the central nervous system. The hypothalamus shares a small, closed circulatory system with the anterior pituitary gland, known as the **hypothalamic-hypophyseal portal system**. This system allows hormones produced in the hypothalamus to travel directly to the anterior pituitary gland so that only very small amounts are wasted in systemic circulation.

The endocrine function of the hypothalamus is to produce regulatory hormones (see Table 64-1). Some of these hormones are released into the blood and travel to the anterior pituitary, where they either stimulate or inhibit the release of anterior pituitary hormones.

The pituitary gland is located at the base of the brain in a protective pocket of the sphenoid bone (see Fig. 64-1). The pituitary gland is about 1 cm in diameter and is divided into the anterior lobe (**adenohypophysis**) and the posterior lobe (**neurohypophysis**). Nerve fibers in the hypophyseal stalk connect the hypothalamus to the posterior pituitary (Fig. 64-4).

In response to the releasing hormones of the hypothalamus, the anterior pituitary secretes **tropic hormones**, which are hormones that stimulate other endocrine glands. Other pituitary hormones, such as prolactin, produce their effect directly on final target tissues (Table 64-2).

The hormones of the posterior pituitary, vasopressin (antidiuretic hormone [ADH]) and oxytocin, are produced in the hypothalamus and sent through the nerve tracts that connect the hypothalamus with the posterior pituitary. These

hormones are stored in the nerve endings of the posterior pituitary and are released into the blood when needed.

Other factors can affect the release of hormones from the pituitary gland. Drugs, diet, lifestyle, and pathologic conditions can increase or decrease pituitary hormone secretion.

Gonads

The **gonads** are the male and female reproductive endocrine glands. Male gonads are the *testes*, and female gonads are the *ovaries*. Function of these glands begins at puberty.

During puberty in the male, the increased secretion of gonadotropins (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]) from the anterior pituitary gland stimulates maturation of the testes, production of testosterone, and maturation of the external genitalia. During puberty in the female, increased secretion of the same gonadotropins stimulates ovarian maturation, estrogen production, ovulation, and maturation of the external genitalia.

FIG. 64-4 The hypothalamus, hypophyseal stalk, anterior pituitary gland, and posterior pituitary gland.

TABLE 64-2 PITUITARY HORMONES: TARGET TISSUES AND SUBSEQUENT ACTIONS

HORMONE	TARGET TISSUE	ACTIONS
Anterior Pituitary		
TSH (thyroid-stimulating hormone or thyrotropin)	Thyroid	Stimulates synthesis and release of thyroid hormone
ACTH (adrenocorticotrophic hormone, corticotropin)	Adrenal cortex	Stimulates synthesis and release of corticosteroids and adrenocortical growth
LH (luteinizing hormone [known as <i>Leydig cell-stimulating hormone</i> in males])	Ovary Testis	Stimulates ovulation and progesterone secretion Stimulates testosterone secretion
FSH (follicle-stimulating hormone [known as <i>interstitial cell- or Sertoli cell-stimulating hormone</i> in males])	Ovary Testis	Stimulates estrogen secretion and follicle maturation Stimulates spermatogenesis
PRL (prolactin)	Mammary glands	Stimulates breast milk production
GH (growth hormone)	Bone and soft tissue	Promotes growth through lipolysis, protein anabolism, and insulin antagonism
MSH (melanocyte-stimulating hormone)	Melanocytes	Promotes pigmentation
Posterior Pituitary*		
Vasopressin (antidiuretic hormone [ADH])	Kidney	Promotes water reabsorption
Oxytocin	Uterus and mammary glands	Stimulates uterine contractions and ejection of breast milk

*These hormones are synthesized in the hypothalamus and are stored in the posterior pituitary gland. They are transported from the hypothalamus down the hypothalamic stalk to the posterior pituitary while bound to proteins known as *neurophysins*.

FIG. 64-5 The structural detail of the adrenal gland.

The function of the testes and ovaries is detailed in Chapter 72.

Adrenal Glands

The adrenal glands are vascular, tent-shaped organs on the top of each kidney that have an outer cortex and an inner medulla (see Fig. 64-1). The adrenal hormones have effects throughout the body.

Adrenal Cortex

The adrenal cortex makes up about 90% of the adrenal gland and has cells divided into three layers (Fig. 64-5). **Mineralocorticoids** are the hormones produced in the zona glomerulosa and help control the body's sodium and potassium content. Glucocorticoids, androgens, and estrogens are produced in the zona fasciculata and zona reticularis. The hormones secreted by the cortex are often called **adrenal steroids** or **corticosteroids**.

Mineralocorticoids are produced and secreted by the adrenal cortex to help control body fluids and electrolytes. **Aldosterone** is the major mineralocorticoid and maintains extracellular fluid volume. It promotes sodium and water reabsorption and potassium excretion in the kidney tubules. Aldosterone secretion is regulated by the renin-angiotensin system, serum potassium ion concentration, and adrenocorticotropic hormone (ACTH).

Renin is produced by specialized cells of the renal afferent arterioles. Its release is triggered by a decrease in extracellular fluid volume from blood loss, sodium loss, or posture changes. Renin converts renin substrate (formerly called *angiotensinogen*), a plasma protein, to angiotensin I. Angiotensin I is converted by a converting enzyme to form angiotensin II, the active form of angiotensin. In turn, angiotensin II stimulates the secretion of aldosterone. Chapter 13 (see Fig. 13-6) further explains the renin-angiotensin system. Aldosterone causes the kidney to reabsorb sodium and water to bring the plasma volume and osmolarity back to normal.

Serum potassium level also controls aldosterone secretion. The adrenal cortex secretes aldosterone when the serum potassium level increases above normal by as little as 0.1 mEq/L. Aldosterone then enhances kidney excretion of potassium to reduce the blood level back to normal.

Glucocorticoids are produced by the adrenal cortex and are essential for life. The main glucocorticoid produced by the adrenal cortex is **cortisol**. Cortisol affects:

TABLE 64-3 FUNCTIONS OF GLUCOCORTICOID HORMONES

- Prevent hypoglycemia by increasing liver gluconeogenesis and inhibiting peripheral glucose use
- Maintain excitability and responsiveness of cardiac muscle
- Increase lipolysis, releasing glycerol and free fatty acids
- Increase protein catabolism
- Degrade collagen and connective tissue
- Increase the number of mature neutrophils released from bone marrow
- Exert anti-inflammatory effects that decrease the migration of inflammatory cells to sites of injury
- Maintain behavior and cognitive functions

- Carbohydrate, protein, and fat metabolism
- The body's response to stress
- Emotional stability
- Immune function

Cortisol also influences other important body processes. For example, it must be present for catecholamine action and maintaining the normal excitability of the heart muscle cells. Glucocorticoid functions are listed in Table 64-3.

Glucocorticoid release is regulated directly by the anterior pituitary hormone *ACTH* and indirectly by the hypothalamic corticotropin-releasing hormone (*CRH*). The release of *CRH* and *ACTH* is affected by the serum level of free cortisol, the normal sleep-wake cycle, and stress.

As described earlier and shown in Fig. 64-3, when blood cortisol levels are low, the hypothalamus secretes *CRH*, which triggers the pituitary to release *ACTH*. Then *ACTH* triggers the adrenal cortex to secrete cortisol. Adequate or elevated blood levels of cortisol *inhibit* the release of *CRH* and *ACTH*. This inhibitory effect is an example of a negative feedback system.

Glucocorticoid release peaks in the morning and reaches its lowest level 12 hours after each peak. Emotional, chemical, or physical stress increases the release of glucocorticoids.

Sex hormones (androgens and estrogens) are secreted in low levels by the adrenal cortex in both genders. Adrenal secretion of these hormones is usually not significant because the gonads (testes and ovaries) secrete much larger amounts of androgens and estrogens. In women, however, the adrenal gland is the major source of androgens. Women who have adrenal insufficiency or who have had surgical removal of the adrenals may need a small amount of testosterone replacement.

Adrenal Medulla

The adrenal medulla is a sympathetic nerve ganglion that has secretory cells. Stimulation of the sympathetic nervous system causes the release of adrenal medullary hormones, the **catecholamines** (which include epinephrine and norepinephrine). These hormones travel to all areas of the body through the blood and exert their effects on target cells. The adrenal medullary hormones are not essential for life because they also are secreted by other body tissues, but they do play a role in the physiologic stress response.

The adrenal medulla secretes about 15% norepinephrine (NE) and 85% epinephrine. Hormone effects vary with the specific receptor in the cell membranes of the target tissue.

TABLE 64-4 CATECHOLAMINE RECEPTORS AND EFFECTS OF ADRENAL MEDULLARY HORMONE STIMULATION ON SELECTED ORGANS AND TISSUES

ORGAN OR TISSUE	RECEPTORS	EFFECTS
Heart	Beta ₁	Increased heart rate Increased contractility
Blood vessels	Alpha Beta ₂	Vasoconstriction Vasodilation
Gastrointestinal tract	Alpha Beta	Increased sphincter tone Decreased motility
Kidneys	Beta ₂	Increased renin release
Bronchioles	Beta ₂	Relaxation; dilation
Bladder	Alpha Beta ₂	Sphincter contractions Relaxation of detrusor muscle
Skin	Alpha	Increased sweating
Fat cells	Beta	Increased lipolysis
Liver	Alpha	Increased gluconeogenesis and glycogenolysis
Pancreas	Alpha Beta	Decreased glucagon and insulin release Increased glucagon and insulin release
Eyes	Alpha	Dilation of pupils

These receptors are of two types: alpha adrenergic and beta adrenergic. Both types of receptors are further classified as alpha₁ and alpha₂ receptors and beta₁, beta₂, and beta₃ receptors. NE acts mainly on alpha-adrenergic receptors, and epinephrine acts mainly on beta-adrenergic receptors.

Catecholamines exert their actions on many target organs (Table 64-4). Activation of the sympathetic nervous system, which then releases adrenal medullary catecholamines, is an important part of the body's response to stress. Catecholamines are secreted in small amounts at all times to maintain homeostasis. Stress triggers increased secretion of these hormones. This sympathetic activation results in the "fight-or-flight" response, a state of heightened physical and emotional awareness.

Thyroid Gland

The thyroid gland is in the anterior neck, directly below the cricoid cartilage (Fig. 64-6). It has two lobes joined by a thin strip of tissue (*isthmus*) in front of the trachea.

The thyroid gland has a rich blood supply and is composed of follicular and parafollicular cells. Follicular cells produce the thyroid hormones **thyroxine (T₄)** and **triiodo-L-thyronine (T₃)**. Parafollicular cells produce **thyrocalcitonin (TCT, or calcitonin)**, which helps regulate serum calcium levels.

Control of metabolism occurs through T₃ and T₄. Both hormones increase metabolism, which causes an increase in oxygen use and heat production in all tissues. The two hormones differ in structure, but their functions are the same. Most circulating T₄ and T₃ are bound to plasma proteins. The free hormone moves into the cell, where it binds to its receptor in the cell nucleus. Once in the cell, T₄ is converted to T₃,

**FIG. 64-6** Anatomic location of the thyroid gland.**TABLE 64-5 FUNCTIONS OF THYROID HORMONES IN ADULTS**

- Control metabolic rate of all cells
- Promote sufficient pituitary secretion of growth hormone and gonadotropins
- Regulate protein, carbohydrate, and fat metabolism
- Exert effects on heart rate and contractility
- Increase red blood cell production
- Affect respiratory rate and drive
- Increase bone formation and decrease bone resorption of calcium
- Act as insulin antagonists

the most active thyroid hormone. The conversion of T₄ to T₃ is impaired by stress, starvation, dyes, beta blockers, amiodarone, corticosteroids, and propyl-thiouracil (PTU). Cold temperatures increase the conversion. Table 64-5 lists thyroid hormone functions.

Secretion of T₃ and T₄ is controlled by the hypothalamic-pituitary-thyroid gland axis negative feedback mechanism. The hypothalamus secretes thyrotropin-releasing hormone (TRH). TRH triggers the anterior pituitary gland to secrete thyroid-stimulating hormone (TSH), which then stimulates the thyroid gland to make and release thyroid hormones. If thyroid hormone levels are high, TRH and TSH release is inhibited. If thyroid hormone levels are low, TRH and TSH release is increased. Cold and stress are two factors that cause the hypothalamus to secrete TRH, which then stimulates the anterior pituitary to secrete TSH.

Thyroid hormone production involves a series of steps. Dietary intake of protein and iodine is needed to produce thyroid hormones. Iodine is absorbed from the intestinal tract as iodide. The thyroid gland withdraws iodide from the blood and concentrates it. After iodide is in the thyroid, it combines with the amino acid *tyrosine* to form T₄ and T₃. These hormones bind to thyroglobulin and are stored in the follicular cells of the thyroid gland. With stimulation, T₄ and

FIG. 64-7 Effects of parathyroid hormone on target tissues to maintain calcium balance.

T_3 break off from thyroglobulin and are released into the blood. They enter many cells, bind to the nucleus, and turn on genes important in metabolism. Thus the presence of T_4 and T_3 directly regulates basal metabolic rate (BMR).

Calcium and phosphorus balance occurs through the actions of calcitonin (also called *thyrocalcitonin*, or TCT). This hormone also is produced in the thyroid gland. Calcitonin lowers serum calcium and serum phosphorus levels by reducing bone resorption (breakdown). Its actions are opposite of parathyroid hormone.

The serum calcium level determines calcitonin secretion. Low serum calcium levels suppress the release of calcitonin. Elevated serum calcium levels increase its secretion.

Parathyroid Glands

The parathyroid glands consist of four small glands located close to or within the back surface of the thyroid gland (see Fig. 64-1). The chief cells of the parathyroid glands secrete parathyroid hormone (PTH).

Parathyroid hormone regulates calcium and phosphorus metabolism by acting on bones, the kidneys, and the GI tract (Fig. 64-7). Bone is the main storage site of calcium. PTH increases **bone resorption** (bone release of calcium into the blood from bone storage sites), thus increasing serum calcium. In the kidneys, PTH activates vitamin D, which then increases the absorption of calcium and phosphorus from the intestines. In the kidney tubules, PTH allows calcium to be reabsorbed and put back into the blood.

Serum calcium level determines PTH secretion. Secretion decreases when serum calcium levels are high, and it increases when serum calcium levels are low. Serum phosphorus levels also affect PTH secretion. PTH and calcitonin work together to maintain normal calcium levels in the blood and extracellular fluid.

Pancreas

The pancreas lies behind the stomach and has exocrine and endocrine functions. The exocrine function of the pancreas involves the secretion of digestive enzymes through ducts that empty into the duodenum. The cells in the islets of Langerhans perform the pancreatic endocrine functions (Fig. 64-8). About one million islet cells are found throughout the pancreas.

The islets have three distinct cell types: alpha cells, which secrete glucagon; beta cells, which secrete insulin; and delta cells, which secrete somatostatin. Glucagon and insulin affect carbohydrate, protein, and fat metabolism. Somatostatin, which is secreted not only in the pancreas but also in the intestinal tract and the brain, inhibits the release of glucagon

FIG. 64-8 The cells of the islets of Langerhans of the pancreas.

and insulin from the pancreas. It also inhibits the release of gastrin, secretin, and other GI peptides.

Glucagon is a hormone that increases blood glucose levels. It is triggered by decreased blood glucose levels and increased blood amino acid levels. Together with epinephrine, growth hormone (GH), and cortisol, glucagon prevents hypoglycemia. Chapter 67 discusses glucagon function in more detail.

Insulin promotes the movement and storage of carbohydrate (CHO), protein, and fat (Table 64-6). It lowers blood glucose levels by enhancing glucose movement across cell membranes and into the cells of many tissues. Basal levels of insulin are secreted continuously to control metabolism. Insulin secretion rises in response to an increase in blood

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Which hormone levels should the nurse expect to change in response to a client receiving a continuous cortisol infusion over a 24-hour period when the endocrine negative feedback mechanism is functioning properly?

- Lower-than-normal serum cortisol levels; lower-than-normal serum ACTH levels
- Lower-than-normal serum cortisol levels; higher-than-normal serum ACTH levels
- Higher-than-normal serum cortisol levels; lower-than-normal serum ACTH levels
- Higher-than-normal serum cortisol levels; higher-than-normal serum ACTH levels

CHART 64-1 NURSING FOCUS ON THE OLDER ADULT

Changes in the Endocrine System Related to Aging

CHANGES	CLINICAL FINDINGS	NURSING ACTIONS/ADAPTATIONS
Decreased antidiuretic hormone (ADH) production	Urine is more dilute and may not concentrate when fluid intake is low.	The patient is at greater risk for dehydration as a result of urine loss. Assess the older patient more frequently for dehydration. If fluids are not restricted because of another health problem, teach unlicensed assistive personnel (UAP) to offer fluids at least every 2 hours while awake.
Decreased ovarian production of estrogen	Bone density decreases. Skin is thinner, drier, and at greater risk for injury. Perineal and vaginal tissues become drier, and the risk for cystitis increases.	Teach the patient to engage in regular exercise and weight-bearing activity to maintain bone density. Handle the patient carefully to avoid injury from pathologic fractures. Avoid pulling or dragging the patient. Use minimal tape on the skin. Assist patients confined to bed or chairs to change positions at least every 2 hours. Teach patients to use moisturizers on the skin and to avoid agents that promote skin dryness. Perform or assist the patient to perform perineal care at least twice daily. Unless another health problem requires fluid restriction, encourage all women to drink at least 2 liters of fluids daily. Teach sexually active women to urinate immediately after sexual intercourse. Teach sexually active women that using vaginal lubricants with sexual activity can reduce discomfort and the risk for tissue damage.
Decreased glucose tolerance	Weight becomes greater than ideal along with: - Elevated fasting blood glucose level - Elevated random blood glucose level - Slow wound healing - Frequent yeast infections - Polydipsia - Polyuria	Obtain a family history of obesity and type 2 diabetes. Encourage the patient to engage in regular exercise and to keep body weight within 10 lbs of ideal. Teach patients the clinical manifestations of diabetes, and instruct them to report any of these manifestations to the health care provider. Suggest diabetes testing for any patient with: - Persistent vaginal candidiasis - Failure of a foot or leg skin wound to heal in 2 weeks or less - Increased hunger and thirst - Noticeable decrease in energy level
Decreased general metabolism	Less tolerant of cold. Decreased appetite. Decreased heart rate & blood pressure (BP).	Can be difficult to distinguish from hypothyroidism. Check for additional manifestations of: - Lethargy - Constipation (as a change from usual bowel habits) - Decreased cognition - Slowed speech - Body temperature consistently below 97° F (36° C) - Heart rate below 60 beats/min Teach patients to dress warmly in cool or cold weather.

TABLE 64-6 ANABOLIC EFFECTS OF INSULIN

Effects on Liver - Promotes glycogen synthesis and storage - Inhibits glycogenolysis, gluconeogenesis, and ketogenesis - Increases triglyceride synthesis	Effects on Muscle - Promotes protein synthesis - Increases amino acid transport - Promotes glycogenesis Effects on Fat - Increases fatty acid synthesis - Promotes triglyceride storage - Decreases lipolysis
--	--

glucose levels. More information on insulin is presented in Chapter 67.

Endocrine Changes Associated with Aging

The effects of aging on the endocrine system vary widely. The three endocrine tissues that usually have reduced function with aging are the gonads, the thyroid gland, and the endocrine pancreas (Lamberts, 2008; Touhy & Jett, 2010). It is difficult to distinguish normal from abnormal endocrine activity because of these other age-related variables:

- Acute and chronic illnesses
- Alterations in diet, activity, and lean body mass-to-fat ratio
- Disturbances in sleep patterns
- Decreased metabolic clearance rate of hormones
- Increased use of multiple drugs that may affect hormone function

It is important to consider these factors when assessing the older adult with endocrine dysfunction.

Encourage the older adult to participate in regular screening examinations, including fasting and random blood glucose checks, calcium level determinations, and thyroid function testing. Chart 64-1 lists the endocrine changes that occur in the older adult.

ASSESSMENT METHODS

Patient History

Use a systems approach to obtain the history of patients with a possible endocrine problem. This approach can be difficult because of the variety and combination of clinical manifestations. Identify the patient's response to actual or perceived changes, and discuss the potential diagnostic and

CHART 64-2 ENDOCRINE ASSESSMENT

Using Gordon's Functional Health Patterns**Nutritional-Metabolic Pattern**

- What is your typical daily food intake? Describe a day's meals, snacks, and vitamins.
- How much salt do you typically add to your food? Do you use salt substitutes?
- How is your appetite?
- Do you have any difficulty chewing or swallowing?
- What is your typical daily fluid intake? What types of fluids (water, juices, soft drinks, coffee, tea)? How much?
- Have you had any recent change in your weight? Weight gain? Weight loss? How much?
- Have you noticed a change in the tightness of your rings or shoes? Tighter? Looser?
- Have you noticed any change in thirst?

Elimination Pattern

- What is your usual bowel elimination pattern? Frequency? Character? Discomfort? Laxative use?
- What is your usual urinary elimination pattern? Frequency? Amount? Color? Odor? Control?
- Have you noticed a change in the amount of urine?
- Do you have any problem with excessive perspiration?
- Do you have any other type of drainage?

Sleep-Rest Pattern

- Do you have any difficulty falling asleep when you go to bed?
- Is there a change in the number of hours you sleep per night?
- Do you take any drugs to help you sleep?
- About how many times do you awaken during the night?
- Do you have any difficulty getting back to sleep?
- Are you bothered by nightmares or vivid dreams?
- Do you have difficulty awakening in the morning?
- Do you feel generally rested and ready for daily activities after sleep?
- Do you take scheduled naps or rest periods during the day?
- Do you find yourself falling asleep at work or at home while reading or watching television?
- Have you noticed any difficulty in your ability to concentrate?

Sexuality-Reproductive Pattern

- Are you sexually active?
- Are you satisfied with your level of sexual activity?

- Do you participate in sex as often as you would like?
- Do you participate in sex as often as your partner would like?
- Have you noticed a change in your interest in having sex over the past year?

Female:

- At what age did menstruation start?
- How regular are your periods?
- Do you have any pain, cramping, or clotting during your periods?
- Have you ever been pregnant? What was the outcome of the pregnancy(ies)?
- Do you use contraceptives? What type? Have you had any problems with your chosen method of contraception?
- Do you have any pain during intercourse?

Activity-Exercise Pattern

- Do you feel you have sufficient energy to perform tasks or routines that are required of you?
- Do you feel you have sufficient energy to do what you would like to do?
- Do you exercise? How often? For how long each time? What type(s) of exercise do you perform?
- What activities do you perform in your spare time?
- What is your ability to perform the following tasks?

Feeding _____	Grooming _____
Bathing _____	General Mobility _____
Toileting _____	Cooking _____
Bed Mobility _____	Home Maintenance _____
Dressing _____	Shopping _____

Functional Levels Code

Level 0: Full self-care

Level I: Requires use of equipment or device

Level II: Requires help from another person(s): assistance, supervision, teaching

Level III: Requires help from another person(s) and equipment or device

Level IV: Dependent; does not participate in self-care

Based on Gordon, M. (2011). *Manual of nursing diagnosis* (12th ed.). New York: Jones & Bartlett.

management plan. Chart 64-2 lists assessment questions based on Gordon's Functional Health Patterns (Gordon, 2011). Although endocrine problems can disturb any health pattern, the patterns most commonly affected are nutritional-metabolic, activity-exercise, elimination, sleep-rest, and sexuality-reproductive. These data are combined with physical, psychosocial, and laboratory findings for a complete assessment of endocrine function.

The age and gender of the patient provide baseline assessment data. Certain disorders are more common in older than in younger patients, such as diabetes mellitus, loss of ovarian function, and decreased thyroid function.

Manifestations of endocrine disorders can be gender related, such as the sexual effects of hyperpituitarism and hypopituitarism (see Chapter 65). Thyroid problems are more common in women (McCance et al., 2010). Assess for a history of endocrine dysfunction, manifestations that could indicate an endocrine disorder, and hospitalizations. Ask about past and current drugs, such as hydrocortisone, levothyroxine, oral contraceptives, and antihypertensive agents.

The use of exogenous hormone drugs, when not needed for hormone replacement, can cause serious dysfunction in many endocrine glands. Use the opportunity to warn patients about the dangers of misusing or abusing hormone-based drugs such as androgens and thyroid hormones.

Because the patient's socioeconomic status is a sensitive issue, explore whether his or her resources are adequate for a healthy diet, needed drugs, and consistent health care follow-up. It may be appropriate to involve social service and home care agencies at an early stage.

Nutrition History

Nutritional changes or GI tract disturbances may reflect many different endocrine problems. Ask about a history of nausea, vomiting, and abdominal pain. An increase or decrease in food or fluid intake may also indicate specific disorders. For example, diabetes insipidus triggers excessive thirst, and adrenal hypofunction triggers salt craving. Hunger and thirst also are associated with diabetes mellitus. Rapid changes in weight without diet changes are often associated

with several endocrine disorders, including diabetes mellitus and thyroid problems.

Dietary deficiencies, especially of protein and iodide-containing foods (saltwater fish and seafood, iodized table salt), may be a cause of an endocrine disorder. Teach the patient about a well-balanced diet that includes at least 60 g of protein daily, less animal fat, and fewer concentrated simple sugars. Teach patients who do not eat saltwater fish on a regular basis to use iodized salt in food preparation.

Family History and Genetic Risk

Ask the patient about any family history of obesity, growth or development difficulties, diabetes mellitus, infertility, or thyroid disorders. These problems may have an autosomal dominant, recessive, or cluster pattern of inheritance.

Current Health Problems

Focus on the patient's reason for seeking health care, asking questions such as:

- Did the symptoms occur gradually, or was the onset sudden?
- Have you been treated for this problem in the past?
- How have the current problems affected your activities of daily living?

These questions can provide clues to specific endocrine disorders. Also explore changes in energy levels, elimination patterns, sexual and reproductive functions, and physical features.

Energy level changes occur with many endocrine problems, especially thyroid problems (see [Chapter 66](#)) and adrenal problems (see [Chapter 65](#)). Ask the patient about any change in ability to perform ADLs, and assess his or her current energy level. For instance, has he or she been sleeping longer, or are fatigue and generalized weakness present?

Elimination is also affected by the endocrine system. Identify the patient's past pattern of elimination to determine deviations from the normal routine. Ask about the amount and frequency of urination. Does he or she urinate frequently in large amounts? Does the patient wake during the night to urinate ([nocturia](#)), or is pain present with urination ([dysuria](#))? Information about the frequency of bowel movements and their consistency and color may provide clues to problems in fluid balance or metabolic rate (i.e., thyroid function).

Sexual and reproductive functions are greatly affected by endocrine disturbances. Ask women about any changes in the menstrual cycle, such as increased flow, duration, and frequency of menses; pain or excessive cramping; or a recent change in the regularity of menses. Ask men whether they have experienced impotence. Question both men and women about a change in libido (sexual desire) or any fertility problems.

Physical appearance changes can reflect an endocrine problem. Discuss any changes that the patient perceives in physical features. Obvious changes are identified during the physical assessment, but patients may be able to describe some of the more subtle changes. Ask about changes in:

- Hair texture and distribution
- Facial contours and eye protrusion
- Voice quality
- Body proportions
- Secondary sexual characteristics

For example, you might ask a man whether he is shaving less often or a woman if she has noticed an increase in facial hair. These changes may be associated with pituitary, thyroid, parathyroid, or adrenal dysfunction.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Which client assessment finding indicates to the nurse the need to assess further for a possible endocrine problem?

- A. A history of taking oral contraceptives for more than 2 years
- B. A weight loss of 15 lbs in the past 6 weeks without dieting
- C. The client's father's diagnosis of prostate cancer
- D. A recent need for corrective lenses

Physical Assessment

Inspection

An endocrine problem can change physical features because of its effect on growth and development, regulation of sex hormone levels, fluid and electrolyte balance, and the body's use of nutrients. Different clinical findings can occur with many endocrine disorders or with nonendocrine problems.

Use a head-to-toe approach to inspect the patient. Observe the patient's general appearance, and assess height, weight, fat distribution, and muscle mass in relation to age. It is important to remember that heredity and age rather than a health problem may be responsible for some physical features (e.g., short stature).

When examining the head, focus on abnormalities of facial structure, features, and expression, such as:

- Prominent forehead or jaw
- Round or puffy face
- Dull or flat expression
- Exophthalmos (protruding eyeballs and retracted upper lids)

Check the lower half of the neck for a visible enlargement of the thyroid gland. Normally the thyroid tissue cannot be observed. The isthmus may be noticeable when the patient swallows. Jugular vein distention may be seen on inspection of the neck and can indicate fluid overload.

Skin changes may reflect a specific endocrine dysfunction. Observe skin color, and look for areas of pigment loss (hypopigmentation) or hyperpigmentation. Fungal skin infections, slow wound healing, bruising, and petechiae are often seen in patients with adrenal hyperfunction. Skin infections, foot ulcers, and slow wound healing are common among patients with diabetes mellitus. In secondary hypofunction of the adrenal glands, the skin over the finger joints, elbows, and knees, as well as any scar tissue, may show increased pigmentation due to increased levels of adrenocorticotrophic hormone (ACTH) and melanocyte-stimulating hormone.

Vitiligo (patchy areas of pigment loss with increased pigmentation at the edges) is seen with primary hypofunction of the adrenal glands and is caused by autoimmune destruction of melanocytes in the skin. Areas of pigment loss most often occur on the face, neck, and extremities. Mucous membranes may have large areas of uneven pigmentation. Document the location, color, distribution, and size of skin color changes and lesions.

Inspect the patient's fingernails for malformation, thickness, or brittleness, all of which may suggest thyroid gland problems. Examine the extremities and the base of the spine for edema, which suggests a fluid and electrolyte imbalance.

Inspection of the trunk can show signs of specific endocrine dysfunction. Check for any abnormalities in chest size and symmetry. Truncal obesity and the presence of a "buffalo hump" between the shoulders on the back may indicate adrenocortical excess. Hormonal imbalance may also change secondary sexual characteristics. Inspect the breasts of both men and women for size, symmetry, pigmentation, and discharge. **Striae** (reddish purple "stretch marks") on the breasts or abdomen are often seen with adrenocortical excess.

Assess the patient's hair distribution for indications of endocrine gland dysfunction. Changes can include **hirsutism** (excessive growth of body hair, especially on the face, chest, and the linea alba of the abdomen of women), excessive hair loss, or changes in hair texture.

Examination of the genitalia may reveal a dysfunction in hormone secretion. Observe the size of the scrotum and penis or of the labia and clitoris in relation to standards for the patient's age. The distribution and quantity of pubic hair are often affected in hypogonadism.

Palpation

The thyroid gland and the testes can be examined by palpation. Chapters 72 and 75 discuss examination of the testes. The thyroid gland is palpated for size, symmetry, general shape, and the presence of nodules or other irregularities.

Palpate the thyroid gland by standing either behind or in front of the patient (Fig. 64-9). The posterior approach may be easier (Jarvis, 2012). Having the patient swallow sips of water during the examination helps the clinician palpate the thyroid gland.

Ask the patient to sit and to lower the chin. Using the posterior approach, place the thumbs of both your hands on the back of the patient's neck, with the fingers curved around to the front of the neck on either side of the trachea. Ask the patient to swallow, and then locate the isthmus of the thyroid as you feel it rising. Identify the anterior surface of the thyroid lobe. To examine the thyroid, proceed in this way:

- Turn the patient's head to the right.
- Displace the thyroid cartilage to the right with the fingers of your left hand.
- Palpate the right lobe with your right hand.
- Reverse this procedure to examine the left lobe.

! NURSING SAFETY PRIORITY

Action Alert

Always palpate the thyroid gently because vigorous palpation can stimulate a thyroid storm in a person who has or is suspected to have hyperthyroidism.

Auscultation

Auscultate the chest to assess cardiac rate and rhythm. Document this information to use later as a means of assessing treatment effectiveness. Some endocrine problems induce dysrhythmias. Many endocrine disturbances can cause dehydration and volume depletion. Therefore document any

FIG. 64-9 Techniques for palpation of the thyroid gland.

difference in the patient's blood pressure and pulse in the lying, standing, or sitting positions (orthostatic vital signs).

If an enlarged thyroid gland is palpated, auscultate the area of enlargement for bruits. Hypertrophy of the thyroid gland causes an increase in vascular flow, which may result in bruits.

Psychosocial Assessment

Information obtained from the history and physical examination may help identify psychosocial problems. Assess the patient's coping skills, support systems, and health-related beliefs. Many endocrine problems can change a patient's behaviors, personality, and psychological responses. Ask the patient whether he or she has noticed a change in how stress is handled, frequency of crying, or degree of patience and anger expression. The patient may not recognize these changes in himself or herself. When possible, ask the family about changes in the patient's behaviors or personality.

A number of endocrine disorders affect the patient's perception of self. For example, body features can change significantly in disorders of the pituitary, adrenal, and thyroid

CHART 64-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Endocrine Testing

For blood tests:

- Check your laboratory's method of handling hormone test samples for tube type, timing, drugs to be administered as part of the test, etc. For example, blood samples drawn for catecholamines must be placed on ice and taken to the laboratory immediately.
- Explain the procedure and any restrictions to the patient.
- If you are drawing blood samples from a line, clear the IV line thoroughly. Do not use a double- or triple-lumen line to obtain samples; contamination or dilution from another port is possible.
- Emphasize the importance of taking a drug prescribed for the test on *time*. Tell the patient to set an alarm if the drug is to be taken during the night.

For urine tests:

- Instruct the patient to begin the urine collection (whether for 2, 4, 8, 12, or 24 hours) by first emptying his or her bladder.
- Remind the patient to *not* save the urine specimen that begins the collection. The timing for the urine collection begins *after* this specimen.
- Tell the patient to note the time of the discarded specimen and to plan to collect all urine from this time until the end of the urine collection period.
- To end the collection, instruct the patient to empty his or her bladder at the end of the timed period and *add* that urine to the collection.
- Check with the laboratory to determine any special handling of the urine specimen (e.g., Is a preservative needed? Does the container need to be kept cold?).
- If needed, make sure that the preservative has been added to the collection container at the *beginning* of the collection.
- Tell the patient about any preservative and the need to avoid splashing urine from the container, because some preservatives make the urine caustic.
- If the specimen must be kept cool or cold, instruct the patient to place the container in an inexpensive cooler with ice. The specimen container should not be kept with food or drinks.

glands. Infertility, impotence, and other changes in sexual function may result from endocrine dysfunction. Encourage the patient to express his or her feelings and concerns about a change in appearance or in sexual function. Ask about any difficulty in coping with such changes.

Patients with endocrine problems may require lifelong drugs and follow-up care. Assess their readiness to learn and ability to carry out specific self-management skills. Patients may also face financial difficulties resulting from a prolonged medical regimen or loss of employment. A referral to social service agencies may be needed.

Diagnostic Assessment

Laboratory Assessment

For the patient with possible endocrine dysfunction, laboratory tests are an essential part of the diagnostic process. Body fluids commonly used for these tests include blood, urine, and saliva (Klee, 2008). Regardless of the test requested, check with the agency's laboratory to ensure proper collection and handling of the specimen for accurate results. The specialized testing for specific disorders is described in [Chapters 65 to 67](#). Best practices for the collection of specimens for general endocrine testing are listed in [Chart 64-3](#).

Stimulation/Suppression Tests. Measurement of specific hormone blood levels does not always distinguish between the normal and the abnormal. The wide normal range for some hormones makes it necessary to trigger responses by stimulation or suppression tests.

For the patient who might have an underactive endocrine gland, a stimulus may be provided to determine whether the gland is capable of normal hormone production. This method is called *stimulation testing*. Measured amounts of selected hormones are given to stimulate the target gland to maximum production. Hormone levels are then measured and compared with expected normal values. Failure of the hormone level to rise with stimulation indicates hypofunction. For example, insulin injection should stimulate increased release of growth hormone (GH) and adrenocorticotrophic hormone (ACTH) from a normal anterior pituitary gland. When insulin injection does not result in increased release of these hormones, a problem with the anterior pituitary gland is likely, especially hypofunction.

Suppression tests are used when hormone levels are high or in the upper range of normal. Failure of suppression of hormone production during testing indicates hyperfunction. For example, when a bolus of glucose is given orally or intravenously, the normal anterior pituitary responds by suppressing the release of GH. A hyperfunctioning anterior pituitary gland fails to suppress GH release when blood glucose levels are elevated rapidly.

Assays. An assay measures the level of a specific hormone in blood or other body fluid. Some assays are indirect, such as the radioimmunoassay. Other hormone assay methods include immunometric assays, chromatographic assays, and mass spectrometry. An immunometric assay uses a large antibody with a component that “captures” the hormone and a second component that creates a signal when the antibody binds to the hormone (antigen). Chromatographic assays separate molecules in the serum by size, light absorption, and other properties. Each hormone has very specific properties that allow it to separate from other blood substances and form a unique bandwidth. Mass spectrometry methods also allow individual hormones to separate from other serum molecules based on the amount (mass) and charge of individual components. On a graph, these separate hormones each shows as a unique “spike” pattern. Many different hormone concentrations can be analyzed at the same time by this method.

Venous Sampling. In addition to general blood levels of hormones, another endocrine assessment test is venous sampling of blood from specific endocrine glands. Blood samples are taken directly from veins that drain a specific endocrine gland and hormone levels are measured. This test is used when a biopsy fails to identify a suspected mass. Unexpected blood hormone levels may indicate the location of a mass, a dysfunctional gland, or a dysfunctional part of a gland.

Urine Tests. Hormone levels and their metabolites in the urine are often measured to determine endocrine function. Because many of the endocrine hormones are secreted in a pulsatile fashion, measurement of a specific hormone in a 24-hour urine collection, rather than as a single blood or urine sample, better reflects the overall function of certain glands, such as the adrenal gland. Teach the patient how to collect a 24-hour urine sample (see also [Chart 64-3](#)).

Certain hormones require additives in the container at the beginning of the collection. Instruct the patient not to discard

the preservative from the container and to use caution when handling it because some solutions are caustic. Remind him or her that this collection is timed for *exactly* 24 hours. Instruct the patient to avoid taking any unnecessary drugs during endocrine testing because some drugs can interfere with the laboratory assays.

Tests for Glucose. Tests for functions of the islet cells of the pancreas are indirect. They measure the *result* of pancreatic islet cell function. Blood glucose values and the oral glucose tolerance test help diagnose diabetes mellitus. The glycosylated hemoglobin (HbA_{1c}) value reveals the *average* blood glucose level over a period of 2 to 3 months. (See Chapter 67 for a full discussion of diabetes mellitus.)

Imaging Assessment

Anterior, posterior, and lateral skull x-rays may be used to view the sella turcica. Erosion of the sella turcica indicates invasion of the wall from an abnormal growth.

Magnetic resonance imaging (MRI) with contrast is the most sensitive method of imaging the pituitary gland, although computed tomography (CT) scans can also be used to evaluate it. The thyroid, parathyroid glands, ovaries, and testes are evaluated by ultrasound. In addition, CT

scans are used to evaluate the adrenal glands, ovaries, and pancreas.

Other Diagnostic Assessment

Needle biopsy is a relatively safe and quick outpatient procedure used to indicate the composition of thyroid nodules. It is used to determine whether surgical intervention is needed.

DECISION-MAKING CHALLENGE

Patient-Centered Care

The patient is a 50-year-old man who is being seen because he has been leaking clear fluid from both breasts for several weeks. Among the tests that have been requested to check for a pituitary tumor is a suppression test with IV glucose. He is very nervous over the possibility of having what he calls a “brain tumor” and of receiving the glucose intravenously. He tells you he does not need this test because he does not have diabetes, but his older brother does have the disease.

1. Is the patient correct in thinking that a pituitary tumor is a brain tumor? Why or why not?
2. How is the glucose suppression test related to diabetes?
3. Can this test be avoided or changed to reduce his apprehension? If so, in what way?

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Follow the laboratory’s procedures for collecting and handling specimens for endocrine function studies.

Health Promotion and Maintenance

- Teach all patients that abusing or misusing hormones or steroids can have an adverse effect on endocrine function.

Psychosocial Integrity

- Encourage the patient to express concerns about a change in appearance, sexual function, or fertility as a result of a possible endocrine problem.

- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for endocrine tests.
- Ask family members about changes in the patient’s personality or behavior.

Physiological Integrity

- The onset of endocrine problems can be slow and insidious or abrupt and life threatening.
- Ask the patient about other family members with endocrine disorders, because some problems have a genetic component.
- Ask the patient what prescribed and over-the-counter drugs are taken on a regular basis, because some drugs can alter endocrine function.

Care of Patients with Pituitary and Adrenal Gland Problems

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Protect the patient with antidiuretic hormone (ADH) deficiency from dehydration.
2. Use appropriate interventions to prevent injury in the patient who has hypercortisolism.
3. Modify the environment to reduce stimulation for the patient with pheochromocytoma.

Health Promotion and Maintenance

4. Teach patients how to avoid increasing intracranial pressure after pituitary surgery.
5. Identify the teaching priorities for the patient taking hormone replacement therapy for pituitary or adrenal hypofunction.
6. Teach patients how to monitor therapy effectiveness for diabetes insipidus or syndrome of inappropriate ADH (SIADH).

Psychosocial Integrity

7. Be accepting of patient behavior.

8. Encourage the patient and family to express concerns about a change in endocrine health.
9. Explain all disease management–related procedures to the patient and family.

Physiological Integrity

10. Compare the common clinical manifestations associated with pituitary hypofunction and pituitary hyperfunction.
11. Coordinate nursing care for the patient immediately after a transsphenoidal hypophysectomy.
12. Interpret clinical changes and laboratory data to determine the effectiveness of therapy for diabetes insipidus and for SIADH.
13. Compare the clinical manifestations of hypercortisolism and adrenal insufficiency.
14. Prioritize nursing care for the patient with acute adrenal insufficiency.
15. Coordinate nursing care for the patient with Cushing's disease or syndrome.

Hormones secreted from the pituitary gland and adrenal glands influence the function of many tissues and organs. When any of these glands secrete too much or too little of one or more hormones, the effects are widespread and may induce psychological, as well as physical, changes. The anterior pituitary gland regulates growth, metabolism, pigmentation, and sexual development. The posterior pituitary gland secretes **vasopressin**, also known as *antidiuretic hormone* or *ADH*. Posterior pituitary problems result in fluid and

electrolyte imbalances. The adrenal gland produces and secretes hormones that influence homeostasis and are life sustaining. Nursing care for the patient with pituitary or adrenal gland disorders includes assessment, patient education, evaluation of patient response to therapy, and providing support.

A complete history and physical examination are performed to detect specific clinical findings. The patient also often undergoes many diagnostic tests and relies on the nurse

for specific instructions and explanations. Surgical intervention may be indicated. The patient often needs lifelong hormone replacement therapy, and physical and emotional support are critical.

DISORDERS OF THE ANTERIOR PITUITARY GLAND

The anterior pituitary gland (**adenohypophysis**) controls growth, metabolic activity, and sexual development through the actions of these hormones:

- Growth hormone (GH; somatotropin)
- Thyrotropin (thyroid-stimulating hormone [TSH])
- Corticotropin (adrenocorticotrophic hormone [ACTH])
- Follicle-stimulating hormone (FSH)
- Luteinizing hormone (LH)
- Melanocyte-stimulating hormone (MSH)
- Prolactin (PRL)

Hormone disorders of the anterior pituitary gland can result from problems arising within the anterior pituitary gland itself (*primary pituitary dysfunction*) or from problems in the hypothalamus that change anterior pituitary function (*secondary pituitary dysfunction*). In either case, one or more hormones may be undersecreted (*pituitary hypofunction*) or oversecreted (*pituitary hyperfunction*).

HYPOPITUITARISM

Pathophysiology

A person with hypopituitarism has a deficiency of one or more anterior pituitary hormones, resulting in metabolic problems and sexual dysfunction. If only one hormone is affected, the condition is known as *selective hypopituitarism*. Decreased production of *all* of the anterior pituitary hormones is an extremely rare condition known as **panhypopituitarism**.

More commonly, there is a decrease in the secretion of one hormone and a lesser decrease in the secretion of other hormones. Deficiencies of *adrenocorticotrophic hormone (ACTH)* and *thyroid-stimulating hormone (TSH)* are the *most* life threatening because they cause a decrease in the secretion of vital hormones from the adrenal and thyroid glands. Adrenal gland hypofunction is discussed on pp. 1381-1384; hypothyroidism is discussed in **Chapter 66**.

Deficiency of the **gonadotropins** (luteinizing hormone [LH] and follicle-stimulating hormone [FSH])—hormones that stimulate the ovaries and testes to produce sex hormones) changes sexual function in both men and women. In men, gonadotropin deficiency results in testicular failure, with decreased testosterone production from the Leydig cells and decreased or absent sperm production. Decreased testosterone levels in men cause sterility. In women, gonadotropin deficiency results in ovarian failure, amenorrhea, and infertility.

Growth hormone (GH) deficiency changes tissue growth patterns indirectly. GH itself has little effect on tissues and cells; however, it stimulates the liver to produce somatomedins. These substances, especially somatomedin C, then enhance growth activities in cells and tissues. Somatomedin C is responsible for bone and cartilage growth and maintenance.

GH deficiency may be a result of decreased GH production, failure of the liver to produce somatomedins, or a failure of the cells or tissues to respond to the somatomedins. Deficiency in children leads to short stature and other manifestations of growth retardation. Deficiency in adults does not affect height but does increase the rate of bone destructive activity, leading to thinner, more fragile bones (**osteoporosis**) and an increased risk for fractures.

The cause of hypopituitarism varies. Benign or malignant pituitary tumors can compress and destroy pituitary tissue. Pituitary function can be impaired by severe malnutrition or rapid loss of body fat, such as in people with **anorexia nervosa** (a disorder in which people see themselves as overweight and eat so little that starvation results). Shock or severe hypotension reduces blood flow to the pituitary gland, leading to hypoxia and infarction. Other causes of hypopituitarism include head trauma, brain tumors or infection, radiation or surgery of the head and brain, and acquired immune deficiency syndrome (AIDS) (**Melmed & Kleinberg, 2008**). *Idiopathic hypopituitarism* is an isolated hormone deficiency with an unknown cause.

Postpartum hemorrhage is the most common cause of pituitary infarction, which results in decreased hormone secretion. This clinical problem is known as *Sheehan's syndrome*. The pituitary gland normally enlarges during pregnancy, and when hypotension results from hemorrhage, ischemia and necrosis of the gland occur. Usually this condition develops immediately after delivery, although some cases have occurred several years later.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Changes in physical appearance and target organ function occur with deficiencies of specific pituitary hormones (**Chart 65-1**). Gonadotropin (LH and FSH) deficiency results in the loss of or change in secondary sex characteristics in men and women. While assessing the male patient, look for facial and body hair loss. Ask about episodes of impotence and decreased *libido* (sex drive). Women may report **amenorrhea** (absence of menstrual periods), **dyspareunia** (painful intercourse), infertility, and decreased libido. While examining the female patient, check for dry skin, breast atrophy, and a decreased amount or absence of axillary and pubic hair.

Neurologic manifestations of hypopituitarism as a result of tumor growth often first occur as changes in vision. Assess the patient's visual acuity, especially peripheral vision, for changes or loss. Temporal headaches are a common finding. Other manifestations may include **diplopia** (double vision) and ocular muscle paralysis, limiting eye movement.

Laboratory findings vary widely with hypopituitarism. Some pituitary hormone levels may be measured directly. Often, however, the *effects* of the hormones, rather than their actual levels, are assessed. Blood levels of triiodothyronine (T₃) and thyroxine (T₄) from the thyroid, as well as testosterone and estradiol from the gonads, are measured easily. If levels of one or all of these hormones are low or in the low-normal range, further evaluation is necessary. Levels of pituitary gonadotropins (LH and FSH) and TSH are sufficient if function of the target organ is apparent. Function of LH

CHART 65-1 KEY FEATURES

Pituitary Hypofunction**DEFICIENT HORMONE CLINICAL MANIFESTATIONS****Anterior Pituitary Hormones**

Growth hormone (GH)	Decreased bone density Pathologic fractures Decreased muscle strength Increased serum cholesterol levels
Gonadotropins (luteinizing hormone [LH], follicle-stimulating hormone [FSH])	Women: • Amenorrhea • Anovulation • Low estrogen levels • Breast atrophy • Loss of bone density • Decreased axillary and pubic hair • Decreased libido Men: • Decreased facial hair • Decreased ejaculate volume • Reduced muscle mass • Loss of bone density • Decreased body hair • Decreased libido • Impotence
Thyroid-stimulating hormone (thyrotropin) (TSH)	Decreased thyroid hormone levels Weight gain Intolerance to cold Scalp alopecia Hirsutism Menstrual abnormalities Decreased libido Slowed cognition Lethargy
Adrenocorticotrophic hormone (ACTH)	Decreased serum cortisol levels Pale, sallow complexion Malaise and lethargy Anorexia Postural hypotension Headache Hypoglycemia Hyponatremia Decreased axillary and pubic hair (women)

Posterior Pituitary Hormones

Vasopressin (antidiuretic hormone [ADH])	Diabetes insipidus: • Greatly increased urine output • Low urine specific gravity (<1.005) • Hypovolemia: • Hypotension • Dehydration • Increased plasma osmolarity • Increased thirst • Output does not decrease when fluid intake decreases
--	---

and FSH is assessed by observing for the presence of secondary sexual characteristics. Function of TSH is assessed by measuring circulating levels of thyroid hormones. ACTH levels may be normal or low, and prolactin (PRL) levels are low to high.

Stimulation testing can be useful to evaluate pituitary function. For example, insulin injection in people with normal pituitary function causes an increased release of GH

and ACTH. With decreased pituitary function, levels of either of these hormones remain unchanged.

Pituitary problems may cause changes in the sella turcica (the bony nest where the pituitary gland rests) that can be seen with skull x-rays. Changes may include enlargement, erosion, and calcifications as a result of pituitary tumors. Computed tomography (CT) and magnetic resonance imaging (MRI) can more distinctly define bone or soft-tissue lesions. An angiogram may be used to rule out the presence of an aneurysm or other vascular problems in the area before surgery.

INTERVENTIONS

Management of the adult with hypopituitarism focuses on replacement of deficient hormones. Older patients or those with a chronic disease often require a lower amount of hormone replacement. Men who have gonadotropin deficiency receive sex steroid replacement therapy with androgens (testosterone). The most effective route of androgen replacement is IM, although use of transdermal testosterone patches is increasing. Instruct the patient in self-administration. Therapy begins with high-dose testosterone and is continued until **virilization** (presence of male secondary sex characteristics) is achieved. Maximal effects of treatment include increases in penis size, libido, muscle mass, bone size, and bone strength. Chest, facial, pubic, and axillary hair growth also increases, and the voice deepens. Patients usually report improved self-esteem and body image after therapy is initiated. The dose may then be decreased, but therapy continues throughout life.

Androgen therapy is avoided in men with prostate cancer. Side effects of testosterone therapy include **gynecomastia** (male breast tissue development), acne, baldness, and prostate enlargement.

Achieving fertility in these patients is difficult and requires additional parenteral testosterone therapy and injections of human chorionic gonadotropin (hCG). Teach the patient about the additional therapy, and provide emotional support because the outcome of fertility treatment is uncertain.

Women who have gonadotropin deficiency receive hormone replacement with a combination of estrogen and progesterone. The risk for hypertension or **thrombosis** (formation of blood clots in deep veins) is increased with estrogen therapy, especially among women who smoke. Emphasize measures to reduce risk and the need for regular health visits. For women who wish to become pregnant, clomiphene (Clomid) may be given to induce ovulation. Gonadotropin-releasing hormone (GnRH) and hCG are used to stimulate ovulation if therapy with clomiphene fails.

Adult patients with GH deficiency may be treated with injections of GH, although this treatment is rare.

**NCLEX EXAMINATION CHALLENGE****Health Promotion and Maintenance**

Which precaution is most important for the nurse to teach the female client undergoing drug therapy with estrogen and progesterone for hypopituitarism?

- "Use a nonhormonal form of contraception to prevent an unplanned pregnancy."
- "Wear a hat with a brim and use sunscreen when outdoors."
- "Do not smoke or use nicotine in any form."
- "Avoid drinking alcoholic beverages."

HYPERPITUITARISM

Pathophysiology

Hyperpituitarism is hormone oversecretion that occurs with pituitary tumors or tissue hyperplasia (tissue overgrowth). Tumors occur most often in the anterior pituitary cells that produce growth hormone (GH), prolactin (PRL), and adrenocorticotrophic hormone (ACTH). Overproduction of PRL also may occur in response to tumors that overproduce GH and ACTH. Excess ACTH may occur with increased secretion of melanocyte-stimulating hormone (MSH).

GENETIC/GENOMIC CONSIDERATIONS

An uncommon cause of hyperpituitarism is multiple endocrine neoplasia, type 1 (*MEN1*), in which there is inactivation of the suppressor gene *MEN1* (Melmed & Kleinberg, 2008). This problem has an autosomal dominant inheritance pattern and is usually expressed as a benign tumor that affects the pituitary, parathyroid glands, and pancreas. In pituitary function, *MEN1* leads to excessive production of growth hormone and acromegaly. Ask a patient suspected of having acromegaly whether either parent also has this problem or has had a tumor of the pancreas or parathyroid glands.

The most common cause of hyperpituitarism is a pituitary adenoma—a benign tumor of one or more tissues within the anterior pituitary. Adenomas are classified by size, invasiveness, and the hormone secreted. An invasive pituitary adenoma involves a portion or all of the sella turcica. When the sella turcica is not involved, the adenoma is “enclosed.”

As an adenoma gets larger and compresses brain tissue, neurologic symptoms, as well as endocrine symptoms, may occur. Such symptoms may include visual changes, headache, and increased intracranial pressure (ICP).

Prolactin (PRL)-secreting tumors are the most common type of pituitary adenoma. Excessive PRL inhibits the secretion of gonadotropins and sex hormones in men and women, resulting in *galactorrhea* (breast milk production), amenorrhea, and infertility.

Overproduction of GH in adults results in *acromegaly* (Fig. 65-1). The onset may be gradual with slow progression, and changes may remain unnoticed for years before diagnosis of the disorder. Early detection and treatment are essential to prevent irreversible changes in the soft tissues, such as those of the face, hands, feet, and skin. Other changes include increased skeletal thickness, hypertrophy of the skin, and enlargement of many organs, such as the liver and heart. Some changes may be reversible after treatment, but skeletal changes are permanent.

Bone thinning and bone cell overgrowth occur slowly. Degeneration of joint cartilage and hypertrophy of ligaments, vocal cords, and eustachian tubes are common. Nerve entrapment occurs because of tissue overgrowth and myelin loss in peripheral nerves. Because GH blocks the action of insulin, **hyperglycemia** (elevated blood glucose levels) is also common.

Excess ACTH overstimulates the adrenal cortex. The result is excessive production of glucocorticoids, mineralocorticoids, and androgens, which leads to the development of Cushing's disease (see Hypercortisolism [Cushing's Disease], pp. 1384-1390).

Usually, hyperpituitarism is caused by hormone-secreting benign tumors (*adenomas*) arising from one pituitary cell

type. It can also be caused by hypothalamic problems that lead to excessive production of releasing hormones, which then overstimulate the normal pituitary gland.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The manifestations of hyperpituitarism vary, depending on which hormone is produced in excess. Obtain data about the patient's age, gender, and family history. Ask about any change in hat, glove, ring, or shoe size. Fatigue and lethargy are common. The patient with high GH levels may have backache and **arthralgias** (joint pain) from bone changes. Ask specifically about headaches and changes in vision.

The patient with hypersecretion of PRL often reports difficulties in sexual functioning. Ask women about menstrual changes (e.g., amenorrhea, irregular menses, and difficulty in becoming pregnant) and about decreased libido or *dyspareunia* (painful intercourse). Men may report decreased libido and impotence.

Changes in appearance and target organ function occur with excesses of specific anterior pituitary hormones (Chart 65-2). Initial manifestations of GH excess are increases in lip and nose sizes, a prominent brow ridge, and increases in head, hand, and foot sizes. The patient with hyperpituitarism often seeks health care because of dramatic changes in appearance. Assess the impact of these changes on self-image and personal relationships.

In hyperpituitarism, usually only one hormone is produced in excess because the cell types within the pituitary gland are so individually organized. The most common hormones produced in excess are PRL, ACTH, and GH. Tumors producing TSH, luteinizing hormone (LH), or follicle-stimulating hormone (FSH) are rare, and elevations of these hormones warrant evaluation. Elevations of LH and FSH are normal in the postmenopausal woman.

Imaging assessment for hyperpituitarism is the same as for hypopituitarism. Skull x-rays are used to identify abnormalities of the sella turcica. CT scans and MRI can define soft-tissue lesions, and angiography can rule out an aneurysm or vascular malformations.

Suppression testing can help diagnose hyperpituitarism and determine whether the normal negative feedback control mechanisms for hormonal regulation are intact. For example, high blood glucose levels suppress the release of GH. In a suppression test, 100 g of oral glucose or 0.5 g/kg of body weight is given IV. GH levels are measured serially for up to 120 minutes. GH levels that do not fall below 5 ng/mL indicate a positive (abnormal) result.

INTERVENTIONS

The expected outcomes of management for the patient who has hyperpituitarism are to return hormone levels to normal or near normal, reduce or eliminate headache and visual disturbances, prevent complications, and reverse as many of the body changes as possible.

Nonsurgical Management

Encourage the patient to express concerns about his or her altered physical appearance. Help him or her identify personal strengths and positive characteristics, reinforcing each

FIG. 65-1 The progression of acromegaly.

patient's uniqueness and importance. Galactorrhea, gynecomastia, and reduced sexual functioning can disturb self-image and personal identity. Reassure the patient that treatment may reverse some of these problems. Encourage the patient to discuss his or her feelings.

Drug therapy may be used alone or in combination with surgery and/or radiation. The most common drugs used are dopamine agonists, including bromocriptine mesylate (Parlodel), cabergoline (Dostinex), and pergolide (Permax) (Melmed & Kleinberg, 2008). These drugs stimulate dopamine receptors in the brain and inhibit the release of GH and PRL. In most cases, small tumors decrease until the pituitary gland is of normal size. Large pituitary tumors usually decrease to some extent. In patients with acromegaly, bromocriptine reduces GH levels and decreases tumor size,

especially when GH levels remain high after surgery or before the full effect of radiation therapy has occurred.

Side effects of bromocriptine include **orthostatic** (postural) hypotension, gastric irritation, nausea, headaches, abdominal cramps, and constipation. Give bromocriptine with a meal or a snack to reduce some of these side effects. Treatment starts with a low dose and is gradually increased until the desired level (usually 7.5 mg/day) is reached. *If pregnancy occurs, the drug is stopped immediately.*

Other agents used for acromegaly are the somatostatin analogs, especially octreotide (Sandostatin), and a growth hormone receptor blocker, pegvisomant (Somavert). Octreotide inhibits GH release through negative feedback. Pegvisomant blocks growth hormone (GH) receptor activity and production of insulin-like growth factor (IGF). Although

CHART 65-2 KEY FEATURES

Anterior Pituitary Hyperfunction**Prolactin (PRL)**

- Hypogonadism (loss of secondary sexual characteristics)
- Decreased gonadotropin levels
- Galactorrhea
- Increased body fat
- Increased serum prolactin levels

**Growth Hormone (GH)
Acromegaly**

- Folding of the scalp skin
- Thickened lips
- Coarse facial features
- Increasing head size
- Protrusion of the lower jaw
- Deepening of the voice
- Tufting of the fingertips
- Enlarged hands and feet
- Joint enlargement and pain
- Kyphosis and backache
- Barrel-shaped chest
- Excessive sweating
- Hyperglycemia
- Airway narrowing, sleep apnea
- Enlarged heart, lungs, and liver

Adrenocorticotrophic Hormone (ACTH)**Cushing's Disease (Pituitary)**

- Elevated plasma cortisol levels
- Weight gain
- Truncal obesity
- "Moon face"
- Extremity muscle wasting
- Loss of bone density
- Hypertension
- Hyperglycemia
- Purple striae
- Acne
- Thin, easily damaged skin
- Hyperpigmentation

Thyrotropin (Thyroid-Stimulating Hormone [TSH])

- Elevated plasma TSH levels
- Elevated plasma thyroid hormone levels
- Weight loss
- Tachycardia and dysrhythmias
- Heat intolerance
- Increased GI motility
- Fine tremors

Gonadotropins (Luteinizing Hormone [LH], Follicle-Stimulating Hormone [FSH])**Men:**

- Elevated LH and FSH levels
- Hypogonadism or hypergonadism

Women:

- Normal LH and FSH levels
- (The most common clinical manifestations in men and women are related to the physical presence of a tumor rather than to excessive hormone secretion.)

FIG. 65-2 The transsphenoidal surgical approach to the pituitary gland. Selective adenomectomy leaves normal pituitary tissue undisturbed.

these therapies are effective, a disadvantage is that they must be given as an injection on a daily or weekly schedule. A major side effect is gallbladder disease. Pegvisomant may cause an increase in tumor size.

! NURSING SAFETY PRIORITY**Drug Alert**

Teach patients taking bromocriptine to seek medical care immediately if chest pain, dizziness, or watery nasal discharge occurs because of the possibility of serious side effects, including cardiac dysrhythmias, coronary artery spasms, and cerebrospinal fluid leakage.

Radiation therapy is not useful in the immediate management of acute hyperpituitarism. These therapy regimens take a long time to complete, and several years may pass before a therapeutic effect can be seen. Side effects of radiation therapy include hypopituitarism, optic nerve damage, and other eye

and vision problems. Use of the gamma knife procedure is increasing the accuracy of radiation therapy.

Surgical Management

Surgical removal of the pituitary gland and tumor (**hypophysectomy**) is the most common treatment for hyperpituitarism.

Preoperative Care. Explain that hypophysectomy decreases hormone levels, relieves headaches, and may reverse changes in sexual functioning. Body changes, organ enlargement, and visual changes are not usually reversible. Explain that because nasal packing is present for 2 to 3 days after surgery, it will be necessary to breathe through the mouth, and a "mustache" dressing ("drip" pad) will be placed under the nose. Instruct the patient not to brush teeth, cough, sneeze, blow the nose, or bend forward after surgery. These activities can increase intracranial pressure (ICP) and delay healing.

Operative Procedures. Depending on tumor size and other patient factors, a minimally invasive endoscopic transnasal approach may be used instead of the more traditional transsphenoidal approach (Fig. 65-2). Although both procedures are less invasive than a craniotomy, the endoscopic approach uses smaller diameter instruments and results in less damage to nasal structures (Graham et al., 2009). Both procedures are performed with the patient in a semi-sitting position. For the transsphenoidal approach, the surgeon makes an incision just above the upper lip and reaches the pituitary gland through the sphenoid sinus. After the gland is removed, a muscle graft is taken, often from the thigh, to support the area and prevent leakage of cerebrospinal fluid (CSF). Nasal packing is inserted after the incision is closed, and a mustache dressing is applied. If the tumor cannot be reached by either the endoscopic transnasal approach or the transsphenoidal approach, a craniotomy may be indicated (see Chapter 47).

Postoperative Care. Monitor the patient's neurologic response, and document any changes in vision or mental

CHART 65-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE***The Patient After Hypophysectomy***

- Monitor the patient's neurologic status hourly for the first 24 hours and then every 4 hours.
- Monitor fluid balance, especially for output greater than intake, because transient diabetes insipidus can occur.
- Encourage the patient to maintain pulmonary hygiene through deep-breathing exercises.
- Instruct the patient to not cough, blow the nose, or sneeze.
- Instruct the patient to use dental floss and oral mouth rinses, because brushing the teeth is not permitted until the incision heals sufficiently.
- Instruct the patient to avoid bending at the waist for any reason, because this position increases intracranial pressure.
- Monitor the nasal drip pad for the type and amount of drainage. The presence of the halo sign may indicate a CSF leak.
- Monitor bowel movements to prevent constipation and subsequent "straining."
- Teach the patient self-administration of the prescribed hormones.

CSF, Cerebrospinal fluid.

status, altered level of consciousness, or decreased strength of the extremities. Observe the patient for complications such as transient diabetes insipidus (discussed on pp. 1378-1380), CSF leakage, infection, and increased ICP.

Teach the patient to report any postnasal drip or increased swallowing, which might indicate leakage of CSF. Keep the head of the bed elevated after surgery. Assess nasal drainage for quantity, quality, and the presence of glucose (which indicates that the fluid is CSF). A light yellow color at the edge of the clear drainage on the dressing is called the "halo sign" and indicates CSF. If the patient has persistent, severe headaches, CSF fluid may have leaked into the sinus area. Most CSF leaks resolve with bedrest. If the CSF leak persists, the physician may perform a spinal tap to reduce CSF pressure. Surgical intervention is rarely necessary.

Teach the patient to avoid coughing early after surgery because it increases pressure in the incision area and may lead to a CSF leak. Remind the patient to perform deep-breathing exercises hourly while awake to prevent pulmonary problems. Patients may have mouth dryness from mouth breathing. Perform frequent oral rinses, and apply a lubricating jelly to dry lips.

Infection can occur after surgery. Specifically assess for manifestations of meningitis, such as headache, fever, and nuchal (neck) rigidity. The surgeon may prescribe antibiotics, analgesics, and antipyretics.

If the entire pituitary gland has been removed, replacement of thyroid hormones and glucocorticoids is lifelong. Best practices for care after surgery are listed in [Chart 65-3](#).

After surgery, the patient needs daily self-management regimens and frequent checkups. He or she may need strategies to reduce stress. The home care nurse performs a focused assessment during any home visit to a patient who has undergone a hypophysectomy ([Chart 65-4](#)). Review drug regimens and manifestations of infection and cerebral edema with the family.

After a transsphenoidal hypophysectomy, advise the patient to avoid activities that might interfere with healing. Teach him or her to avoid bending over from the waist to pick

CHART 65-4 HOME CARE ASSESSMENT***The Patient Who Has Undergone Transsphenoidal or Endoscopic Nasal Hypophysectomy for Hyperpituitarism***

Assess cardiovascular status:

- Vital signs, including apical pulse, pulse pressure, presence or absence of orthostatic hypotension, and the quality/rhythm of peripheral pulses

Assess cognition and mental status:

- Level of consciousness
- Orientation to time, place, and person
- Accurate reading of a seven-word sentence containing no words longer than three syllables

Assess condition of operative site:

- Observe nasal area for drainage:
If present, note color, clarity, and odor
Test clear drainage for the presence of glucose

Assess neuromuscular status:

- Reactivity of patellar and biceps reflexes
- Oral temperature
- Handgrip strength
- Steadiness of gait
- Visual fields
- Distant and near visual acuity
- Pupillary responses to light

Assess kidney function:

- Observe urine specimen for color, odor, cloudiness, and amount

Ask about:

- Headaches or visual disturbances
- Ease of bowel movements
- 24-hour fluid intake and output
- 24-hour diet recall
- 24-hour activity recall
- Over-the-counter and prescribed drugs taken

Assess patient's understanding of illness and adherence with treatment:

- Signs and symptoms to report to health care provider
- Drug plan (correct timing and dose)

up objects or tie shoes because this position increases ICP. Teach the patient to bend the knees and then lower the body to pick up fallen objects. ICP also increases when the patient strains to have a bowel movement. Suggest techniques to prevent constipation, such as eating high-fiber foods, drinking plenty of fluids, and using stool softeners or laxatives. Activities that increase ICP should be avoided for up to 2 months after surgery.

Teach the patient to avoid toothbrushing for about 2 weeks after surgery until the incision has healed. Frequent mouth care (every 4 to 6 hours) with mouthwash and daily flossing provide adequate oral hygiene. Numbness in the area of the incision and a decreased sense of smell are expected after surgery and usually last 3 to 4 months. Advise the patient to use a mirror to check the gums for bleeding, because reduced sensation increases the risk for injury.

After a hypophysectomy, hormone replacement with vasopressin may be needed to maintain fluid balance. (See discussion of Interventions on pp. 1378-1380 in the Diabetes Insipidus section.) If the anterior portion of the pituitary gland is removed, instruct the patient in cortisol, thyroid, and gonadal hormone replacement. Teach the patient to report the return of any symptoms of hyperpituitarism immediately to the primary health care provider.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The nurse notes that the mustache dressing of a client who is 12 hours postoperative from a transsphenoidal hypophysectomy is wet. What is the nurse's best action?

- Reapply a dry dressing and document this expected response.
- Ask the client whether other symptoms of a cold are present.
- Notify the surgeon or the Rapid Response Team.
- Test the drainage for the presence of glucose.

DISORDERS OF THE POSTERIOR PITUITARY GLAND

Disorders of the posterior pituitary gland (**neurohypophysis**) are related to a deficiency or excess of the hormone *vasopressin* (antidiuretic hormone [ADH]) and usually occur independently from anterior pituitary problems. Diabetes insipidus occurs with ADH deficiency, and the syndrome of inappropriate antidiuretic hormone (SIADH) occurs with ADH excess.

DIABETES INSIPIDUS

Pathophysiology

Diabetes insipidus (DI) is a water metabolism problem caused by an ADH deficiency (either a decrease in ADH synthesis or an inability of the kidneys to respond to ADH). ADH deficiency results in the excretion of large volumes of dilute urine. Without ADH, distal kidney tubules and collecting ducts do not reabsorb water, leading to **polyuria** (excessive water loss through urination) and dehydration.

Dehydration caused by this massive water loss increases plasma osmolarity, which stimulates the osmoreceptors to relay a sensation of thirst to the cerebral cortex. Thirst promotes increased fluid intake and aids in maintaining water homeostasis. *If the thirst mechanism is poor or absent or if the person is unable to obtain water, dehydration becomes more severe and can lead to death.*

NURSING SAFETY PRIORITY

Critical Rescue

Ensure that no patient suspected of having DI is deprived of fluids for more than 4 hours, because he or she cannot reduce urine output and severe dehydration can result.

ADH deficiency is classified as nephrogenic, drug-related, primary, or secondary, depending on whether the problem is caused by insufficient production of ADH or an inability of the kidney to respond to the presence of ADH (Simmons, 2010).

Nephrogenic diabetes insipidus is an inherited disorder. The kidney tubules do not respond to the actions of ADH, which results in poor water reabsorption by the kidney. The actual amount of hormone produced is not deficient.

Primary diabetes insipidus is caused by a defect in the hypothalamus or pituitary gland, resulting in a lack of ADH production or release. **Secondary diabetes insipidus** can result from tumors in or near the hypothalamus or pituitary gland, head trauma, infectious processes, surgical procedures

CHART 65-5

KEY FEATURES

Diabetes Insipidus

Cardiovascular Manifestations

- Hypotension
- Decreased pulse pressure
- Tachycardia
- Peripheral pulses weak, easily blocked
- Hemoconcentration:
 - Increased hemoglobin
 - Increased hematocrit
 - Increased BUN

Kidney/Urinary Manifestations

- Increased urine output:
 - Dilute, low specific gravity
 - Hypo-osmolar

Skin Manifestations

- Poor turgor
- Dry mucous membranes

Neurologic Manifestations

- Increased sensation of thirst
- Irritability*
- Decreased cognition*
- Hyperthermia*
- Lethargy to coma*
- Ataxia*

BUN, Blood urea nitrogen.

*Occurs when access to water is limited and rapid dehydration results.

(hypophysectomy), or metastatic tumors. Less often, it is caused by brain hemorrhage, brain disease, or cerebral aneurysm, which reduces ADH production.

Drug-related diabetes insipidus is usually caused by lithium carbonate (Eskalith, Lithobid, Carbolith) and demeclocycline (Declomycin). These drugs can interfere with the response of the kidneys to ADH.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Most manifestations of DI are related to dehydration (Chart 65-5) (Simmons, 2010). The key manifestations are an increase in the frequency of urination and excessive thirst. Ask about a history of any known causative factors, such as recent surgery, head trauma, or drug use (e.g., lithium). Although increased fluid intake prevents serious volume depletion, the patient who is deprived of fluids or who cannot increase oral fluid intake may develop shock from fluid loss. Manifestations of dehydration, such as poor skin turgor and dry or cracked mucous membranes or skin, may be present. (See Chapter 13 for further discussion of dehydration.)

Water loss produces changes in blood and urine tests. The first step in diagnosis is to measure a 24-hour fluid intake and output without restricting food or fluid intake. DI is considered if urine output is more than 4 L during this period and is greater than the volume ingested. *The amount of urine excreted in 24 hours may vary from 4 to 30 L/day.* Urine is dilute with a low specific gravity (less than 1.005) and low osmolarity (50 to 200 mOsm/kg).

INTERVENTIONS

Management focuses on controlling manifestations with drug therapy (Chart 65-6). If only a partial deficit of ADH is present, effective control can be achieved with oral chlorpropamide (Diabinese, Novo-Propamide). This drug increases the action of existing ADH and possibly has a stimulating effect on the production of ADH in the hypothalamus.

CHART 65-6 COMMON EXAMPLES OF DRUG THERAPY

Diabetes Insipidus

DRUG/DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Desmopressin (DDAVP, Rhinal Tube, Minirin, Stiminate) Tablets: 0.1-0.2 mg orally twice daily Nasal spray: 10-20 mcg every 8-12 hr Parenteral: 1-2 mcg IV or subcutaneously every 12 hr	The drug is a synthetic type of ADH that serves as a replacement. It binds to kidney receptors and enhances the reabsorption of water, thus reducing urine output.	Teach the patient using the inhaled form of the drug to blow the nose before taking the drug. Teach the patient using the inhaled form to sit upright and hold his or her breath when spraying or using the rhinal tube. Warn the patient not to drink more than 3 L of fluids daily while on this drug. Teach the patient to weigh himself or herself daily and to notify the health care provider if 2 lbs or more is gained in 24 hours. Tell the patient to notify the health care provider if he or she experiences a persistent headache or acute confusion.	Drug is absorbed through the nasal mucosa. Nasal secretions can dilute the drug and inhibit its absorption. Sitting upright and holding the breath keeps the drug in contact with the nasal mucosa, rather than going down the throat, enhancing drug absorption. Drug promotes fluid retention and can lead to fluid overload. A rapid increase in weight is an indicator of excessive fluid retention and may require a change in drug dosage. These are manifestations of water toxicity, which must be treated before seizure activity occurs.
Vasopressin (Pitressin) 5-10 units parenterally two to four times daily	The drug is an exogenous form of ADH that serves as a replacement. It binds to kidney receptors and enhances the reabsorption of water, thus reducing urine output.	For the hospitalized patient, monitor for signs of water intoxication, such as listlessness, drowsiness, confusion, headache, anuria, and weight gain. Warn the patient not to drink more than 3 L of fluids daily while on this drug. Teach the patient to weigh himself or herself daily and to notify the health care provider if 2 lbs or more is gained in 24 hours. Tell the patient to notify the health care provider if he or she experiences a persistent headache or acute confusion.	Vasopressin-induced water intoxication can also lead to seizures, coma, and death. Drug promotes fluid retention and can lead to fluid overload. A rapid increase in weight is an indicator of excessive fluid retention and may require a change in drug dosage. These are manifestations of water toxicity, which must be treated before seizure activity occurs.
Chlorpropamide (Diabinese, Insulase) 250-500 mg orally daily	The drug is an antidiabetic agent that also has some antidiuretic activity through an unknown mechanism. It decreases urine output.	Ask whether the patient has any allergies to sulfa-based drugs. Teach patients the manifestations of hypoglycemia and to always carry candy or concentrated sugar with them.	Drug contains sulfa, and a person who is hypersensitive to sulfa drugs is likely to also be hypersensitive to this drug. The main action of the drug is to lower blood glucose levels. When taken by a person whose blood glucose level is normal, hypoglycemia can result.

ADH, Antidiuretic hormone.

! NURSING SAFETY PRIORITY**Drug Alert**

Diabinese and Diamox are sound-alike, look-alike drugs. Do not confuse them. Diamox is a type of diuretic, which could increase urine output and the risk for dehydration.

When ADH deficiency is severe, ADH is replaced in amounts sufficient to maintain water balance. Desmopressin acetate (DDAVP) is a synthetic form of vasopressin given orally or intranasally in a metered spray and is the drug of choice (Robinson & Verbalis, 2008). The frequency of dosing varies with patient responses. Teach patients that each metered spray delivers 10 mcg, and those with mild DI may need only one or two doses in 24 hours. For more severe DI, one or two metered doses two or three times daily may be needed. During severe dehydration, ADH may be given IV or IM. Ulceration of the mucous membranes, allergy, a sensation of chest tightness, and lung inhalation of the spray may occur with use of the intranasal preparations. If side effects occur or if the patient has an upper respiratory infection, oral or subcutaneous vasopressin is used.

! NURSING SAFETY PRIORITY**Drug Alert**

The parenteral form of desmopressin is 10 times stronger than the oral form, and the dosage must be reduced.

For the hospitalized patient with DI, nursing management focuses on early detection of dehydration and maintaining adequate hydration. Interventions include accurately measuring fluid intake and output, checking urine specific gravity, and recording the patient's weight daily.

Urge the patient to drink fluids in an amount equal to urine output. If fluids are given IV, ensure the patency of the access catheter and accurately monitor the amount infused hourly.

The patient with permanent DI requires lifelong desmopressin or vasopressin therapy. Assess his or her ability to follow instructions and participate in health care. Teach that polyuria and polydipsia are signals for the need for another dose.

Drugs for DI induce water retention and can cause fluid overload (see Chapter 13). *Teach all patients taking these drugs*

to weigh themselves daily to identify weight gain. Stress the importance of using the same scale and weighing at the same time of day while wearing a similar amount of clothing. If weight gain or other signs of water toxicity occur (e.g., persistent headache, acute confusion), instruct the patient or family that the patient must go to the emergency department or call 911. Instruct the patient to wear a medical alert bracelet identifying the disorder and drugs.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Which response in a client with diabetes insipidus indicates to the nurse that another dose of desmopressin acetate (DDAVP) is needed?

- A. Urine output and specific gravity are increased.
- B. Urine output is increased and urine specific gravity is decreased.
- C. Urine output and specific gravity are decreased.
- D. Urine output is decreased and urine specific gravity is increased.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Pathophysiology

The **syndrome of inappropriate antidiuretic hormone (SIADH)** is a problem in which vasopressin (antidiuretic hormone [ADH]) is secreted even when plasma osmolarity is low or normal. A decrease in plasma osmolarity normally inhibits ADH production and secretion. SIADH is also known as the *Schwartz-Bartter syndrome*. SIADH occurs with many pathologic conditions (e.g., cancer therapy) and with specific drugs, including selective serotonin reuptake inhibitors (Fitzgerald, 2008). Table 65-1 lists specific drugs and other common causes of SIADH.

In SIADH, ADH continues to be released even when plasma is hypo-osmolar. Water is *retained*, which results in dilutional **hyponatremia** (a decreased serum sodium level) and fluid overload. The increase in plasma volume increases the glomerular filtration rate and inhibits the release of renin

and aldosterone. The combined effect is an increased sodium loss in urine, leading to greater hyponatremia.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Ask the patient about his or her medical history, which may reveal conditions that occur with the development of SIADH. Information about these conditions should be obtained:

- Recent head trauma
- Cerebrovascular disease
- Tuberculosis or other pulmonary disease
- Cancer
- All past and current drug use

The early manifestations of SIADH are related to water retention. GI disturbances, such as loss of appetite, nausea, and vomiting, may occur first. Weigh the patient, and document any recent weight gain. Use this information to monitor responses to therapy. In SIADH, free water (not salt) is retained and dependent edema is not usually present, even though water is retained.

Water retention, hyponatremia, and fluid shifts affect central nervous system function, especially when the serum sodium level drops below 115 mEq/L. The patient may have lethargy, headaches, hostility, disorientation, and a change in level of consciousness. Manifestations can progress from lethargy and headaches to decreased responsiveness, seizures, and coma. Assess deep tendon reflexes, which are usually decreased.

Vital sign changes include a full and bounding pulse (caused by the increased fluid volume) and hypothermia (caused by central nervous system disturbance). Chapter 13 presents other findings that occur with hyponatremia.

Water retention changes both plasma and urine osmolarity. Urine volume decreases, and urine osmolarity increases. Plasma volume increases, and plasma osmolarity decreases. Elevated urine sodium levels and specific gravity reflect increased urine concentration. Serum sodium levels are decreased, often as low as 110 mEq/L, because of fluid retention and sodium loss.

Radioimmunoassay of ADH can diagnose SIADH when ADH levels are inappropriately elevated when plasma osmolarity is normal or decreased.

INTERVENTIONS

Medical interventions for SIADH focus on restricting fluid intake, promoting the excretion of water, replacing any lost sodium, and interfering with the action of ADH. Nursing interventions focus on monitoring response to therapy, preventing complications, teaching the patient and family about fluid restrictions and drug therapy, and preventing injury.

Fluid restriction is essential because fluid intake further dilutes plasma sodium levels. In some cases, fluid intake may be kept as low as 500 to 600 mL/24 hr. Dilute tube feedings with saline rather than plain water, and use saline to irrigate GI tubes. Mix drugs to be given by GI tube with saline.

Measure intake, output, and daily weights to assess the degree of fluid restriction needed. A weight gain of 2 pounds or more per day or a gradual increase over several days is

TABLE 65-1 CONDITIONS CAUSING THE SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Malignancies • Small cell lung cancer • Pancreatic, duodenal, and GU carcinomas • Thymoma • Hodgkin's lymphoma • Non-Hodgkin's lymphoma	CNS Disorders • Trauma • Infection • Tumors (primary or metastatic) • Strokes • Porphyrria • Systemic lupus erythematosus
Pulmonary Disorders • Viral and bacterial pneumonia • Lung abscesses • Active tuberculosis • Pneumothorax • Chronic lung diseases • Mycoses • Positive-pressure ventilation	Drugs • Exogenous ADH • Chlorpropamide • Vincristine • Cyclophosphamide • Carbamazepine • Opioids • Tricyclic antidepressants • General anesthetics

ADH, Antidiuretic hormone; CNS, central nervous system; GU, genitourinary.

cause for concern. A 1-kg weight increase is equal to a 1000-mL fluid retention (1 kg = 1 L). The patient may be uncomfortable during fluid restriction. Keep mucous membranes moist by offering frequent oral rinsing (remind the patient not to swallow the rinses).

Drug therapy with tolvaptan (Samsca) or conivaptan (Vaprisol) is used to treat SIADH when hyponatremia is present in hospitalized patients. These drugs are vasopressin antagonists that promote water excretion without causing sodium loss (Belavic, 2010). Tolvaptan is an oral drug, and conivaptan is given IV. Tolvaptan has a black box warning that rapid increases in serum sodium levels (those greater than a 12 mEq/L increase in 24 hours) have been associated with central nervous system demyelination that can lead to serious complications and death.

NURSING SAFETY PRIORITY

Drug Alert

Administer tolvaptan or conivaptan only in the hospital setting so that serum sodium levels can be monitored closely for the development of hypernatremia.

Diuretics may be used to manage SIADH when sodium levels are near normal and heart failure is present. Be aware of the diuretic effects on sodium loss. Sodium loss can be potentiated, further contributing to the problems caused by SIADH. For milder SIADH, demeclocycline (Declomycin), an oral antibiotic, may help correct the fluid imbalance, although the drug is not approved for this problem.

Hypertonic saline (i.e., 3% sodium chloride [3% NaCl]) may be used to treat SIADH when the serum sodium level is very low. Give IV saline cautiously because it may add to existing fluid overload and promote heart failure. If the patient needs routine IV fluids, a saline solution rather than a water solution is prescribed.

Monitor the patient's response to therapy to prevent the fluid overload from SIADH from becoming worse, leading to pulmonary edema and heart failure. Any patient with SIADH, regardless of age, is at risk for these complications. The older adult or one who has coexisting cardiac problems, kidney problems, pulmonary problems, or liver problems is at greater risk.

Monitor for increased fluid overload (bounding pulse, increasing neck vein distention, crackles in lungs, increasing peripheral edema, reduced urine output) at least every 2 hours. *Pulmonary edema can occur very quickly and can lead to death.* Notify the health care provider of any change that indicates the fluid overload from SIADH either is not responding to therapy or is becoming worse.

Providing a safe environment is needed when the serum sodium level falls below 120 mEq/L. Possible neurologic changes and the risk for seizures increase as a result of osmotic fluid shifts into brain tissue. Observe for and document changes in the patient's neurologic status. Assess for subtle changes, such as muscle twitching, before they progress to seizures or coma. Check orientation to time, place, and person every 2 hours because disorientation or confusion may be present. Reduce environmental noise and lighting to prevent overstimulation.

Flow sheets with continuing information about the level of consciousness, motor and sensory neurologic assessments,

and laboratory data are helpful in detecting neurologic trends. The frequency of neurologic checks depends on the patient's status. For the patient with SIADH who is hyponatremic but alert, awake, and oriented, neurologic checks every 4 hours are sufficient. For the patient who has had a change in level of consciousness, perform neurologic checks at least every hour. Inspect the environment every shift, making sure that basic safety measures, such as siderails being securely in place, are observed.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The serum electrolyte values for a client with syndrome of inappropriate antidiuretic hormone being treated with tolvaptan (Samsca) indicate the following changes within the past 12 hours. Which change does the nurse report immediately to the health care provider?

- A. Serum potassium decrease from 4.2 mEq/L to 3.8 mEq/L
- B. Serum sodium increase from 122 mEq/L to 140 mEq/L
- C. Serum calcium increase from 9.5 mg/dL to 10.2 mg/dL
- D. Serum chloride decrease from 109 mEq/L to 99 mEq/L

DISORDERS OF THE ADRENAL GLAND

ADRENAL GLAND HYPOFUNCTION

Pathophysiology

Production of adrenocortical steroids may decrease as a result of inadequate secretion of adrenocorticotrophic hormone (ACTH), dysfunction of the hypothalamic-pituitary control mechanism, or direct dysfunction of adrenal gland tissue. Manifestations may develop gradually or occur quickly with stress. In acute adrenocortical insufficiency (**adrenal crisis**), life-threatening manifestations may appear without warning.

Insufficiency of adrenocortical steroids causes problems through the loss of aldosterone and cortisol action. Impaired secretion of cortisol results in decreased **gluconeogenesis** (making glucose from proteins) along with depletion of liver and muscle glycogen, leading to **hypoglycemia** (low blood glucose levels). Glomerular filtration and gastric acid production decrease, leading to reduced urea nitrogen excretion, causing anorexia and weight loss.

Reduced aldosterone secretion causes potassium, sodium, and water imbalances. Potassium excretion is decreased, causing hyperkalemia. Sodium and water excretion are increased, causing hyponatremia and hypovolemia. Potassium retention also promotes reabsorption of hydrogen ions, which can lead to acidosis.

Low adrenal androgen levels decrease the body, axillary, and pubic hair, especially in women, because the adrenals produce most of the androgens in females. The severity of symptoms is related to the degree of hormone deficiency.

Acute adrenal insufficiency, or **addisonian crisis**, is a life-threatening event in which the need for cortisol and aldosterone is greater than the available supply. Often, it occurs in response to a stressful event (e.g., surgery, trauma, severe infection), especially when the adrenal hormone output is already reduced. The problems of acute adrenal insufficiency are the same as those of chronic insufficiency but are more severe. *Unless intervention is initiated promptly, however, sodium levels fall and potassium levels rise rapidly. Severe hypotension results from the blood volume depletion that*

occurs with the loss of aldosterone. Best practices for emergency care of patients with acute adrenal insufficiency are listed in [Chart 65-7](#).

Adrenal insufficiency (Addison's disease) is classified as primary or secondary. Causes of primary and secondary adrenal insufficiency are listed in [Table 65-2](#). A common cause of secondary adrenal insufficiency is the sudden cessation of long-term glucocorticoid therapy. This therapy

CHART 65-7 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient with Acute Adrenal Insufficiency

Hormone Replacement

- Start rapid infusion of normal saline or dextrose 5% in normal saline.
- Initial dose of hydrocortisone sodium succinate (Solu-Cortef) is 100 to 300 mg or dexamethasone 4 to 12 mg as an IV bolus.
- Infuse additional 100 mg of hydrocortisone sodium succinate by continuous IV drip over the next 8 hours.
- Give hydrocortisone 50 mg IM concomitantly every 12 hours.
- Initiate an H₂ histamine blocker (e.g., ranitidine) IV for ulcer prevention.

Hyperkalemia Management

- Administer insulin (20 to 50 units) with dextrose (20 to 50 mg) in normal saline to shift potassium into cells.
- Administer potassium binding and excreting resin (e.g., Kayexalate).
- Give loop or thiazide diuretics.
- Avoid potassium-sparing diuretics, as prescribed.
- Initiate potassium restriction.
- Monitor intake and output.
- Monitor heart rate, rhythm, and ECG for manifestations of hyperkalemia (slow heart rate; heart block; tall, peaked T waves; fibrillation; asystole).

Hypoglycemia Management

- Administer IV glucose, as prescribed.
- Administer glucagon, as needed and prescribed.
- Maintain IV access.
- Monitor blood glucose level hourly.

ECG, Electrocardiogram.

TABLE 65-2 CAUSES OF PRIMARY AND SECONDARY ADRENAL INSUFFICIENCY

Primary Causes

- Idiopathic (autoimmune) disease*
- Tuberculosis
- Metastatic cancer
- Fungal lesions
- AIDS
- Hemorrhage
- Gram-negative sepsis (Waterhouse-Friderichsen syndrome)
- Adrenalectomy
- Abdominal radiation therapy
- Drugs (mitotane) and toxins

Secondary Causes

- Pituitary tumors
- Postpartum pituitary necrosis (Sheehan's syndrome)
- Hypophysectomy
- High-dose pituitary radiation
- High-dose whole-brain radiation

AIDS, Acquired immune deficiency syndrome.

*Most common cause.

suppresses production of glucocorticoids through negative feedback by causing atrophy of the adrenal cortex. Glucocorticoid drugs must be withdrawn gradually to allow for pituitary production of ACTH and activation of adrenal cells to produce cortisol.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

When possible, take the history from the patient. If he or she is confused, ask the family about manifestations and factors that cause adrenal hypofunction. Ask about any change in activity level, because lethargy, fatigue, and muscle weakness are often present. Include questions about salt intake because salt craving often occurs with adrenal hypofunction.

GI problems, such as anorexia, nausea, vomiting, diarrhea, and abdominal pain, often occur. Ask about weight loss during the past months. Women may have menstrual changes related to weight loss, and men may report impotence.

Ask whether the patient has had radiation to the abdomen or head. Document medical problems (e.g., tuberculosis or previous brain surgery) and all past and current drugs, especially steroids, anticoagulants, opioids, or cytotoxic drugs.

Physical Assessment/Clinical Manifestations

The manifestations of adrenal insufficiency vary, and the severity is related to the degree of hormone deficiency ([Chart 65-8](#)). In patients with primary insufficiency, plasma ACTH and melanocyte-stimulating hormone (MSH) levels are in response to the adrenal-hypothalamic-pituitary feedback system. Elevated MSH levels result in areas of increased pigmentation ([Fig. 65-3](#)). In primary autoimmune disease, patchy areas of decreased pigmentation may occur because of destruction of skin melanocytes. Body hair may also be decreased. In secondary disease, skin pigmentation is not changed.

Assess for signs of hypoglycemia (e.g., sweating, headaches, tachycardia, and tremors) and fluid depletion (postural hypotension and dehydration). [Hyperkalemia](#) (elevated blood potassium levels) can cause dysrhythmias with an irregular heart rate and result in cardiac arrest.

CHART 65-8 KEY FEATURES

Adrenal Insufficiency

Neuromuscular Manifestations

- Muscle weakness
- Fatigue
- Joint/muscle pain

Gastrointestinal Manifestations

- Anorexia
- Nausea, vomiting
- Abdominal pain
- Bowel changes (constipation/diarrhea)
- Weight loss
- Salt craving

Skin Manifestations

- Vitiligo
- Hyperpigmentation

Cardiovascular Manifestations

- Anemia
- Hypotension
- Hyponatremia
- Hyperkalemia
- Hypercalcemia

Psychosocial Assessment

Depending on the degree of imbalance, patients may appear lethargic, depressed, confused, and even psychotic or fearful. Observe the patient, and check his or her orientation to person, place, and time. Families may report that the patient has a decreased energy level, experiences wide mood swings, and is forgetful.

Diagnostic Assessment

Laboratory findings include low serum cortisol, low fasting blood glucose, low sodium, elevated potassium, and increased blood urea nitrogen (BUN) levels (Chart 65-9). In primary disease, the eosinophil count and ACTH level are elevated. Plasma cortisol levels do not rise during stimulation tests.

Urinary 17-hydroxycorticosteroids are the glucocorticoid metabolites, and 17-ketosteroid levels reflect the adrenal

androgen metabolites. Both levels are in the low or low-normal range in adrenal hypofunction.

An ACTH stimulation test is the most definitive test for adrenal insufficiency (Stewart, 2008). ACTH 0.25 to 1 mg is given IV, and plasma cortisol levels are obtained at 30-minute and 1-hour intervals. In primary insufficiency, the cortisol response is absent or very decreased. In secondary insufficiency, it is increased. When acute adrenal insufficiency is suspected, treatment is started without stimulation testing.

Imaging Assessment

Skull x-rays, CT, MRI, and arteriography may help determine the cause of pituitary problems leading to adrenal insufficiency. CT scans may show adrenal gland atrophy.

INTERVENTIONS

Nursing interventions focus on promoting fluid balance, monitoring for fluid deficit, and preventing hypoglycemia. Weigh the patient daily, and record intake and output. Assess vital signs every 1 to 4 hours, depending on the patient's condition and the presence of dysrhythmias or postural hypotension. Monitor laboratory values to identify hemoconcentration (e.g., increased hematocrit or BUN). Chapter 13 discusses fluid volume deficit in detail.

Cortisol and aldosterone deficiencies are corrected by replacement therapy. Hydrocortisone corrects glucocorticoid deficiency (Chart 65-10). Oral cortisol replacement regimens vary. The most common drug used for this purpose is prednisone. Generally, divided doses are given, with two-thirds given in the morning and one-third in the late afternoon to mimic the normal release of this hormone. Although most patients do well on this regimen, some may not tolerate the dosage or may need more.

An additional mineralocorticoid hormone, such as fludrocortisone (Florinef), may be needed to maintain electrolyte balance (especially sodium and potassium). Dosage adjustment may be needed, especially in hot weather when more sodium is lost because of excessive perspiration. Salt

FIG. 65-3 The increased pigmentation seen in primary adrenocortical insufficiency.

CHART 65-9 LABORATORY PROFILE

Adrenal Gland Assessment

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS	
		HYPOFUNCTION OF THE ADRENAL GLAND	HYPERFUNCTION OF THE ADRENAL GLAND
Sodium	136-145 mEq/L	Decreased	Increased
Potassium	3.5-5.0 mEq/L	Increased	Decreased
Glucose	70-115 mg/dL <i>Older adults:</i> slightly increased	Normal to decreased	Normal to increased
Calcium	9-10.5 mg/dL (total) 4.5-5.6 mg/dL (ionized) <i>Older adults:</i> slightly decreased	Increased	Decreased
Bicarbonate	23-30 mEq/L	Increased	Decreased
BUN	10-20 mg/dL <i>Older adults:</i> may be slightly higher	Increased	Normal
Cortisol	6 AM to 8 AM: 5-23 mcg/dL or 138-635 SI units (nmol/L) 4 PM to 6 PM: 3-13 mcg/dL or 83-359 SI units (nmol/L)	Decreased	Increased

BUN, Blood urea nitrogen; SI, International System of Units.

CHART 65-10 COMMON EXAMPLES OF DRUG THERAPY

Hypofunction of the Adrenal Gland

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Cortisone	25-50 mg orally either once daily in AM or daily in divided doses	Instruct the patient to take the drug with meals or a snack.	GI irritation can occur.
Hydrocortisone (Cortef, Hycort )	20-50 mg orally either once daily in AM or daily in divided doses	Instruct the patient to report these signs or symptoms of excessive drug therapy: • Rapid weight gain • Round face • Fluid retention	Cushing's syndrome, which indicates a need for dosage adjustment, can occur.
Prednisone (Winpred )	5-10 mg orally either once daily in AM or daily in divided doses	Instruct the patient to report illness, such as: • Severe diarrhea • Vomiting • Fever	Other conditions may indicate a need for dosage change. The usual daily dosage may not be adequate during periods of illness or severe stress.
Fludrocortisone (Florinef)	0.05-0.2 mg orally daily	Monitor the patient's blood pressure. Instruct the patient to report weight gain or edema.	Hypertension is a potential side effect. Sodium-related fluid retention is possible.

! NURSING SAFETY PRIORITY**Drug Alert**

Prednisone and prednisolone are sound-alike drugs, and care is needed not to confuse them. Although they are both corticosteroids, they are not interchangeable because prednisolone is several times more potent than prednisone and dosages are not the same.

restriction or diuretic therapy should not be started without considering whether it might lead to an adrenal crisis.

ADRENAL GLAND HYPERFUNCTION

The adrenal gland may oversecrete just one hormone or all adrenal hormones. Hypersecretion by the adrenal cortex results in hypercortisolism (e.g., **Cushing's disease** or **Cushing's syndrome**), **hyperaldosteronism** (excessive mineralocorticoid production), or excessive androgen production. Hyperstimulation of the adrenal medulla caused by a tumor (**pheochromocytoma**) results in excessive secretion of catecholamines (epinephrine and norepinephrine).

HYPERCORTISOLISM (CUSHING'S DISEASE)**Pathophysiology**

Cushing's disease is the exaggerated secretion of cortisol from the adrenal cortex, causing widespread problems. It is caused by either a problem in the adrenal cortex itself, a problem in the anterior pituitary gland, or a problem in the hypothalamus. In addition, glucocorticoid therapy can also lead to problems of hypercortisolism.

The presence of excess glucocorticoids, regardless of the cause, affects metabolism and all body systems. An increase in total body fat results from slow turnover of plasma fatty acids. This fat is redistributed, producing truncal obesity, "buffalo hump," and "moon face" (Fig. 65-4). Increases in the breakdown of tissue protein and an increase in urine nitrogen excretion also occur, resulting in decreased muscle mass and muscle strength, thin skin, and fragile capillaries. The effects on minerals lead to bone density loss.

High levels of corticosteroids kill lymphocytes and shrink organs containing lymphocytes, such as the spleen and the

FIG. 65-4 The typical appearance of a patient with Cushing's disease or syndrome. Note truncal obesity, moon face, buffalo hump, thinner arms and legs, and abdominal striae.

lymph nodes. Eosinophils and macrophages are reduced. Although the number of neutrophils may be increased, the reduction of cytokines makes these cells less active. Thus inflammatory and immune response protections are reduced.

TABLE 65-3 CONDITIONS CAUSING INCREASED CORTISOL SECRETION

Endogenous Secretion (Cushing's Disease)	Exogenous Administration (Cushing's Syndrome)
- Bilateral adrenal hyperplasia* - Pituitary adenoma increasing the production of ACTH (pituitary Cushing's disease) - Malignancies: carcinomas of the lung, GI tract, pancreas - Adrenal adenomas or carcinomas	- Therapeutic use of ACTH or glucocorticoids—most commonly for treatment of: - Asthma - Autoimmune disorders - Organ transplantation - Cancer chemotherapy - Allergic responses - Chronic fibrosis

ACTH, Adrenocorticotrophic hormone.

*Most common cause.

In most cases, increased androgen production also occurs and causes acne, **hirsutism** (increased hair growth), and occasionally clitoral hypertrophy. Increased androgen production disrupts the normal ovarian hormone feedback mechanism, decreasing the ovary's production of estrogens and progesterone. **Oligomenorrhea** (scant or infrequent menses) occurs as a result.

Etiology

Cushing's disease or syndrome is a group of clinical problems caused by an excess of cortisol. Table 65-3 lists causes of cortisol excess. When the anterior pituitary gland oversecretes adrenocorticotrophic hormone (ACTH), this hormone causes hyperplasia of the adrenal cortex in both adrenal glands and an excess of most hormones secreted by the adrenal cortex. (See Fig. 64-3 in Chapter 64.) This problem is known as **pituitary Cushing's disease** because the tissue causing the problem is the pituitary. When the excess glucocorticoids are caused by a problem in the actual adrenal cortex, usually a benign tumor (*adrenal adenoma*), the problem is called **adrenal Cushing's disease** and usually occurs in only one adrenal gland. When glucocorticoid excess results from drug therapy for another health problem, it is known as **Cushing's syndrome**.

Incidence/Prevalence

The most common cause of Cushing's disease is a pituitary adenoma. Adrenal adenomas account for only about 15% of the disease (Stewart, 2008). Women are more likely than men to develop Cushing's disease. The actual incidence of Cushing's syndrome from chronic use of exogenous corticosteroids is not known. However, because these drugs are commonly used to control serious chronic inflammatory conditions such as asthma, other respiratory problems, and rheumatoid arthritis, Cushing's syndrome is more common than Cushing's disease and affects both genders equally.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Ask about the patient's other health problems and drug therapies, because glucocorticoid therapy is a common cause of hypercortisolism. Regardless of cause, the patient has many

CHART 65-11 KEY FEATURES

Hypercortisolism (Cushing's Disease/Syndrome)

General Appearance

- Fat redistribution:
 - Moon face
 - Buffalo hump
 - Truncal obesity
- Weight gain

Cardiovascular Manifestations

- Hypertension
- Increased risk for thromboembolic events
- Frequent dependent edema
- Capillary fragility:
 - Bruising
 - Petechiae

Musculoskeletal Manifestations

- Muscle atrophy (most apparent in extremities)
- Osteoporosis (bone density loss)
 - Pathologic fractures
 - Decreased height with vertebral collapse
 - Aseptic necrosis of the femur head
 - Slow or poor healing of bone fractures

Skin Manifestations

- Thinning skin ("paper-like" appearance, especially on the back of the hands)
- Striae
- Increased pigmentation (with ectopic or pituitary production of ACTH)

Immune System Manifestations

- Increased risk for infection
- Decreased immune function:
 - Decreased circulating lymphocytes
 - Decreased production of immunoglobulins (antibodies)
- Decreased inflammatory responses:
 - Decreased eosinophil count
 - Slight increase in neutrophil count but activity is reduced
- Decreased production of pro-inflammatory cytokines, histamine, and prostaglandins
- Manifestations of infection/inflammation may be masked

ACTH, Adrenocorticotrophic hormone.

changes because of the widespread effect of excessive cortisol levels. Record age, gender, and usual weight. He or she may report a significant weight gain and an increased appetite. Ask about changes in activity or sleep patterns, fatigue, and muscle weakness. Ask about bone pain or a history of fractures because osteoporosis is common in hypercortisolism. Ask about a history of frequent infections and easy bruising, which suggest hypercortisolism. Women often stop menstruating. GI problems include ulcer formation from increased hydrochloric acid secretion and decreased production of protective gastric mucus.

Physical Assessment/Clinical Manifestations

The patient with hypercortisolism has specific physical changes, although all body systems are affected (see Fig. 65-4 and Chart 65-11). Observe the patient's general appearance. Changes in fat distribution may result in fat pads on the neck, back, and shoulders ("buffalo hump"); an enlarged trunk with thin arms and legs; and a round face ("moon face"). Other changes include muscle wasting and weakness. Assess and document changes, and use these findings to prioritize patient problems and interventions.

Skin changes result from increased blood vessel fragility and include bruises, thin or translucent skin, and wounds that have not healed. Reddish purple **striae** ("stretch marks") occur on the abdomen, thighs, and upper arms because of the destructive effect of cortisol on collagen.

Excessive cortisol secretion causes acne and a fine coating of hair over the face and body. In women, look for the

presence of hirsutism, clitoral hypertrophy, and male pattern balding related to androgen excess.

Cardiac changes occur as a result of altered water and mineral metabolism. Both sodium and water are reabsorbed and retained, leading to hypervolemia and edema formation. Blood pressure is elevated and pulses are full and bounding.

Musculoskeletal changes occur as a result of nitrogen depletion and mineral loss. Muscle mass decreases, especially in arms and legs, which look too small in proportion to the trunk (see Fig. 65-4). Muscle weakness increases the risk for falls. Bone is thinner as a result of mineral loss, and osteoporosis is common, increasing the risk for pathologic fractures.

Glucose metabolism is profoundly affected by hypercortisolism. Fasting blood glucose levels are high because the liver is stimulated to convert more glycogen to glucose and the insulin receptors are less sensitive, so blood glucose does not move as easily into the tissues. In addition, muscle mass loss reduces glucose uptake.

Immune changes caused by excess cortisol result in immunosuppression and an increased risk for infection. Excess cortisol reduces the number of circulating lymphocytes, inhibits macrophage activity, reduces antibody synthesis, and inhibits production of cytokines and inflammatory chemicals (e.g., histamine). These patients not only are at greater risk for infection but also may not have the expected inflammatory manifestations (fever, purulent exudate, redness in the affected area) when an infection is present.

Psychosocial Assessment

Hypercortisolism can result in emotional instability, and patients often say that they do not feel like themselves anymore. Ask about mood swings, irritability, confusion, or depression. Ask the patient whether he or she has been crying or laughing inappropriately or has had difficulty concentrating. Family members often report changes in the patient's mental or emotional status. The patient may have neurotic or psychotic behavior as a result of high blood cortisol levels. In addition, the hormones stimulate the central nervous system, heightening the awareness of and responses to sensory stimulation. The patient often reports sleep difficulties and fatigue.

Laboratory Assessment

Laboratory tests include blood, salivary, and urine cortisol levels. These are high in patients with hypercortisolism regardless of the origin of the disorder. Plasma ACTH levels vary, depending on the cause of the problem. In pituitary Cushing's disease, ACTH levels are elevated. In adrenal Cushing's disease or when Cushing's syndrome results from chronic steroid use, ACTH levels are very low.

Salivary cortisol levels may be used to detect hypercortisolism. This test is accurate in assessing cortisol levels because cortisol-binding proteins are not present in saliva. Usually, salivary cortisol levels are obtained at midnight (Stewart, 2008). Saliva, not spit, is needed for the assay. Saliva is easily and painlessly collected with the use of a salivary specimen cushion placed in the cheek next to the salivary gland. A normal salivary cortisol level is lower than 2.0 ng/mL. Higher levels indicate hypercortisolism.

Urine is tested to measure levels of free cortisol and the metabolites of cortisol and androgens (17-hydroxycorticosteroids and 17-ketosteroids). In Cushing's disease, levels of

urine cortisol and androgens are all elevated in a 24-hour specimen, as are urine calcium, potassium, and glucose levels (Fraser & Van Uum, 2010).

Dexamethasone suppression testing can screen for hypercortisolism and may take place overnight or over a 3-day period. Set doses of dexamethasone are given. A 24-hour urine collection follows drug administration. When urinary 17-hydroxycorticosteroid excretion and cortisol levels are suppressed by dexamethasone, Cushing's disease is not present.

Additional laboratory findings that accompany hypercortisolism include:

- Increased blood glucose level
- Decreased lymphocyte count
- Increased sodium level
- Decreased serum calcium level
- Decreased serum potassium level

Imaging Assessment

Imaging for hypercortisolism includes x-rays, CT scans, MRI, and arteriography. These images can identify lesions of the adrenal or pituitary glands, lung, GI tract, or pancreas.

ANALYSIS

The priority problems for patients with Cushing's disease or Cushing's syndrome are:

1. Fluid overload
2. Risk for Injury related to skin thinning, poor wound healing, and bone density loss
3. Potential for infection
4. Potential for acute adrenal insufficiency

PLANNING AND IMPLEMENTATION

Expected outcomes of hypercortisolism management are the reduction of plasma cortisol levels, removal of tumors, and restoration of normal or acceptable body appearance. When the disorder is caused by pituitary or adrenal problems, cure is possible. When caused by drug therapy for another health problem, the focus is to prevent complications from hypercortisolism.

Restoring Fluid Volume Balance

Planning: Expected Outcomes. The patient with hypercortisolism is expected to achieve and maintain an acceptable fluid balance. Indicators include that these parameters are within or close to the normal range:

- Blood pressure
- Stable body weight
- Serum electrolytes

Interventions. Interventions for patients with fluid overload from hypercortisolism focus on ensuring patient safety, restoring fluid balance, and providing supportive care. Depending on the cause, surgical management may be used to reduce cortisol production.

Nonsurgical Management. Patient safety, drug therapy, nutrition therapy, and monitoring are the basis of nonsurgical interventions for hypercortisolism and fluid overload.

Patient safety includes preventing fluid overload from becoming worse, leading to pulmonary edema and heart failure. Any patient with fluid overload, regardless of age, is at risk for these complications. The older adult or one who has coexisting cardiac problems, kidney problems, pulmonary problems, or liver problems is at greater risk.

Monitor for indicators of increased fluid overload (bounding pulse, increasing neck vein distention, lung crackles, increasing peripheral edema, reduced urine output) at least every 2 hours. *Pulmonary edema can occur very quickly and can lead to death.* Notify the health care provider of any change that indicates fluid overload either is not responding to therapy or is becoming worse.

The patient with fluid overload and dependent edema is at risk for skin breakdown. Use a pressure-reducing or pressure-relieving overlay on the mattress. Assess skin pressure areas, especially the coccyx, elbows, hips, and heels, daily for redness or open areas. Many patients with fluid overload may be receiving oxygen by mask or nasal cannula. Check the skin around the mask, nares, and ears and under the elastic band. Assist the patient to change positions every 2 hours, or ensure that others delegated to perform this intervention are diligent in this action.

Drug therapy involves the use of drugs that interfere with adrenocorticotrophic hormone (ACTH) production or adrenal hormone synthesis for temporary relief. Aminoglutethimide (Elipten, Cytadren) and metyrapone (Metopirone) use different pathways to decrease cortisol production. For patients with hypercortisolism from increased ACTH production, cyproheptadine (Periactin) may be used because it interferes with ACTH production. Mitotane (Lysodren) is an adrenal cytotoxic agent used for inoperable tumors causing hypercortisolism.

Monitor the patient for response to drug therapy, especially weight loss and increased urine output. Observe for manifestations of electrolyte imbalance, especially changes in electrocardiogram (ECG) patterns. Assess laboratory findings, especially sodium and potassium values, every 8 hours or whenever they are drawn.

Nutrition therapy for the patient with hypercortisolism may involve restrictions of both fluid and sodium intake to control fluid volume. Review the patient's serum sodium levels whenever fluid overload is present. Often sodium restriction involves only "no added salt" to ordinary table foods when fluid overload is mild. For more pronounced fluid overload, the patient may be restricted to anywhere from 2 g/day to 4 g/day of sodium. When sodium restriction is ongoing, teach the patient and family how to check food labels for sodium content and how to keep a daily record of sodium ingested. Explain to the patient and family the reason for any fluid restriction and the importance of adhering to the prescribed restriction.

Monitoring intake and output, as well as weight, provides information on therapy effectiveness. Ensure that unlicensed assistive personnel (UAP) understand that these measurements need to be accurate, not just estimated, because treatment decisions are based on these findings. In addition to regulating the total amount of fluid ingested in a 24-hour period, schedule fluid offerings throughout the 24 hours. Teach UAP to check urine for color and character and to report these findings. Check the urine specific gravity (a specific gravity below 1.005 may indicate fluid overload). If IV therapy is used, infuse the exact amount prescribed.

Fluid retention may not be visible. Remember that rapid weight gain is the best indicator of fluid retention and overload. Metabolism can account for no more than a half pound of weight gain in one day. Each pound of weight gained (after the first half pound) equates to 500 mL of retained

water. Weigh the patient at the same time every day (before breakfast), using the same scale. Whenever possible, have the patient wear the same type of clothing for each weigh-in.

Radiation therapy may be used to treat hypercortisolism caused by pituitary adenomas. However, radiation is not always effective and often destroys normal tissue. Observe for any changes in the patient's neurologic status, such as headache, elevated blood pressure or pulse, disorientation, or changes in pupil size or reaction. The patient may have skin dryness, redness, flushing, or alopecia at the radiation site. Review these possible side effects with the patient. [Chapter 47](#) discusses radiation therapy to the head.

Surgical Management. The surgical treatment of adrenocortical hypersecretion depends on the cause of the disease. When adrenal hyperfunction is due to increased pituitary secretion of ACTH, removal of a pituitary adenoma may be attempted. In many instances, a total **hypophysectomy** (surgical removal of the pituitary gland) is needed. Hypophysectomy is performed via the transsphenoidal or transfrontal craniotomy route. (See earlier discussion of hypophysectomy on pp. 1376-1377; see also [Chapter 47](#) for nursing care of patients undergoing a craniotomy.) If hypercortisolism is caused by adrenal tumors, a partial or complete **adrenalectomy** (removal of the adrenal gland) may be needed.

Preoperative Care. Electrolyte imbalances are corrected before surgery. Continue to monitor blood potassium, sodium, and chloride levels. Dysrhythmias from potassium imbalance may occur, and cardiac monitoring is needed. Hyperglycemia is controlled before surgery, and blood glucose levels are monitored.

The patient with hypercortisolism is at risk for complications such as infections and fractures. Prevent infection with handwashing and aseptic technique. Decrease the risk for falls by raising top siderails and encouraging the patient to ask for assistance when getting out of bed. A high-calorie, high-protein diet is prescribed before surgery.

Glucocorticoid preparations are given before surgery. The patient continues to receive glucocorticoids during surgery to prevent adrenal crisis because the removal of the tumor results in a sudden drop in cortisol levels. Before surgery, discuss the care needs for after surgery and the need for long-term drug therapy.

Operative Procedures. A unilateral adrenalectomy is performed when one gland is involved. A bilateral adrenalectomy is needed when ACTH-producing tumors cannot be treated by other means or when both adrenal glands are diseased. Surgery can be abdominal or through the lateral flank. The flank approach is preferred because the abdominal cavity is not entered and complications are reduced. A laparoscopic adrenalectomy, a minimally invasive surgical approach, is increasingly being used and reduces some complications after surgery.

Postoperative Care. After an adrenalectomy, the patient is usually sent to a critical care unit. Immediately after surgery, assess the patient every 15 minutes for shock (e.g., hypotension; a rapid, weak pulse; and a decreasing urine output) due to possible insufficient glucocorticoid replacement. Monitor ongoing vital signs and other hemodynamic variables (central venous pressure, pulmonary wedge pressure), intake and output, daily weights, and serum electrolyte levels.

After a bilateral adrenalectomy, patients require lifelong glucocorticoid and mineralocorticoid replacement, starting

immediately after surgery. In unilateral adrenalectomy, hormone replacement continues until the remaining adrenal gland increases hormone production. This therapy may be needed for up to 2 years after surgery.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which precaution is most important for the nurse to teach a client who is prescribed oral corticosteroids for hormone replacement therapy after a unilateral adrenalectomy?

- A. "Do not stop taking this drug without consulting your prescriber."
- B. "Avoid crowds and people who are ill."
- C. "Be sure to take this drug with food."
- D. "Reduce your salt intake."

Preventing Injury

The patient who has hypercortisolism is at risk for injury from skin breakdown, bone fractures, and GI bleeding. Prevention of these injuries is a major nursing care focus.

Planning: Expected Outcomes. The patient with hypercortisolism is expected to avoid injury. Indicators include:

- Skin is intact.
- Minimal or no bruising is present.
- Bones are intact.
- Stools, vomitus, and other GI secretions contain no gross or occult blood.

Interventions. Priority nursing interventions for prevention of injury focus on skin assessment and protection, coordinating care to ensure gentle handling, and patient teaching regarding drug therapy for prevention of GI ulcers.

Skin injury is a continuing risk for any patient who has hypercortisolism. Even when surgery has corrected the cortisol excess, the changes induced in the skin and blood vessels remain for weeks to months. Assess the skin for reddened areas, excoriation, breakdown, and edema. If mobility is decreased, turn the patient every 2 hours and pad bony prominences.

Instruct the patient to avoid activities that can result in skin trauma. To reduce tissue injury, teach him or her to use a soft toothbrush and an electric shaver. Instruct patients to keep the skin clean and to dry it thoroughly after washing. Excessive dryness can be prevented by using a moisturizing lotion.

Adhesive tape often causes skin breakdown. Use tape sparingly, and use caution when removing it. After venipuncture or arterial puncture, the patient may have increased bleeding because of blood vessel fragility. Exert pressure over the site for longer than normal to prevent bleeding and bruising.

Pathologic fractures from bone density loss and osteoporosis are possible for months to years after cortisol levels return to normal. Teach the patient about safety issues and dietary needs. When helping the patient move in bed, use a lift sheet instead of grasping him or her. Remind the patient to call for help when ambulating. Review the use of walkers or canes, if needed. Keep rooms free of objects that might cause a fall. Teach UAP to use a gait belt when walking with a patient who has bone density loss.

Coordinate with a dietitian to teach the patient about nutrition therapy. A high-calorie diet is prescribed that includes items from all of the major food groups and increased amounts of calcium and vitamin D. Generous amounts of milk, cheese, yogurt, and green leafy and root vegetables add calcium to promote bone density. Advise the patient to avoid caffeine and alcohol, which increase the risk for GI ulcers and may promote bone density loss.

GI bleeding is common with hypercortisolism as a result of systemic changes. Cortisol inhibits production of the thick, gel-like mucus that protects the stomach lining, decreases blood flow to the area, and triggers the release of excess hydrochloric acid. Although surgery reduces the hypercortisolism, the normal protective mucus and increased blood flow may take days to weeks to return. Interventions focus on reducing gastric irritation, usually through drug therapy to protect the GI mucosa and decrease the secretion of hydrochloric acid.

Antacids buffer stomach acids and protect the GI mucosa. Teach the patient that these drugs should be taken on a regular schedule rather than on an as-needed basis.

Some agents block the H₂ receptors in the gastric mucosa. When histamine binds to these receptors, a series of actions release hydrochloric acid. Drugs that block the H₂-receptor site include cimetidine (Tagamet, Peptol , Novo-Cimetine , ranitidine (Zantac, Apo-Ranitidine , famotidine (Pepcid), and nizatidine (Axid). Omeprazole (Losec , Prilosec) and esomeprazole (Nexium) inhibit the gastric proton pump and prevent the formation of hydrochloric acid.

Encourage the patient to reduce or eliminate habits that contribute to gastric irritation, such as consuming alcohol or caffeine, smoking, and fasting. Discuss other prescribed and over-the-counter drugs that he or she may be taking. NSAIDs and drugs that contain aspirin or other salicylates can cause gastritis and intensify GI bleeding.

Preventing Infection

Glucocorticoids reduce both inflammation and the immune responses, increasing the risk for infection. For the patient who is taking glucocorticoid replacement therapy, the risk is ongoing. For the patient who is recovering from surgery to prevent hypercortisolism, the infection risk continues for weeks after surgery.

Planning: Expected Outcomes. The patient with hypercortisolism is expected to remain free from infection and avoid situations that increase the risk for infection. Indicators include these manifestations and behaviors:

- Absence of fever and foul-smelling or purulent drainage
- Absence of cough, chest pain, and dyspnea
- Absence of urinary frequency, urgency, or pain and burning
- Avoids crowds and large gatherings
- Obtains appropriate vaccinations
- Washes hands frequently

Interventions. A major focus in caring for the patient with hypercortisolism is protection from infection. All personnel must use extreme care during all nursing procedures. Thorough handwashing is of the utmost importance. Anyone with an upper respiratory tract infection who must enter the patient's room must wear a mask. Observe strict procedures

when performing dressing changes or any invasive procedure.

Continually assess the patient for possible infection. Manifestations may not be obvious because hypercortisolism suppresses manifestations of infection. Fever and the formation of pus (indicators of infection) depend on the presence of white blood cells (WBCs). The immunosuppressed patient may have a severe infection without pus and with only a low-grade fever.

Monitor the patient's daily complete blood count (CBC) with differential WBC count and absolute neutrophil count (ANC). Inspect the mouth during every shift for lesions and mucosa breakdown. Assess the lungs every 8 hours for crackles, wheezes, or reduced breath sounds. Assess all urine for odor and cloudiness. Ask about any urgency, burning, or pain on urination.

Take vital signs at least every 4 hours to assess for fever. A temperature elevation of even 1° F (or 0.5° C) above baseline is significant for a patient who is immunosuppressed and indicates infection until it has been proved otherwise.

Skin care is important for preventing infection because the skin may be the patient's only intact defense. Teach him or her about hygiene, and urge daily bathing. If the patient is immobile, turn him or her every hour and apply skin lubricants.

Perform pulmonary hygiene every 2 to 4 hours. Listen to the lungs for crackles, wheezes, or reduced breath sounds. Urge the patient to cough and deep breathe or to perform sustained maximum inhalations every hour while awake.

Preventing Acute Adrenal Insufficiency

The patient most at risk for acute adrenal insufficiency is the one who has Cushing's syndrome as a result of glucocorticoid drug therapy. The exogenous drug inhibits the feedback control pathway (see Fig. 64-3 in Chapter 64), preventing the hypothalamus from secreting corticotropin-releasing hormone (CRH). The lack of CRH inhibits secretion of

ACTH from the anterior pituitary gland. Without normal levels of ACTH, the adrenal glands atrophy and completely stop production of any of the corticosteroids. As a result, the patient completely depends on the exogenous drug. If the drug is stopped, even for a day or two, the atrophied adrenal glands cannot produce the glucocorticoids and the patient develops acute adrenal insufficiency, a life-threatening condition. Management of this problem is described on p. 1382.

Community-Based Care

Home Care Management

The patient with hypercortisolism usually has muscle weakness and fatigue for some weeks after surgery and remains at risk for falls and other injury. These problems may necessitate one-floor living for a short time, and a home health aide may be needed to assist with hygiene, meal preparation, and maintenance.

Teaching for Self-Management

The patient taking exogenous glucocorticoids who is discharged to home remains at continuing risk for fluid volume excess. Teach him or her and the family to monitor the patient's weight at home. Verify that the patient understands the relationship between body weight and fluid balance. Suggest that a record of these daily weights be kept to show the health care provider at any checkups. Also, instruct the patient to call the health care provider if he or she gains more than 3 lbs in a week or more than 1 to 2 lbs in a 24-hour period.

Lifelong hormone replacement is needed after bilateral adrenalectomy. Teach the patient and family about adherence to the drug regimen and its side effects (Chart 65-12).

Protecting the patient from infection at home is just as important as it was during hospitalization. Urge him or her to use proper hygiene and to avoid crowds or others with infections. Encourage the patient and all people living in the same home with him or her to have yearly influenza vaccinations. Stress that the patient should immediately notify the

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

The patient is a 45-year-old woman who has recently been diagnosed with a chronic lung inflammation with pulmonary fibrosis. She has been prescribed 45 mg of prednisone daily to slow the progression of this disease and has been adherent to this therapy for the past 12 weeks. She now has a moon face, buffalo hump, acne, thinning scalp hair, and muscle weakness. Today, her blood pressure is elevated and she is being started on an antihypertensive drug, along with an H₂ histamine blocker. Since her last visit, she has gained 18 lbs. She tells you that she feels as though she has aged 20 years in 2 months, and that her appearance changes are "devastating." She is concerned about now having to take two more drugs on a daily basis. She also reveals to you that she did not take her prednisone for 3 days last week hoping that she would lose weight.

1. In what ways does prednisone induce the changes she shows and has described?
2. How should you address the issue of her not taking the prednisone as prescribed?
3. Is her weight gain irreversible while she is taking prednisone? Why or why not?
4. What should you tell her about the newly prescribed drugs?
5. What resources can you suggest to improve her appearance?

CHART 65-12 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Cortisol Replacement Therapy

- Take your medication in divided doses—the first dose in the morning and the second dose between 4 and 6 PM.
- Take your medication with meals or snacks.
- Weigh yourself daily.
- Increase your dosage as directed for increased physical stress or severe emotional stress, including surgery, dental work, influenza, fever, pregnancy, and family problems.
- Never skip a dose of medication. If you have persistent vomiting or severe diarrhea and cannot take your medication by mouth for 24 to 36 hours, call your physician. If you cannot reach your physician, go to the nearest emergency department. You may need an injection to take the place of your usual oral medication.
- Always wear your medical alert bracelet or necklace.
- Make regular visits for health care follow-up.
- Learn how to give yourself an intramuscular injection of hydrocortisone.

health care provider if he or she has a fever or any other sign of infection. [Chart 42-11](#) in [Chapter 42](#) lists guidelines for patients for infection prevention.

Health Care Resources

Immediately after returning home, the patient may need a support person to stay and provide more attention than could be given by a visiting nurse or home care aide. Contact with the health care team is needed for follow-up and identification of potential problems. The patient taking corticosteroid therapy may have manifestations of adrenal insufficiency if the dosage is inadequate. Suggest that the patient obtain and wear a medical alert bracelet listing the condition and the drug replacement therapy.

EVALUATION: OUTCOMES

Evaluate the care of the patient with hypercortisolism based on the identified priority patient problems. The expected outcomes are that the patient should:

- Have an acceptable fluid balance
- Remain free from injury
- Remain free from infection
- Not experience acute adrenal insufficiency

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

HYPERALDOSTERONISM

Pathophysiology

Hyperaldosteronism is an increased secretion of aldosterone with mineralocorticoid excess. Primary hyperaldosteronism (*Conn's syndrome*) results from excessive secretion of aldosterone from one or both adrenal glands, usually caused by a benign adrenal adenoma. In secondary hyperaldosteronism, excessive secretion of aldosterone is caused by high levels of angiotensin II that are stimulated by high plasma renin levels. Causes of high renin levels include kidney hypoxemia and the use of thiazide diuretics.

Increased aldosterone levels affect the kidney tubules and cause sodium retention with potassium and hydrogen ion excretion. Hyponatremia, hypokalemia, and metabolic alkalosis result. Sodium retention increases blood volume, which raises blood pressure but usually does not cause peripheral edema. The elevated blood pressure may cause strokes, heart attacks, and kidney damage. (See [Chapter 13](#) for discussion of electrolyte imbalances.)

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Hypokalemia and elevated blood pressure are the most common problems of the patient with hyperaldosteronism. He or she may have headache, fatigue, muscle weakness, **nocturia** (excessive urination at night), and loss of stamina. **Polydipsia** (excessive fluid intake) and **polyuria** (excessive urine output) occur less frequently. **Paresthesias** (sensations of numbness and tingling) may occur if potassium depletion is severe ([Crawford, & Harris, 2011](#)).

Hyperaldosteronism is diagnosed on the basis of laboratory studies, x-rays, and imaging with CT or MRI. Serum

potassium levels are decreased, and sodium levels are elevated. Plasma renin levels are low, and aldosterone levels are high. Hydrogen ion loss leads to metabolic alkalemia (elevated blood pH). Urine has a low specific gravity and high aldosterone levels.

INTERVENTIONS

Surgery is the most common treatment for early-stage hyperaldosteronism. One or both adrenal glands may be removed. Surgery is not performed, however, until the patient's potassium levels are normal. Drugs used to increase potassium levels include spironolactone (Aldactone, Spiro, Sincomen ) , a potassium-sparing diuretic and aldosterone antagonist. Potassium supplements may be prescribed to increase potassium levels before surgery. The patient may also benefit from a low-sodium diet before surgery, but sodium restriction is not needed after surgery because aldosterone levels return to normal.

The patient who has undergone a unilateral adrenalectomy may need temporary glucocorticoid replacement. Replacement is lifelong if both adrenal glands are removed. Glucocorticoids are given before surgery to prevent adrenal crisis. The patient receiving long-term replacement therapy should wear a medical alert bracelet. (See the discussion of adrenalectomy on pp. 1387-1389 in the Hypercortisolism [Cushing's Disease] section for more discussion of care after surgery and patient education.)

When surgery cannot be performed, spironolactone therapy is continued to control hypokalemia and hypertension. Because spironolactone is a potassium-sparing diuretic, hyperkalemia can occur in patients who have impaired kidney function or excessive potassium intake. Advise the patient to avoid potassium supplements and foods rich in potassium. Hyponatremia can occur with spironolactone therapy, and the patient may need increased dietary sodium. Instruct the patient to report symptoms of hyponatremia, such as dryness of the mouth, thirst, lethargy, or drowsiness. Teach patients to report any additional side effects of spironolactone therapy, including gynecomastia, diarrhea, drowsiness, headache, rash, **urticaria** (hives), confusion, erectile dysfunction, hirsutism, and amenorrhea.

PHEOCHROMOCYTOMA

Pathophysiology

Pheochromocytoma is a catecholamine-producing tumor that arises in the adrenal medulla. These tumors usually occur as a single lesion in one adrenal gland, although they can be bilateral or in the abdomen. Pheochromocytomas are usually benign, but at least 10% are malignant ([Young, 2008](#)).

The tumors produce, store, and release epinephrine and norepinephrine (NE). Excessive epinephrine and NE stimulate adrenergic receptors and can have wide-ranging adverse effects mimicking the action of the sympathetic division of the autonomic nervous system.

The cause is unknown, but some pheochromocytomas occur with inherited disorders such as neurofibromatosis (type 1), multiple endocrine neoplasia (MEN-2), Von Hippel-Lindau disease, and pheochromocytoma-paraganglioma syndrome ([Cook, 2009](#)). These tumors are rare and occur slightly more often in women. They can occur at any age but appear most commonly in patients between 40 and 60 years of age.

**PATIENT-CENTERED
COLLABORATIVE CARE****ASSESSMENT**

The patient often has intermittent episodes of hypertension or attacks that range from a few minutes to several hours. During these episodes, the patient has severe headaches, palpitations, profuse diaphoresis, flushing, apprehension, or a sense of impending doom. Pain in the chest or abdomen, with nausea and vomiting, can also occur. Increased abdominal pressure, defecation, and vigorous abdominal palpation can provoke a hypertensive crisis. Drugs such as tricyclic antidepressants, droperidol, glucagon, metoclopramide, phenothiazines, and naloxone can induce a hypertensive crisis in the patient with pheochromocytoma. Foods or beverages high in tyramine (e.g., aged cheese, red wine) also induce hypertension. The patient may also report heat intolerance, weight loss, and tremors.

The most common diagnostic test is a 24-hour urine collection for vanillylmandelic acid (VMA) (a product of catecholamine metabolism), metanephrine, and catecholamines, all of which are elevated in the presence of a pheochromocytoma. Other tests that may be conducted when catecholamine levels are not consistent include the clonidine suppression test and, rarely, stimulation testing. MRI or CT scans can precisely locate tumors in the adrenal gland. After diagnosis, CT scans of the chest and abdomen may be used to locate any other tumors.

INTERVENTIONS

Surgery is the main treatment for a pheochromocytoma. One or both adrenal glands are removed (depending on whether the tumor is bilateral). After surgery, nursing interventions focus on promoting adequate tissue perfusion, nutritional needs, and comfort measures.

Hypertension is the hallmark of the disease and the most common serious complication after surgery (Daub, 2008). Monitor the blood pressure regularly, and place the cuff consistently on the same arm, with the patient in lying and standing positions. Identify stressors that may lead to a hypertensive crisis, and attempt to reduce them. Teach the patient to not smoke, drink caffeine-containing beverages, or change position suddenly. Provide a diet rich in calories, vitamins, and minerals.

! NURSING SAFETY PRIORITY**Action Alert**

Do not palpate the abdomen of a patient with a pheochromocytoma, because this action could stimulate a sudden release of catecholamines and trigger severe hypertension.

The patient often benefits from hydration before surgery because decreased blood volume increases the risk for hypotension during and after surgery. Assess the patient's hydration status, and report manifestations of dehydration or fluid overload.

Provide a calm, restful environment for the patient who has a severe headache. Instruct the patient to limit activity. A private, darkened room helps promote rest. If the patient is sleeping, avoid interruptions if possible.

The patient's blood pressure is stabilized with adrenergic blocking agents such as phenoxybenzamine (Dibenzylin) starting several weeks before surgery because of the increased risk for severe hypertension during surgery (Tsegay et al., 2008). The drug dosages are adjusted for 2 to 3 weeks before surgery until blood pressure is controlled and hypertensive attacks do not occur. The blood volume expands, and blood pressure in the supine position returns to normal.

Anesthetic agents and touching of the tumor during surgery can cause a catecholamine release. Short-acting alpha-adrenergic blockers are given by IV bolus or continuous infusion for a hypertensive crisis.

Nursing care after surgery is similar to that for the patient who has undergone an adrenalectomy (see Hypercortisolism [Cushing's Disease], pp. 1387-1389). Closely monitor the patient for hypertension and for hypotension (from the sudden decrease in catecholamine levels) and for hypovolemia. Hemorrhage and shock are possible, and plasma expanders or fluids may be needed. Monitor vital signs, as well as fluid intake and output. If opioids are given, check for their effect on blood pressure.

Tumors may be inoperable because of the patient's other medical conditions. Management then is medical, with alpha-adrenergic and beta-adrenergic blocking agents, because the tumors do not respond well to chemotherapy or radiation therapy. For these patients, self-measurement of blood pressure with home monitoring equipment is essential. (See Chapter 38 for teaching priorities and community-based care of the patient with chronic hypertension.)

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Handle all patients with bone density loss carefully, using lift sheets whenever possible.
- Use good handwashing techniques before providing any care to a patient who is immunosuppressed.

Health Promotion and Maintenance

- Instruct the patient with adrenal insufficiency to wear a medical alert bracelet and to carry simple carbohydrates with them at all times.
- Teach the patient and family about the clinical manifestations of infection and when to seek medical advice.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Teach patients who have permanent endocrine hypofunction the proper techniques and timing of hormone replacement therapy.
- Teach patients with diabetes insipidus the proper way to self-administer desmopressin orally or by nasal spray.

Psychosocial Integrity

- Encourage the patient and family to express concerns about a change in health status.
- Explain all treatment procedures, restrictions, and follow-up care to the patient.
- Allow patients who experience a change in physical appearance to mourn this change.

Physiological Integrity

- Ensure that hormone replacement drugs are given as close to the prescribed times as possible.

- Use Infection Precautions for patients who are immunosuppressed.
- During the immediate period after a transsphenoidal or an endoscopic nasal hypophysectomy, teach the patient to avoid activities that increase intracranial pressure (e.g., bending at the waist, straining to have a bowel movement, coughing).
- Measure intake and output accurately on patients who have either diabetes insipidus or syndrome of inappropriate antidiuretic hormone (SIADH).
- Teach the patient with diabetes insipidus the manifestations of dehydration.
- Do not palpate the abdomen of a patient who has a pheochromocytoma.

Care of Patients with Problems of the Thyroid and Parathyroid Glands

Concept Map Creator

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Adjust the environment for the patient with severe hypothyroidism or thyrotoxicosis.
2. Ensure the availability of suction and emergency intubation equipment for anyone who has thyroid or parathyroid surgery.
3. Prevent injury in the patient who has bone density loss or hypocalcemia.

Health Promotion and Maintenance

4. Teach patients taking thyroid hormone inhibitors the correct timing of therapy, side effects, adverse effects, and when to seek medical assistance.

Psychosocial Integrity

5. Be accepting of patient behavior and changes in appearance.

6. Inform patients and family members that changes in cognition and behavior resulting from thyroid problems are usually temporary.

Physiological Integrity

7. Compare the clinical manifestations of hyperthyroidism with those of hypothyroidism.
8. Interpret clinical changes and laboratory data to determine the effectiveness of interventions for thyroid problems.
9. Coordinate nursing care for the patient during the first 24 hours after thyroid or parathyroid surgery.
10. Identify teaching priorities for the patient taking thyroid hormone replacement therapy.
11. Compare the clinical manifestations of hyperparathyroidism with those of hypoparathyroidism.

The thyroid and parathyroid glands secrete hormones that affect overall metabolism, electrolyte balance, and excitable membrane activity. Thus problems of either gland usually have widespread effects and manifestations. Mild disturbances produce subtle problems. More severe disturbances may produce life-threatening problems.

THYROID DISORDERS

HYPERTHYROIDISM

Pathophysiology

Hyperthyroidism is excessive thyroid hormone secretion from the thyroid gland. The manifestations of hyper-

thyroidism are called **thyrotoxicosis**, regardless of the origin of the thyroid hormones (Davies & Larsen, 2008). (For example, a person who takes a large amount of synthetic thyroid hormones can have thyrotoxicosis but does not have hyperthyroidism.) Thyroid hormones increase metabolism in all body organs, and excesses produce many different manifestations. Hyperthyroidism can be temporary or permanent, depending on the cause.

In hyperthyroidism the excessive thyroid hormones stimulate most body systems, causing hypermetabolism and increased sympathetic nervous system activity. Many of the manifestations are caused by the body's response to the demands of hypermetabolism (Chart 66-1).

Thyroid hormones stimulate the heart, increasing both heart rate and stroke volume. These responses increase

CHART 66-1 KEY FEATURES

Hyperthyroidism**Skin Manifestations**

- Diaphoresis (excessive sweating)
- Fine, soft, silky body hair
- Smooth, warm, moist skin
- Thinning of scalp hair

Pulmonary Manifestations

- Shortness of breath with or without exertion
- Rapid, shallow respirations
- Decreased vital capacity

Cardiovascular Manifestations

- Palpitations
- Chest pain
- Increased systolic blood pressure
- Widened pulse pressure
- Tachycardia
- Dysrhythmias

Gastrointestinal Manifestations

- Weight loss
- Increased appetite
- Increased stools
- Hypoproteinemia

Musculoskeletal Manifestations

- Muscle weakness
- Muscle wasting

Neurologic Manifestations

- Blurred or double vision
- Eye fatigue
- Corneal ulcers or infections
- Increased tears
- Injected (red) conjunctiva
- Photophobia
- Eyelid retraction, eyelid lag*
- Globe lag*
- Hyperactive deep tendon reflexes
- Tremors
- Insomnia

Metabolic Manifestations

- Increased basal metabolic rate
- Heat intolerance
- Low-grade fever
- Fatigue

Psychological/Emotional Manifestations

- Decreased attention span
- Restlessness
- Irritability
- Emotional lability
- Manic behavior

Reproductive Manifestations

- Amenorrhea
- Decreased menstrual flow
- Increased libido

Other Manifestations

- Goiter
- Wide-eyed or startled appearance (exophthalmos)*
- Decreased total white blood cell count
- Enlarged spleen

*Present in Graves' disease only.

cardiac output, systolic blood pressure, and blood flow (Burton, 2011).

Elevated thyroid hormone levels affect protein, lipid, and carbohydrate metabolism. Protein **synthesis** (buildup) and **degradation** (breakdown) are increased, but breakdown exceeds buildup, causing a net loss of body protein known as a **negative nitrogen balance**. Glucose tolerance is decreased, and the patient has **hyperglycemia** (elevated blood glucose levels). Fat metabolism is increased, and body fat decreases. Although the patient has an increased appetite, the increased metabolism causes weight loss and nutritional deficiency.

Thyroid hormones are produced in response to the stimulation hormones secreted by the hypothalamus and anterior pituitary glands. Thus oversecretion of thyroid hormones changes the secretion of hormones from the hypothalamus and anterior pituitary gland through negative feedback (see Chapter 64). Thyroid hormones also have some influence over sex hormone production in both men and women. Women have menstrual problems and decreased fertility.

Both men and women with hyperthyroidism have an increased **libido** (sexual urge or interest).

Etiology and Genetic Risk

Hyperthyroidism has many causes, the most common of which is Graves' disease, also called *toxic diffuse goiter*. **Graves' disease** is an autoimmune disorder in which antibodies (thyroid-stimulating immunoglobulins [TSIs]) are made and attach to the thyroid-stimulating hormone (TSH) receptors on the thyroid tissue. The thyroid gland responds by increasing the number and size of glandular cells, which enlarges the gland, forming a **goiter**, and overproduces thyroid hormones (thyrotoxicosis). Other manifestations specific to Graves' disease include **exophthalmos** (abnormal protrusion of the eyes) and **pretibial myxedema** (dry, waxy swelling of the front surfaces of the lower legs). *Not all patients with a goiter have hyperthyroidism.*

Hyperthyroidism caused by multiple thyroid nodules is termed **toxic multinodular goiter**. The nodules may be enlarged thyroid tissues or benign tumors (adenomas). These patients usually have had a goiter for years. The overproduction of thyroid hormones is milder than that seen in Graves' disease, and the patient does not have exophthalmos or pretibial edema.

Hyperthyroidism also can be caused by excessive use of thyroid replacement hormones. This type of problem is called **exogenous hyperthyroidism**.

GENETIC/GENOMIC CONSIDERATIONS

Graves' disease has a strong association with other autoimmune disorders, such as diabetes mellitus, vitiligo, and rheumatoid arthritis. It often occurs in both members of identical twins, with an inheritance pattern of familial clustering or complex, which suggests a polygenic gene-environmental interaction (Nussbaum et al., 2007).

Incidence/Prevalence

Hyperthyroidism is a common endocrine disorder. Graves' disease can occur at any age but is diagnosed most often in women between 20 and 40 years of age, affecting women about ten times more often than men (Davies & Larsen, 2008). Toxic multinodular goiter usually occurs after the age of 50 and affects women four times more often than men (McCance et al, 2010).

PATIENT-CENTERED COLLABORATIVE CARE**ASSESSMENT****History**

The patient may have noticed many changes and problems because hyperthyroidism affects all body systems, although changes may occur over such a long period that not all patients are aware of them. Record age, gender, and usual weight. The patient may report a recent unplanned weight loss, an increased appetite, and an increase in the number of bowel movements per day.

A hallmark of hyperthyroidism is heat intolerance. The patient may have **diaphoresis** (increased sweating) even when environmental temperatures are comfortable for others. He or she often wears lighter clothing in cold weather. The patient

FIG. 66-1 Exophthalmos.

may also report palpitations or chest pain as a result of the cardiovascular effects. Ask about changes in breathing patterns, because dyspnea (with or without exertion) is common.

Visual changes may be the earliest problem the patient notices, especially exophthalmos with Graves' disease (Fig. 66-1). Ask about changes in vision, such as blurring or double vision and tiring of the eyes.

Ask whether he or she has noticed a change in energy level or in the ability to perform ADLs. Fatigue, weakness, and insomnia are common. Family and friends may report that the patient has become irritable or depressed.

Ask women about changes in menses, because amenorrhea or a decreased menstrual flow is common. Initially, both men and women may have an increase in libido, but this changes as the patient becomes more fatigued.

Explore the patient's medical history. Information about previous thyroid surgery or radiation therapy to the neck is important to obtain because some people remain hyperthyroid after surgery or are resistant to radiation therapy. Ask about past and current drugs, especially the use of thyroid hormone replacement or antithyroid drugs.

Physical Assessment/Clinical Manifestations

Exophthalmos is common in patients with Graves' disease. The wide-eyed or "startled" look is due to edema in the extraocular muscles and increased fatty tissue behind the eye, which pushes the eyeball forward. Pressure on the optic nerve may impair vision. Swelling and shortening of the muscles may cause problems with focusing. If the eyelid fails to close completely and the eye is unprotected, the eye may become overly dry and develop corneal ulcers or infection. Observe the patient's eyes for excessive tearing and a bloodshot appearance, and ask about sensitivity to light (**photophobia**).

Observe the patient's general appearance. In addition to the exophthalmos of Graves' disease, two other eye problems are common in all types of hyperthyroidism: eyelid retraction (eyelid lag) and globe (eyeball) lag. In eyelid lag, the upper eyelid fails to descend when the patient gazes slowly

FIG. 66-2 Goiter.

TABLE 66-1 GOITER CLASSIFICATION

GOITER GRADE	DESCRIPTION
0	No palpable or visible goiter.
1	Mass is not visible with neck in the normal position. Goiter can be palpated and moves up when the patient swallows.
2	Mass is visible as swelling when the neck is in the normal position. Goiter is easily palpated and is usually asymmetric.

downward. In globe lag, the upper eyelid pulls back faster than the eyeball when the patient gazes upward. During assessment, ask the patient to look down and then up, and document the response.

Observe the size and symmetry of the thyroid gland. Palpate the thyroid gland to assess the presence of a mass or general enlargement. In goiter, a generalized thyroid enlargement, the thyroid gland may increase to four times its normal size (Fig. 66-2). Goiters are common in Graves' disease and are classified by size (Table 66-1). **Bruits** (turbulence from increased blood flow) may be heard in the neck with a stethoscope. (See Chapter 64 for thyroid palpation and auscultation.)

The cardiovascular problems of hyperthyroidism include increased systolic blood pressure, tachycardia, and dysrhythmias. Usually the diastolic pressure is decreased, causing a widened pulse pressure.

Inspect the hair and skin. Fine, soft, silky hair and smooth, warm, moist skin are common. Muscle weakness and hyperactive deep tendon reflexes are common. Observe motor movements of the hands for tremors. The patient may appear restless, irritable, and fatigued.

Psychosocial Assessment

The patient with hyperthyroidism often has wide mood swings, irritability, decreased attention span, and manic behavior. Hyperactivity often leads to fatigue because of the inability to sleep well. Some patients describe their activity as

having two modes—either “full speed ahead” or “completely stopped.” Ask whether he or she cries or laughs without cause or has difficulty concentrating. Family members often report a change in the patient’s mental or emotional status.

Laboratory Assessment

Testing for hyperthyroidism involves measurement of blood values for triiodothyronine (T_3), thyroxine (T_4), T_3 resin uptake (T_3RU), and thyroid-stimulating hormone (TSH). Antibodies to TSH (TSH-RAb) are measured to diagnose Graves’ disease. The most common changes in laboratory tests for Graves’ disease and other forms of hyperthyroidism are listed in Chart 66-2.

Other Diagnostic Assessment

Thyroid scan evaluates the position, size, and functioning of the thyroid gland. Radioactive iodine (RAI [^{123}I]) is given by mouth, and the uptake of iodine by the thyroid gland (radioactive iodine uptake [RAIU]) is measured. The half-life of ^{123}I is short, and radiation precautions are not needed. Pregnancy should be ruled out before the scan is performed. The normal thyroid gland has an uptake of 5% to 35% of the given dose at 24 hours. RAIU is increased in hyperthyroidism.

Assess whether the patient has undergone procedures or has taken drugs that might affect the results of the scan. Procedures that use iodine-containing dye (e.g., renography) should not be performed for at least 4 weeks before a thyroid scan is done. Any drug that contains iodine should be discontinued for 1 week before the scan.

Ultrasonography of the thyroid gland can determine its size and the general composition of any masses or nodules. This

procedure takes about 30 minutes to perform and is painless.

Electrocardiography (ECG) usually shows tachycardia. Other ECG changes with hyperthyroidism include atrial fibrillation, dysrhythmias, and changes in P and T waveforms.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Why is a goiter often present in clients who have Graves’ disease?

- The low circulating levels of thyroid hormones stimulate the feedback system and trigger the anterior pituitary gland to secrete more thyroid-stimulating hormone, which increases the numbers and size of glandular cells in the thyroid gland.
- The autoantibodies stimulate the inflammatory and immune responses to increase the number of white blood cells circulating in the thyroid gland, which increases tissue size without increasing the number of glandular cells.
- The excessive autoantibodies bind to the thyroid hormone receptor sites, which increases the number and size of glandular cells in the thyroid gland.
- The autoantibodies stimulate blood vessel growth and blood storage within the thyroid gland, increasing its overall size.

INTERVENTIONS

Because Graves’ disease is the most common form of hyperthyroidism, the interventions discussed in the following sections include those specific for the problems that occur with Graves’ disease. The purposes of medical management are to decrease the effect of thyroid hormone on cardiac function

CHART 66-2 LABORATORY PROFILE

Thyroid Function

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS	
		HYPERTHYROIDISM	HYPOTHYROIDISM
Serum T_3	70-205 ng/dL, or 1.2-3.4 SI units	Increased	Decreased
Serum T_4	4-12 mcg/dL, or 51-154 SI units	Increased	Decreased
Free T_4 index	0.8-2.4 ng/dL, or 10-31 SI units	Increased	Decreased
T_3 resin uptake	24%-34% (varies with different laboratories)	Increased	Decreased
TRH stimulation test	Doubling of baseline TSH 30 min after IV injection of 500 mcg TRH (women have greater response)	Little or no TSH response	Delayed or poor TSH response in secondary hypothyroidism (pituitary failure) Elevated two or more times the normal in primary hypothyroidism (thyroid gland failure)
Thyroid suppression test	N/A	Fails to suppress RAIU or T_4 levels	No change in RAIU or T_4 levels
TSH stimulation test (thyroid stimulation test)	>10% in RAIU or >1.5 mcg/dL	N/A (test differentiates primary from secondary hypothyroidism)	No response in primary hypothyroidism Normal response in secondary hypothyroidism
Thyroid antibodies (antithyroglobulin antibody)	Titer <1:100	High titer of antithyroglobulin antibodies	Increased titers
Thyrotropin receptor antibodies (TSH-RAb)	Titer <130% of basal activity	High titers indicate Graves’ disease	No response
TSH	0.3-5.0 μ U/mL or 0.3-5.0 SI units.	Low in Graves’ disease High in secondary or tertiary hyperthyroidism	High in primary disease Low in secondary or tertiary disease

N/A, Not applicable; RAIU, radioactive iodine uptake; SI, International System of Units; T_3 , triiodothyronine; T_4 , thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

and to reduce thyroid hormone secretion. The priorities for nursing care focus on monitoring for complications, reducing stimulation, promoting comfort, and teaching the patient and family about therapeutic drugs and procedures.

Nonsurgical Management

Monitoring includes measuring the patient's apical pulse, blood pressure (BP), and temperature at least every 4 hours. Instruct the patient to report immediately any palpitations, dyspnea, vertigo, or chest pain. Increases in temperature may indicate a rapid worsening of the patient's condition and the onset of **thyroid storm**, a life-threatening event that occurs with uncontrolled hyperthyroidism and is characterized by high fever and severe hypertension. *Immediately report a temperature increase of even one degree Fahrenheit.* If this task is delegated to unlicensed assistive personnel (UAP), instruct them to report the patient's temperature to you as soon as it has been obtained. If a temperature elevation is reported, immediately assess the patient's cardiac status. If the patient has a cardiac monitor, check for dysrhythmias.

Reducing stimulation is important because a noisy or stressful environment can increase the manifestations of hyperthyroidism and increase the risk for cardiac complications. Encourage the patient to rest. Keep the environment as quiet as possible by closing the door to his or her room, limiting visitors, and eliminating or postponing nonessential care or treatments.

Promoting comfort can be accomplished through actions such as reducing the room temperature to decrease discomfort caused by heat intolerance. Instruct UAP to ensure the patient always has a fresh pitcher of ice water and to change the bed linen whenever it becomes damp from diaphoresis. Suggest that the patient take a cool shower several times each day. If showering is not possible, cool sponge baths may increase comfort. Prevent eye dryness in patients with exophthalmos by encouraging the use of artificial tears and by taping the eyelids closed for sleep.

Drug therapy with antithyroid drugs is the initial treatment of hyperthyroidism. **Chart 66-3** lists teaching priorities for the patient receiving drug therapy for hyperthyroidism. The preferred drugs are the thionamides, which include propylthiouracil (PTU) and methimazole (Tapazole). These drugs block thyroid hormone production by preventing iodide binding in the thyroid gland (see **Chart 66-3**). In addition, PTU also prevents T_4 from being converted to the more powerful T_3 in the tissues. Methimazole doses are lower than PTU doses. The response to these drugs is delayed because the patient may have large amounts of stored thyroid hormones that continue to be released.

! NURSING SAFETY PRIORITY

Drug Alert

Both propylthiouracil and methimazole are effective but dangerous drugs. Propylthiouracil now has a black box warning because it is associated with an incidence of serious liver injury and liver failure. Methimazole can cause birth defects. The Food and Drug Administration recommends that unless a patient is pregnant or is allergic to methimazole, propylthiouracil should be avoided. Assess any patient taking propylthiouracil for manifestations of liver problems (e.g., yellowing of the sclera and skin, dark urine, clay-colored stools, elevated liver enzymes) (Aschenbrenner, 2009).

Iodine preparations may be used for short-term therapy before surgery. They decrease blood flow through the thyroid gland, reducing the production and release of thyroid hormone. Improvement usually occurs within 2 weeks, but it may be weeks before metabolism returns to normal. This treatment can result in hypothyroidism, and the patient is monitored closely for the need to adjust the drug regimen.

Lithium also inhibits thyroid hormone release. However, its use is limited because of side effects such as depression, diabetes insipidus, tremors, nausea, and vomiting. Lithium may be used for a patient who cannot tolerate other antithyroid drugs.

Beta-adrenergic blocking drugs, such as propranolol (Inderal, Detensol ) may be used as supportive therapy. These drugs relieve diaphoresis, anxiety, tachycardia, and palpitations but do not inhibit thyroid hormone production. See **Chapters 36 and 40** for a discussion of the actions and nursing implications of these agents.

Radioactive iodine (RAI) therapy is not used in pregnant women because ^{131}I crosses the placenta and can damage the fetal thyroid gland. The patient with hyperthyroidism may receive RAI in the form of oral ^{131}I . The dosage depends on the thyroid gland's size and sensitivity to radiation. The thyroid gland picks up the RAI, and some of the cells that produce thyroid hormone are destroyed by the local radiation. Because the thyroid gland stores thyroid hormones to some degree, the patient may not have complete symptom relief until 6 to 8 weeks after RAI therapy. Additional drug therapy for hyperthyroidism is still needed during the first few weeks after RAI treatment.

RAI therapy is performed on an outpatient basis. One dose may be sufficient, although some patients need a second or third dose. The radiation dose is low and is usually completely eliminated within a month; however, the source is unsealed, and some radioactivity is present in the patient's body fluids and stool for a few weeks after therapy (Al-Shakhray, 2008). Radiation precautions are needed to prevent exposure to family members and other people. **Chart 66-4** lists precautions to teach the patient during the first few weeks after receiving ^{131}I .

The degree of thyroid destruction varies. Some patients become hypothyroid as a result of treatment. This problem may occur within a few weeks, or it may take several years to develop. The patient then needs lifelong thyroid hormone replacement. All patients who have undergone RAI therapy should be monitored regularly for changes in thyroid function.

Surgical Management

Antithyroid drugs and RAI therapy are now the most common treatments for patients with hyperthyroidism. Surgery to remove all or part of the thyroid gland may be needed for patients who have a large goiter causing tracheal or esophageal compression or who do not have a good response to antithyroid drugs. Removal of all (**total thyroidectomy**) or part (**subtotal thyroidectomy**) of the thyroid tissue decreases the production of thyroid hormones. After a total thyroidectomy, patients must take lifelong thyroid hormone replacement.

Preoperative Care. If possible, the patient is treated with drug therapy first to have near-normal thyroid function (**euthyroid**) before thyroid surgery. This state is achieved

Hyperthyroidism

DRUG/USUAL DOSAGE	PURPOSE/ACTION	NURSING INTERVENTION	RATIONALE
For Treatment of Mild to Moderate Hyperthyroidism			
Propylthiouracil (PTU, Propyl-Thyracil ) Initial dose 100-150 mg orally every 8 hr Maintenance dose 50-150 mg orally every 8 hr	Reduces manifestations of hyperthyroidism by preventing the new formation of thyroid hormones by inhibiting thyroid binding of iodide and by preventing the conversion of T ₄ to T ₃ in the tissues.	Teach patient to take the drug every 8 hr. Teach patient to avoid crowds and people who are ill. Teach patient to report darkening of the urine, a yellow appearance to the skin or whites of the eyes, and an increased tendency to bruise or bleed. Teach patient to check for weight gain, slow heart rate, and cold intolerance.	Taking the drug evenly throughout the day results in better drug action. Drug reduces blood cell counts and the immune response, increasing the risk for infection. These manifestations may indicate liver toxicity or failure, a possible side effect of the drug. These indicate hypothyroidism and may require a lower drug dose.
Methimazole (Northyx, Tapazole) Initial dose 5-20 mg orally every 8 hr Maintenance dose 1-4 mg orally every 8 hr	Reduces manifestations of hyperthyroidism by preventing the new formation of thyroid hormones by inhibiting thyroid binding of iodide.	Teach patient to take the drug every 8 hr. Remind women to notify their health care providers if they become pregnant. Teach patient to avoid crowds and people who are ill. Teach patient to check for weight gain, slow heart rate, and cold intolerance. Teach patient about the possibility of muscle and joint pain.	Taking the drug evenly throughout the day results in better drug action. This drug causes birth defects and should not be used during pregnancy. Drug reduces blood cell counts and the immune response, increasing the risk for infection. These indicate hypothyroidism and may require a lower drug dose. Knowing the side effects to expect reduces anxiety.
Lithium carbonate (Eskalith, Lithobid, Lithonate) 300 mg orally every 8 hr	Reduces the manifestations of hyperthyroidism by inhibiting the release of thyroid hormones (temporarily). Used only when the patient cannot take a thionamide.	Teach patient to take the drug every 8 hr. Teach patient to drink at least 3 to 4 quarts of fluids daily. Teach patient to check for weight gain, slow heart rate, and cold intolerance.	Taking the drug evenly throughout the day results in better drug action. Drug increases urine output and can cause dehydration. These indicate hypothyroidism and may require a lower drug dose.
For Initial Treatment of Severe Hyperthyroidism or Thyrotoxicosis			
Iodine and iodine-containing agents: Lugol's solution Saturated solution of potassium iodide (SSKI) Dosages vary depending on the agent, how the drug is administered, and the severity of the manifestations	The sudden excess of iodine rapidly inhibits thyroid hormone release and dramatically (but temporarily) resolves the cardiac and other manifestations of hyperthyroidism. These agents are not recommended for long-term therapy.	Administer these drugs 1 hour <i>after</i> a thionamide has been given. Check patient for a fever or rash, and ask about a metallic taste, mouth sores, sore throat, or GI distress.	Initially, the iodine agents can cause an increase in the production of thyroid hormones. Giving a thionamide first prevents this initial increase in thyroid hormone production. These are manifestations of <i>iodism</i> , a toxic effect of the drugs, and may require that the drug be discontinued.

CHART 66-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Safety Precautions for the Patient Receiving an Unsealed Radioactive Isotope

- Use a toilet that is not used by others for least 2 weeks after receiving the radioactive iodine.
- Sit to urinate (males and females) to avoid splashing the seat, walls, and floor.
- Flush the toilet three times after each use.
- If urine is spilled on the toilet seat or floor, use paper tissues or towels to clean it up, bag them in sealable plastic bags, and take them to the hospital's radiation therapy department.
- Men with urinary incontinence should use condom catheters and a drainage bag rather than absorbent gel-filled briefs or pads.
- Women with urinary incontinence should use facial tissue layers in their clothing to catch the urine rather than absorbent gel-filled briefs or pads.
- Using a laxative on the second and third days after receiving the radioactive drug helps you excrete the contaminated stool faster (this also decreases the exposure of your abdominal organs to radiation).
- Wear only machine-washable clothing, and wash these items separately from others in your household.
- After washing your clothing, run the washing machine for a full cycle on empty before it is used to wash the clothing of others.
- Avoid close contact with pregnant women, infants, and young children for the first week after therapy. Remain at least 3 feet (about 1 meter) away from these people, and limit your exposure to them to no more than 1 hour daily.
- Some radioactivity will be in your saliva during the first week after therapy. Precautions to avoid exposing others to this contamination (both household members and trash collectors) include:
 - Not sharing toothbrushes or toothpaste tubes
 - Using disposable tissues, rather than cloth handkerchiefs, and either flushing used ones down the toilet or keeping them in a plastic bag and turning them in to the radiation department of the hospital for disposal
 - Use disposable utensils, plates, and cups
 - Selecting foods that can be eaten completely and do not result in a saliva-coated remnant (Foods to avoid are fruit with a core that can be contaminated, meat with a bone [e.g., chicken wings or legs, ribs])

with antithyroid drugs that decrease the secretion of thyroid hormones. In addition, iodine preparations are used to decrease thyroid size and vascularity, thereby reducing the risk for hemorrhage and the potential for thyroid storm during surgery.

Hypertension, dysrhythmias, and tachycardia must be controlled before surgery. The patient with hyperthyroidism is often not at an optimal weight and may need to follow a high-protein, high-carbohydrate diet for days or weeks before surgery.

Teach the patient to perform coughing and deep-breathing exercises. Stress the importance of supporting the neck when coughing or moving by placing both hands behind the neck. This action reduces the strain on the suture line. Explain that hoarseness may be present for a few days as a result of endotracheal tube placement during surgery.

Patients often fear thyroid surgery, perhaps because the incision is on the neck. Reassure the patient by calmly explaining the surgery and the care after surgery. Remind him or her that a drain as well as a dressing may be in place after surgery. Answer any questions the patient and family have.

Operative Procedures. A thyroidectomy is performed with the patient under general anesthesia. In the traditional open approach, the patient's neck is extended and the surgeon makes a "collar" incision just above the clavicle. The surgeon attempts to avoid the parathyroid glands and recurrent laryngeal nerves to reduce the risk for complications and injury. Minimally invasive video-assisted thyroidectomy is being used for some patients (Snissarenko et al., 2009).

With a subtotal thyroidectomy, the remaining thyroid tissues are sutured to the trachea. With a total thyroidectomy, the entire thyroid gland is removed but the parathyroid glands are left with an intact blood supply to prevent causing hypoparathyroidism.

Postoperative Care. Monitoring the patient for complications is the most important nursing action after thyroid surgery. Monitor vital signs every 15 minutes until the patient is stable and then every 30 minutes for 24 hours. Increase or decrease the monitoring of vital signs based on changes in the patient's condition.

Assess the patient's level of discomfort. Use sandbags or pillows to support the head and neck. Place the patient, while he or she is awake, in a semi-Fowler's position. When positioning the patient, decrease tension on the suture line by avoiding neck extension. Give prescribed drugs for pain control as needed.

Humidifying the air promotes easier respiration and thins respiratory secretions. Assist the patient to cough and deep-breathe every 30 minutes to 1 hour. Suction oral and tracheal secretions when necessary.

Thyroid surgery can cause hemorrhage, respiratory distress, parathyroid gland injury (resulting in **hypocalcemia** [low serum calcium levels] and **tetany** [hyperexcitability of nerves and muscles]), damage to the laryngeal nerves, and thyroid storm. Remain alert to the potential for complications, and identify manifestations early.

Hemorrhage is most likely to occur during the first 24 hours after surgery. Inspect the neck dressing and behind the patient's neck for blood. A drain may be present, and a moderate amount of serosanguineous drainage is normal. Hemorrhage may be seen as bleeding at the incision site or as respiratory distress caused by tracheal compression.

Respiratory distress can result from swelling, tetany, or damage to the laryngeal nerve resulting in spasms. Laryngeal **stridor** (harsh, high-pitched respiratory sounds) is heard in acute respiratory obstruction. Keep emergency tracheostomy equipment in the patient's room. Check that oxygen and suctioning equipment are nearby and in working order.

! NURSING SAFETY PRIORITY

Critical Rescue

When stridor, dyspnea, or other symptoms of obstruction appear after thyroid surgery, notify the Rapid Response Team. In some agencies, nurses can remove clips or sutures when medical assistance is not immediately available and swelling at the surgical site is obstructing the airway.

Hypocalcemia and tetany may occur if the parathyroid glands are removed, damaged or their blood supply is impaired during thyroid surgery, resulting in decreased parathyroid hormone (PTH) levels. Ask the patient hourly about tingling around the mouth or of the toes and fingers. Assess for muscle twitching as a sign of calcium deficiency. Calcium gluconate or calcium chloride for IV use should be available in an emergency situation. (For information on the later signs of hypocalcemia, see the discussion of postoperative care on p. 1407 in the Hyperparathyroidism section, and p. 1408 in the Assessment discussion in the Hypoparathyroidism section. The care of patients with hypocalcemia is also discussed in Chapter 13.)

Laryngeal nerve damage may occur during surgery. This problem results in hoarseness and a weak voice. Assess the patient's voice at 2-hour intervals, and document any changes. Reassure the patient that hoarseness is usually temporary.

Thyroid storm, or **thyroid crisis**, is a life-threatening event that occurs in patients with uncontrolled hyperthyroidism and occurs most often with Graves' disease (McAdams-Jones, 2008). Manifestations of crisis develop quickly. It is often triggered by stressors such as trauma, infection, diabetic ketoacidosis, and pregnancy. Other conditions that can lead to thyroid storm include vigorous palpation of the goiter, exposure to iodine, and radioactive iodine (RAI) therapy. Although thyroid storm after surgery is less common because patients receive antithyroid drugs, beta blockers, and iodides before thyroid surgery, it can still occur.

The manifestations of thyroid storm are caused by excessive thyroid hormone release, which dramatically increases metabolic rate. *Key manifestations include fever, tachycardia, and systolic hypertension.* The patient may have GI problems such as abdominal pain, nausea, vomiting, and diarrhea. Often he or she is very anxious and has tremors. As the crisis progresses, the patient may become restless, confused, or psychotic and may have seizures, leading to coma. *Even with treatment, thyroid storm may lead to death.*

! NURSING SAFETY PRIORITY

Critical Rescue

When caring for a patient with hyperthyroidism, even after a partial thyroidectomy, immediately report a temperature increase of even 1° F because it may indicate an impending thyroid crisis.

CHART 66-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient During Thyroid Storm

- Maintain a patent airway and adequate ventilation.
- Give antithyroid drugs as prescribed: methimazole (Tapazole), up to 60 mg daily; propylthiouracil (PTU, Propyl-Thyracil ) , 300 to 900 mg daily.
- Administer sodium iodide solution, 2 g IV daily as prescribed.
- Give propranolol (Inderal, Detensol ) , 1 to 3 mg IV as prescribed. Give slowly over 3 minutes. The patient should be connected to a cardiac monitor, and a central venous pressure catheter should be in place.
- Give glucocorticoids as prescribed: hydrocortisone, 100 to 500 mg IV daily; prednisone, 4 to 60 mg IV daily; or dexamethasone, 2 mg IM every 6 hours.
- Monitor continually for cardiac dysrhythmias.
- Monitor vital signs every 30 minutes.
- Provide comfort measures, including a cooling blanket.
- Give non-salicylate antipyretics as prescribed.
- Correct dehydration with normal saline infusions.
- Apply cooling blanket or ice packs to reduce fever.

Emergency measures to prevent death vary with the intensity and type of specific symptoms. After the cause has been identified, interventions focus on maintaining airway patency, providing adequate ventilation, reducing fever, and stabilizing the hemodynamic status. [Chart 66-5](#) outlines the best practices for emergency management of thyroid storm.

Eye and vision problems of Graves' disease are not corrected by treatment for hyperthyroidism. Treatment of infiltrative ophthalmopathy is symptomatic. Teach the patient with mild symptoms to elevate the head of the bed at night and to use artificial tears. If [photophobia](#) (sensitivity to light) is present, dark glasses or eye patches are often helpful. For those who cannot close the eyelids completely, recommend gently taping the lids closed with nonallergenic tape at bedtime. These actions prevent irritation and injury. If pressure behind the eye continues and forces the eye forward, blood supply to the eye can be compromised, leading to ischemia and blindness.

In severe cases, short-term steroid therapy is prescribed to reduce swelling and halt the infiltrative process. Prednisone (Deltasone, Winpred ) is given in high doses (often 120 mg daily) at first and then is tapered down according to the patient's response. Explain the need to reduce the prednisone gradually, and review its side effects with the patient.

Diuretics may be prescribed to decrease edema around the eye. Surgical intervention (orbital decompression) may be needed if loss of sight or damage to the eyeball is possible. However, it is not usually performed for cosmetic reasons alone ([Leung et al., 2009](#)).

Health teaching includes reviewing with the patient and family the manifestations of hyperthyroidism and instructing the patient to report an increase or recurrence of symptoms. Also teach about the manifestations of hypothyroidism (discussed in the next section) and the need for thyroid hormone replacement. Reinforce the need for regular follow-up because hypothyroidism can occur several years after radioactive iodine therapy.

If the patient has had surgery, the surgeon usually removes the sutures on the third or fourth postoperative day. Teach the patient to inspect the incision area and to report redness, tenderness, drainage, or swelling to the surgeon.

The discharged patient may continue to have mood changes as a result of hyperthyroidism. Explain the reason for mood swings to the patient and family, and reassure them that these will decrease with continued treatment.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

You are preparing the patient who is 2 days postoperative from a total thyroidectomy for Graves' disease to be discharged to home. She is relieved the surgery is over and tells you that she is so happy that drugs are no longer needed and that her appearance, especially the goiter and the protruding eyes, will return to normal. However, she is concerned that her voice is still hoarse today, although less so than yesterday.

1. Is she correct in thinking that drugs are no longer needed? Why or why not?
2. What will you teach her about her appearance?
3. What will you teach her about the hoarseness?
4. What are the additional teaching priorities for this patient?

HYPOTHYROIDISM

Pathophysiology

The manifestations of hypothyroidism ([Chart 66-6](#)) are the result of decreased metabolism from low levels of thyroid hormones. Thyroid cells may fail to produce sufficient levels of thyroid hormones (THs) for several reasons. Sometimes the cells themselves are damaged and no longer function normally. At other times, the thyroid cells are functional but the person does not ingest enough of the substances needed to make thyroid hormones, especially iodide and tyrosine. When the production of thyroid hormones is too low or absent, the blood levels of TH are very low and the patient has a decreased metabolic rate. This lowered metabolism causes the hypothalamus and anterior pituitary gland to make stimulatory hormones, especially thyroid-stimulating hormone (TSH), in an attempt to trigger hormone release from the poorly responsive thyroid gland. The TSH binds to thyroid cells and causes the thyroid gland to enlarge, forming a goiter, although thyroid hormone production does not increase.

Most tissues and organs are affected by the low metabolic rate caused by hypothyroidism. Cellular energy is decreased, and metabolites that are compounds of proteins and sugars called *glycosaminoglycans* build up inside cells; this buildup increases the mucus and water, forms cellular edema, and changes organ texture. The edema is mucinous (called [myxedema](#)), rather than edema caused by water alone, and changes the patient's appearance ([Fig. 66-3](#)). Nonpitting edema forms everywhere, especially around the eyes, in the hands and feet, and between the shoulder blades. The tongue thickens, and edema forms in the larynx, making the voice husky. All general physiologic function is decreased.

[Myxedema coma](#) is a rare, serious complication of untreated or poorly treated hypothyroidism. The decreased metabolism causes the heart muscle to become flabby and the

CHART 66-6 KEY FEATURES

Hypothyroidism**Skin Manifestations**

- Cool, pale or yellowish, dry, coarse, scaly skin
- Thick, brittle nails
- Dry, coarse, brittle hair
- Decreased hair growth, with loss of eyebrow hair
- Poor wound healing

Pulmonary Manifestations

- Hypoventilation
- Pleural effusion
- Dyspnea

Cardiovascular Manifestations

- Bradycardia
- Dysrhythmias
- Enlarged heart
- Decreased activity tolerance
- Hypotension

Metabolic Manifestations

- Decreased basal metabolic rate
- Decreased body temperature
- Cold intolerance

Musculoskeletal Manifestations

- Muscle aches and pains
- Delayed contraction and relaxation of muscles

Neurologic Manifestations

- Slowing of intellectual functions:
 - Slowness or slurring of speech
 - Impaired memory
 - Inattentiveness
- Lethargy or somnolence
- Confusion
- Hearing loss
- Paresthesia (numbness and tingling) of the extremities
- Decreased tendon reflexes

Psychological/Emotional Manifestations

- Apathy
- Depression
- Paranoia
- Withdrawal

Gastrointestinal Manifestations

- Anorexia
- Weight gain
- Constipation
- Abdominal distention

Reproductive Manifestations**Women**

- Changes in menses (amenorrhea or prolonged menstrual periods)
- Anovulation
- Decreased libido

Men

- Decreased libido
- Impotence

Other Manifestations

- Periorbital edema
- Facial puffiness
- Nonpitting edema of the hands and feet
- Hoarseness
- Goiter (enlarged thyroid gland)
- Thick tongue
- Increased sensitivity to opioids and tranquilizers
- Weakness, fatigue
- Decreased urine output
- Anemia
- Easy bruising
- Iron deficiency
- Folate deficiency
- Vitamin B₁₂ deficiency

FIG. 66-3 Myxedema.

TABLE 66-2 CAUSES OF HYPOTHYROIDISM

Primary Causes**Decreased Thyroid Tissue**

- Surgical removal of the thyroid
- Radiation-induced thyroid destruction
- Autoimmune thyroid destruction
- Congenital thyroid agenesis
- Congenital thyroid hypoplasia
- Congenital thyroid dysgenesis
- Cancer (thyroidal or metastatic)

Decreased Synthesis of Thyroid Hormone

- Endemic iodine deficiency
- Excessive exposure to iodine
- Drugs
 - Lithium
 - Phenylbutazone
 - Propylthiouracil
 - Sodium or potassium perchlorate
 - Aminogluthethimide

Secondary Causes**Inadequate Production of Thyroid-Stimulating Hormone**

- Pituitary tumors, trauma, infections, or infarcts
- Congenital pituitary defects
- Hypothalamic tumors, trauma, infections, or infarcts

chamber size to increase. The result is decreased cardiac output and decreased perfusion to the brain and other vital organs. The decreased perfusion makes the already slowed cellular metabolism worse, resulting in tissue and organ failure. *The mortality rate for myxedema coma is extremely high, and this condition is considered a life-threatening emergency.* Myxedema coma can be caused by a variety of events, drugs, or conditions.

Etiology

Most cases of hypothyroidism in the United States occur as a result of thyroid surgery and radioactive iodine (RAI) treatment of hyperthyroidism. Worldwide, hypothyroidism is common in areas where the soil and water have little natural iodide, causing endemic goiter. (This problem was common in the midwest region of the United States before iodide was

added to table salt and before saltwater fish was widely available.) Hypothyroidism is also caused by a variety of other conditions (Table 66-2).

Incidence/Prevalence

Hypothyroidism occurs most often in women between 30 and 60 years of age. Women are affected 7 to 10 times more often than men (McCance et al., 2010). An association exists between the development of hypothyroidism and diabetes mellitus. Incidence increases with age.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

A decrease in thyroid hormones produces many manifestations related to decreased metabolism. However, changes may have occurred slowly, often over weeks or months, and the patient may not have noticed them. Ask him or her to compare activity now with that of a year ago. The patient often reports an increase in time spent sleeping, sometimes up to 14 to 16 hours daily. Generalized weakness, anorexia, muscle aches, and paresthesias may also be present. Constipation is common, as is cold intolerance. Ask whether more blankets at night or sweaters and extra clothing, even in warm weather, have been needed. Some of these changes may be subtle and missed because they are considered part of the aging process.

Both men and women with hypothyroidism may report a decrease in libido. Women may have had difficulty becoming pregnant or have changes in menses (heavy, prolonged bleeding or amenorrhea). Men may have problems with impotence and infertility.

Ask the patient about current or previous use of drugs, such as lithium, thiocyanates, aminoglutethimide, sodium or potassium perchlorate, or cobalt. All these drugs can impair thyroid hormone production. In particular, the cardiac drug *amiodarone* (Cordarone) often has damaging effects on the thyroid gland (Kessenich & Higgs, 2010). Also determine whether the patient has ever been treated for hyperthyroidism and what specific treatment was used.

Physical Assessment/Clinical Manifestations

Observe the patient's overall appearance. Fig. 66-3 shows the typical appearance of an adult with hypothyroidism. Common changes include coarse features, edema around the eyes and face, a blank expression, and a thick tongue. The patient's overall muscle movement is slow. He or she may not speak clearly and may take a longer time to respond to questions.

Cardiac and respiratory functions are decreased. Heart rate may be below 60 beats per minute, and respiratory rate may be slower than normal. The patient's body temperature is often lower than 97° F.

Weight gain is very common, even when the person is ingesting an appropriate number of calories for size, age, and gender. Weigh the patient, and ask whether the result is the same or different from his or her weight a year ago.

Depending on the cause of hypothyroidism, the patient may have a goiter. However, some types of hypothyroidism do not induce a goiter and some types of hyperthyroidism do. Therefore the presence of a goiter suggests a thyroid problem but does not indicate whether the problem is excessive hormone secretion or too little hormone secretion.

Psychosocial Assessment

Hypothyroidism causes many problems in psychosocial functioning. Depression is the most common reason for seeking medical attention. Family members often bring the patient for the initial evaluation. The patient may be too lethargic, apathetic, or drowsy to recognize changes in his or her condition. Families may report that the patient is withdrawn and has reduced mental function. Assess his or her attention span

and memory, both of which can be impaired by hypothyroidism. Weight gain may have a negative affect on body image. The mental slowness can contribute to social isolation.

Laboratory Assessment

Laboratory findings for hypothyroidism are the opposite of those for hyperthyroidism. Triiodothyronine (T_3) and thyroxine (T_4) serum levels are decreased. TSH levels are high in primary hypothyroidism but can be decreased or near normal in patients with secondary hypothyroidism (see Chart 66-2). Patients older than 80 years may have lower-than-normal levels of thyroid hormones without manifestations of hypothyroidism, and hormone replacement is not used until other manifestations are present (Touhy & Jett, 2010).

ANALYSIS

The priority problems for patients who have hypothyroidism are:

1. Decreased oxygenation related to decreased energy, obesity, muscle weakness, and fatigue
2. Hypotension related to altered heart rate and rhythm as a result of decreased myocardial metabolism
3. Altered cognitive functioning related to impaired brain metabolism and edema
4. Potential for myxedema coma

PLANNING AND IMPLEMENTATION

Both cardiac and respiratory problems are serious, and their management is a priority. However, the most common cause of death among patients with myxedema coma is respiratory failure.

Improving Oxygenation

Planning: Expected Outcomes. The patient with hypothyroidism is expected to have improved respiratory function and oxygenation. Indicators include:

- Maintenance of SpO_2 of at least 90%
- Absence of cyanosis
- Maintenance of cognitive orientation

Interventions. Observe and record the rate and depth of respirations. Measure oxygen saturation by pulse oximetry, and apply oxygen if the patient has hypoxemia. Auscultate the lungs for any problems, such as a decrease in breath sounds. If hypothyroidism is severe, the patient may have such severe respiratory distress that ventilatory support is required. Severe respiratory distress often occurs with myxedema coma.

Sedating a patient with hypothyroidism can make respiratory difficulties worse and is avoided, if possible. When sedation is needed, the dosage is reduced because hypothyroidism increases sensitivity to these drugs. Assess the patient receiving sedation for respiratory adequacy.

Preventing Hypotension

Planning: Expected Outcomes. The patient with hypothyroidism is expected to have adequate cardiovascular function and tissue perfusion. Indicators include that the patient:

- Maintains heart rate above 60 beats/min
- Maintains blood pressure within normal limits for his or her age and general health
- Has no dysrhythmias, peripheral edema, or neck vein distention

Interventions. The patient with hypothyroidism can have decreased blood pressure, bradycardia, and dysrhythmias. Priority nursing actions are focused on monitoring for condition changes and preventing complications. Monitor blood pressure and heart rate and rhythm, and observe closely for signs of shock, such as hypotension, decreasing urine output, and changes in mental status.

If hypothyroidism has been chronic, the patient may have cardiovascular disease. Instruct the patient to report episodes of chest pain or chest discomfort immediately.

The patient with hypothyroidism requires lifelong thyroid hormone replacement. Synthetic hormone preparations are usually prescribed. The most common is levothyroxine sodium (Synthroid, T₄, Eltroxin ). Therapy is started with low doses and gradually increased over a period of weeks. The patient with more severe symptoms of hypothyroidism is started on the lowest dose of thyroid hormone replacement. This caution is especially important when the patient has known cardiac problems. Starting at too high a dose or increasing the dose too rapidly can cause severe hypertension, heart failure, and myocardial infarction (Brent et al., 2008). *Teach patients, as well as their families, who are beginning thyroid replacement hormone therapy to take the drug exactly as prescribed and not to change the dose or schedule without consulting the health care provider. In addition, teach them not to switch brands because the response to different drug brands can vary.*

Assess the patient for chest pain and dyspnea during initiation of therapy. The final dosage is determined by blood levels of TSH and the patient's physical responses. The dosage and time required for symptom relief vary with each patient. Monitor for and teach the patient and family about the manifestations of hyperthyroidism (see Chart 66-1), which can occur with replacement therapy.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which is the nurse's most important assessment before giving the client prescribed levothyroxine (Synthroid) the first oral dose of the drug?

- A. Measuring heart rate and rhythm
- B. Checking core body temperature
- C. Asking about an allergy to "sulfa" drugs
- D. Determining the level of gastric motility

Supporting Cognition

Planning: Expected Outcomes. The patient with hypothyroidism is expected to have cognitive function that is at a level that was present before the thyroid problem started. Indicators include that the patient:

- Demonstrates immediate memory
- Communicates clearly and appropriately for age and ability
- Is attentive during conversations

Interventions. Observe for and record the presence and severity of lethargy, drowsiness, memory deficit, poor attention span, and difficulty communicating. These problems should decrease with thyroid hormone treatment, and mental awareness usually returns to the patient's normal level within 2 weeks. Orient the patient to person, place, and time, and

explain all procedures slowly and carefully. Provide a safe environment.

Family members may have difficulty coping with the patient's behavior. Encourage them to accept the mood changes and mental slowness as manifestations of the disease. Remind the family that these problems should improve with therapy.

Preventing Myxedema Coma

Any patient with hypothyroidism who has any other health problem or who is newly diagnosed is at risk for myxedema coma. Factors leading to myxedema coma include acute illness, surgery, chemotherapy, discontinuing thyroid replacement therapy, and the use of sedatives or opioids. Problems that often occur with this condition include:

- Coma
- Respiratory failure
- Hypotension
- Hyponatremia
- Hypothermia
- Hypoglycemia

NURSING SAFETY PRIORITY

Action Alert

Myxedema coma can lead to shock, organ damage, and death. Assess the patient with hypothyroidism at least every 8 hours for changes that indicate increasing severity, especially changes in mental status, and report these promptly to the health care provider (Simmons, 2010).

Treatment is instituted quickly according to the patient's manifestations and without waiting for laboratory confirmation. Best practices for emergency care of the patient with myxedema coma are listed in Chart 66-7.

Community-Based Care

Hypothyroidism is usually a chronic condition. Patients with hypothyroidism are managed on an outpatient basis and may reside anywhere. Patients in acute care settings, subacute care settings, and rehabilitation centers may have long-standing hypothyroidism in addition to other acute or chronic health

CHART 66-7 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient During Myxedema Coma

- Maintain a patent airway.
- Replace fluids with IV normal or hypertonic saline, as prescribed.
- Give levothyroxine sodium IV as prescribed.
- Give glucose IV as prescribed.
- Give corticosteroids as prescribed.
- Check the patient's temperature hourly.
- Monitor blood pressure hourly.
- Cover the patient with warm blankets.
- Monitor for changes in mental status.
- Turn every 2 hours.
- Institute Aspiration Precautions.

CHART 66-8 NURSING FOCUS ON THE OLDER ADULT**Thyroid Problems**

Teach the patient these facts about changes in the thyroid gland related to aging:

- The thyroid gland decreases in size with increasing age.
- Thyroid hormone secretion decreases with age, but the hormone level remains stable because storage site clearance of the hormone also decreases with age.
- The basal metabolic rate decreases with age, usually as a result of decreased activity. This decrease changes the body composition from predominantly muscular to predominantly fatty.
- Older patients require lower doses of replacement thyroid hormone. Too large a dose may adversely affect the heart muscle.

problems. Ensure that whoever is responsible for overseeing the patient's daily care is aware of the condition and understands its treatment.

Home Care Management

The patient with hypothyroidism does not usually require changes in the home unless cognition has decreased to the point that he or she poses a danger to himself or herself. Activity intolerance and fatigue may necessitate one-floor living for a short time. If manifestations have not improved before discharge, discuss the need for extra heat or clothing because of cold intolerance. The patient who has a decreased attention span may need help with the drug regimen. Discuss this issue with the family and patient, and develop a plan for drug therapy. One person should be clearly designated as responsible for drug preparation and delivery so that doses are neither missed nor duplicated.

Teaching for Self-Management

The most important educational need for the patient with hypothyroidism is about hormone replacement therapy and its side effects. Emphasize the need for lifelong drugs, and review the manifestations of both hyperthyroidism and hypothyroidism. Teach the patient to wear a medical alert bracelet. Teach the patient and family when to seek medical interventions for dosage adjustment and the need for periodic blood tests of hormone levels. Instruct the patient to not take any over-the-counter (OTC) drugs because thyroid hormone preparations interact with many other drugs. Older patients may need additional information about the effects of aging on the thyroid gland (Chart 66-8).

Advise the patient to eat a well-balanced diet with adequate fiber and fluid intake to prevent constipation. Caution him or her that use of fiber supplements may interfere with the absorption of thyroid hormone. Thyroid hormones should be taken on an empty stomach. Remind the patient about the importance of adequate rest. Encourage family members to voice their concerns to the health care provider.

Assist the family in understanding that the time required for resolution of hypothyroidism varies. During this time, the patient may continue to have mental dullness or slowness. Teach the family to orient the patient often and to explain everything clearly, simply, and as often as needed.

Teach the patient to monitor himself or herself for therapy effectiveness. The two easiest parameters to check are need for sleep and bowel elimination. When the patient requires more sleep and is constipated, the dose of replacement hormone may need to be increased. When the patient has difficulty getting to sleep and has more bowel movements than normal for him or her, the dose may need to be decreased.

Health Care Resources

Immediately after returning home, the patient may need a support person to stay and provide more attention than could be given by a visiting nurse or home care aide. Contact with the health care team is needed for follow-up and identification of potential problems. The patient taking thyroid drugs may have manifestations of hypothyroidism if the dosage is inadequate or may have manifestations of hyperthyroidism if the dose is too high. A home care nurse performs a focused assessment at every home visit to the patient with thyroid dysfunction (Chart 66-9).

EVALUATION: OUTCOMES

Evaluate the care of the patient with hypothyroidism based on the identified priority patient problems. The expected outcomes are that the patient should:

- Maintain normal cardiovascular function
- Maintain adequate respiratory function
- Experience improvement in thought processes

Specific indicators for these outcomes are listed for each patient problem in the Planning and Implementation section (see earlier).

**NCLEX EXAMINATION CHALLENGE****Physiological Integrity**

The client who has been taking levothyroxine (Synthroid) for 3 months reports all of the following conditions. Which condition indicates to the nurse that the drug dosage may need to be adjusted?

- A. Difficulty sleeping
- B. Increased urine output
- C. Decreased sense of smell
- D. Difficulty remembering to take the drug

THYROIDITIS**Pathophysiology**

Thyroiditis is an inflammation of the thyroid gland. There are three types: acute, subacute, and chronic. Chronic thyroiditis (Hashimoto's disease) is the most common type.

Acute thyroiditis is caused by bacterial invasion of the thyroid gland. Manifestations include pain, neck tenderness, malaise, fever, and dysphagia (difficulty swallowing). It usually resolves with antibiotic therapy.

Subacute or granulomatous thyroiditis results from a viral infection of the thyroid gland after a cold or other upper respiratory infection. Manifestations include fever, chills, dysphagia, and muscle and joint pain. Pain can radiate to the ears and the jaw. The thyroid gland feels hard and enlarged on palpation. Thyroid function can remain normal, although hyperthyroidism or hypothyroidism may develop.

Chronic thyroiditis (Hashimoto's disease) is a common type of hypothyroidism that affects women more often than

CHART 66-9 HOME CARE ASSESSMENT

The Patient with Thyroid Dysfunction

Assess cardiovascular status:

- Vital signs, including apical pulse, pulse pressure, presence or absence of orthostatic hypotension, and the quality and rhythm of peripheral pulses
- Presence or absence of peripheral edema
- Weight gain or loss

Assess cognition and mental status:

- Level of consciousness
- Orientation to time, place, and person
- Accurately reading a seven-word sentence containing no words greater than three syllables
- Can the patient count backward from 100 by threes?

Assess condition of skin and mucous membranes:

- Moistness of skin, most reliable on chest and back
- Skin temperature and color

Assess neuromuscular status:

- Reactivity of patellar and biceps reflexes
- Oral temperature
- Handgrip strength
- Steadiness of gait
- Presence or absence of fine tremors in the hand

Ask about:

- Sleep in the past 24 hours
- Patient warm enough or too warm indoors
- 24-hour diet recall
- 24-hour activity recall
- Over-the-counter and prescribed drugs taken
- Last bowel movement

Assess patient's understanding of illness and adherence with therapy:

- Manifestations to report to health care provider
- Drug therapy plan (correct timing and dose)

men, usually when patients are in their 30s to 50s (Brent et al., 2008). Hashimoto's disease is an autoimmune disorder that is usually triggered by a bacterial or viral infection. The thyroid is invaded by antithyroid antibodies and lymphocytes, causing thyroid tissue destruction. When large amounts of the gland are destroyed, serum thyroid hormone levels are low and secretion of thyroid-stimulating hormone (TSH) is increased.

PATIENT-CENTERED COLLABORATIVE CARE

The manifestations of Hashimoto's disease are dysphagia and painless enlargement of the gland. Diagnosis is based on circulating antithyroid antibodies and needle biopsy of the thyroid gland. Serum thyroid hormone levels, TSH levels, and radioactive iodine uptake (RAIU) vary with disease stage.

The patient is given thyroid hormone to prevent hypothyroidism and to suppress TSH secretion, which decreases the size of the thyroid gland. Surgery (subtotal thyroidectomy) is needed if the goiter does not respond to thyroid hormone, is disfiguring, or compresses other structures.

Nursing interventions focus on promoting comfort and teaching the patient about hypothyroidism, drugs, and surgery. (See discussion of Postoperative Care on pp. 1399-1400 in the Hyperthyroidism section.)

THYROID CANCER**Pathophysiology**

The four distinct types of thyroid cancer are papillary, follicular, medullary, and anaplastic (American Cancer Society, 2011). The initial manifestation of thyroid cancer is a single, painless lump or nodule in the thyroid gland. Additional manifestations depend on the presence and location of **metastasis** (spread of cancer cells).

Papillary carcinoma, the most common type of thyroid cancer, occurs most often in younger women. It is a slow-growing tumor that can be present for years before spreading to nearby lymph nodes. When the tumor is confined to the thyroid gland, the chance for cure is good with a partial or total thyroidectomy.

Follicular carcinoma occurs most often in older patients. The cancer invades blood vessels and spreads to bone and lung tissue. It can adhere to the trachea, neck muscles, great vessels, and skin, resulting in **dyspnea** (difficulty breathing) and **dysphagia** (difficulty swallowing). When the tumor involves the recurrent laryngeal nerves, the patient may have a hoarse voice.

Medullary carcinoma is most common in patients older than 50 years. This tumor often occurs as part of multiple endocrine neoplasia (MEN) type II, a familial endocrine disorder. The tumor usually secretes calcitonin, adrenocorticotropic hormone (ACTH), prostaglandins, and serotonin.

Anaplastic carcinoma is a rapid-growing, aggressive tumor that directly invades nearby structures. Manifestations include **stridor** (harsh, high-pitched respiratory sounds), hoarseness, and dysphagia.

PATIENT-CENTERED COLLABORATIVE CARE

Radiation therapy is used most often for anaplastic carcinoma because this cancer has usually metastasized (spread) at diagnosis. Surgery is the treatment of choice for papillary, follicular, and medullary carcinomas. A total thyroidectomy is usually performed with a nodal neck dissection if regional lymph nodes are involved. (See the postoperative care discussion in the Surgical Management section for Hyperthyroidism on pp. 1399-1400.) Suppressive doses of thyroid hormone are usually taken for 3 months after surgery. A radioactive iodine uptake (RAIU) study is performed after

**NCLEX EXAMINATION CHALLENGE****Health Promotion and Maintenance**

The client scheduled to receive a radioablative dose of ^{131}I for thyroid cancer asks how long he will need to use radiation precautions after receiving the treatment. What is the nurse's best response?

- "Because the isotope collects in the tumor cells, precautions are needed until the cancer is completely gone."
- "The dose of radiation is low, and most of it is excreted in the first week. Precautions are needed for only 2 weeks."
- "You will need to use radiation precautions until the radiologist removes the radiation source from your thyroid gland."
- "The radiation used is taken up by your thyroid gland, so only your thyroid is considered radioactive. Because the thyroid does not excrete to the outside of the body, precautions are needed only on the days you actually receive the treatment."

FIG. 66-4 The physiologic actions of parathyroid hormone.

drugs are withdrawn. If there is RAI uptake, the patient is treated with **ablative** (enough to destroy the tissue) amounts of RAI. (See [Chart 66-4](#) for precautions to teach the patient receiving unsealed RAI therapy.) If thyroid cancer does not respond to RAI, chemotherapy is initiated.

Usually the patient is hypothyroid after treatment for thyroid cancer. Nursing interventions then focus on teaching the patient about hypothyroidism and its management. (See discussion of Patient-Centered Collaborative Care on pp. 1402-1404 in the Hypothyroidism section.)

PARATHYROID DISORDERS

HYPERPARATHYROIDISM

Pathophysiology

The parathyroid glands maintain calcium and phosphate balance ([Fig. 66-4](#)). Serum calcium level is normally maintained within a narrow range. Phosphate levels vary more widely. Increased levels of parathyroid hormone (PTH) act directly on the kidney, causing increased kidney reabsorption of calcium and increased phosphate excretion. These processes cause **hypercalcemia** (excessive calcium) and **hypophosphatemia** (inadequate phosphate) in the patient with hyperparathyroidism.

In bone, excessive PTH levels increase bone resorption (bone loss of calcium) by decreasing **osteoblastic** (bone production) activity and increasing **osteoclastic** (bone destruction) activity. This process releases calcium and phosphate into the blood and reduces bone density. With chronic calcium excess and hypercalcemia, calcium is deposited in soft tissues.

Although the exact triggering mechanisms are unknown, primary hyperparathyroidism results when one or more

TABLE 66-3 CAUSES OF PARATHYROID DYSFUNCTION

Causes of Hyperparathyroidism

- Parathyroid adenoma
- Parathyroid carcinoma
- Congenital hyperplasia
- Neck trauma or radiation
- Vitamin D deficiency
- Chronic kidney disease with hypocalcemia
- Parathyroid hormone-secreting carcinomas of the lung, kidney, or GI tract

Causes of Hypoparathyroidism

- Surgical or radiation-induced thyroid ablation
- Parathyroidectomy
- Congenital dysgenesis
- Idiopathic (autoimmune) hypoparathyroidism
- Hypomagnesemia

parathyroid glands do not respond to the normal feedback of serum calcium. The most common cause is a benign tumor in one parathyroid gland. [Table 66-3](#) lists other causes of hyperparathyroidism.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Manifestations of hyperparathyroidism may be related either to the effects of excessive PTH or to the effects of the accompanying hypercalcemia.

Ask the patient about any bone fractures, recent weight loss, arthritis, or psychological distress. Determine whether the patient has received radiation treatment to the head or neck. The patient with long-standing disease may have a waxy pallor of the skin and bone deformities in the extremities and back.

High levels of PTH cause **renal calculi** (kidney stones) and deposits of calcium in the soft tissue of the kidney. Bone lesions are due to an increased rate of bone destruction and may result in pathologic fractures, bone cysts, and osteoporosis.

GI problems (e.g., anorexia, nausea, vomiting, epigastric pain, constipation, weight loss) are common, particularly when serum calcium levels are high. Elevated serum gastrin levels are caused by hypercalcemia and lead to peptic ulcer disease. Fatigue and lethargy may be present and become more severe as the serum calcium levels increase. When serum calcium levels are greater than 12 mg/dL, the patient may have psychosis with mental confusion, which leads to coma and death if left untreated. (See [Chapter 13](#) for more information about hypercalcemia.)

Serum PTH, calcium, and phosphate levels and urine cyclic adenosine monophosphate (cAMP) are the most commonly used laboratory tests to detect hyperparathyroidism ([Chart 66-10](#)). X-rays may show kidney stones, calcium deposits, and bone lesions (e.g., cysts or fractures). Loss of bone density occurs in the patient with chronic hyperparathyroidism. Other diagnostic tests include arteriography, computed tomography (CT) scans, venous sampling of the thyroid for blood PTH levels, and ultrasonography. Explain the procedures and care for the patient undergoing diagnostic tests.

CHART 66-10 LABORATORY PROFILE

Parathyroid Function

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS	
		HYPERPARATHYROIDISM	HYPOPARATHYROIDISM
Serum calcium	Total: 9.0-10.5 mg/dL or 2.25-2.75 SI units Ionized (active): 4.64-5.28 mg/dL or 1.16-1.32 SI units	Increased in primary hyperparathyroidism	Decreased
Serum phosphate	3.0-4.5 mg/dL or 0.97-1.45 SI units <i>Older adults:</i> May be slightly lower	Decreased	Increased
Serum magnesium	1.3-2.1 mEq/L	Increased	Decreased
Serum parathyroid hormone	C-terminal 50-330 pg/mL	Increased	Decreased
Vitamin D (calciferol)	14-60 ng/mL	Variable	Decreased
Urine cAMP	18.3-45.4 nmol/L in a 24-hour urine collection specimen	Increased	Decreased

SI, International System of Units; cAMP, cyclic adenosine monophosphate.

INTERVENTIONS**Nonsurgical Management**

Diuretic and hydration therapies are used for reducing serum calcium levels in patients who are not candidates for surgery. Usually furosemide (Lasix, Uritol ) , a diuretic that increases kidney excretion of calcium, is used together with IV saline in large volumes to promote calcium excretion. Priority nursing interventions focus on monitoring and preventing injury.

Monitor cardiac function and intake and output every 2 to 4 hours during hydration therapy. Continuous cardiac monitoring may be needed. Compare recent electrocardiogram (ECG) tracings with the patient's baseline tracings. Especially look for changes in the T waves and the QT interval, as well as changes in rate and rhythm. Closely monitor serum calcium levels, and immediately report any sudden drop to the health care provider. Sudden drops in calcium levels may cause tingling and numbness in the muscles.

Preventing injury is important because the patient with chronic hyperparathyroidism often has significant bone density loss and is at risk for pathologic fractures. Teach all members of the health care team to handle the patient carefully. Use a lift sheet to reposition the patient rather than pulling him or her. Ensure that the hospitalized patient is accompanied when ambulating to prevent falls.

Drug therapy is used when hydration and furosemide cannot reduce hypercalcemia or if it is necessary to discontinue IV fluids. Other drugs can help reduce the manifestations of hyperparathyroidism, especially those related to hypercalcemia.

Oral phosphates inhibit bone resorption and interfere with calcium absorption. IV phosphates are used only when serum calcium levels must be lowered rapidly. Calcitonin decreases the release of skeletal calcium and increases the kidney excretion of calcium. It is not effective when used alone because of its short duration of action. The therapeutic effects are greatly enhanced if calcitonin is given along with glucocorticoids.

Some drugs known as *calcium chelators* lower calcium levels by binding (*chelating*) calcium, which reduces the levels of free calcium. Mithramycin, a cytotoxic agent, is the most effective and potent calcium chelator used to lower serum

calcium levels. In most patients, a single IV dose of 10 to 15 mg/kg of body weight by slow infusion can lower serum calcium levels within 48 hours. However, the toxic effects limit its use to two or three doses. *Thrombocytopenia* (decreased circulating platelets) and kidney and liver toxicity can result after only one dose. Liver function test, blood urea nitrogen and creatinine, complete blood count (CBC), and serum calcium levels are closely monitored in the patient receiving mithramycin. Another calcium chelator is penicillamine (Cuprimine, Pendramine).

Surgical Management

Surgical management of hyperparathyroidism is a parathyroidectomy. Before surgery, the patient is stabilized and calcium levels are decreased to near normal. If mithramycin has been used to lower serum calcium levels, studies to determine bleeding and clotting times are needed, as is a CBC to determine bone marrow function.

The operative procedure involves a transverse incision in the lower neck. All four parathyroid glands are examined for enlargement. If a tumor is present on one side but the other side is normal, the surgeon removes the glands containing tumor and leaves the remaining glands on the opposite side intact. If all four glands are diseased, they are all removed.

Nursing care before and after surgical removal of the parathyroid glands is the same as that for thyroidectomy. See the Preoperative Care section on pp. 1397-1399 and the Postoperative Care section on pp. 1399-1400 for specific nursing interventions.

The remaining glands, which may have atrophied as a result of PTH overproduction, require several days to several weeks to return to normal function. A hypocalcemic crisis can occur during this critical period. Usually, the surgeon requests the serum calcium to be assessed frequently after surgery. Check serum calcium levels immediately after surgery and every 4 hours thereafter until calcium levels stabilize. Monitor for manifestations of hypocalcemia, such as tingling and twitching in the extremities and face. Check for Trousseau's and Chvostek's signs, either of which indicates potential tetany (see [Chapter 13](#)).

The recurrent laryngeal nerve can be damaged. Assess the patient for changes in voice patterns and hoarseness.

When hyperparathyroidism is due to **hyperplasia** (tissue overgrowth), three glands plus half of the fourth gland are usually removed. If all four glands are removed, a small portion of a gland may be implanted in the forearm, where it produces PTH and maintains calcium homeostasis. If all these maneuvers fail, the patient will need lifelong treatment with calcium and vitamin D because the resulting hypoparathyroidism is permanent (see next section).

HYPOPARATHYROIDISM

Pathophysiology

Hypoparathyroidism is a rare endocrine disorder in which parathyroid function is decreased. Problems are directly related to a lack of parathyroid hormone (PTH) secretion or to decreased effectiveness of PTH on target tissue. Whether the problem is a lack of PTH secretion or an ineffectiveness of PTH on tissues, the result is the same: *hypocalcemia*.

Iatrogenic hypoparathyroidism, the most common form, is caused by the removal of all parathyroid tissue during total thyroidectomy or by deliberate surgical removal of the parathyroid glands.

Idiopathic hypoparathyroidism can occur spontaneously. The exact cause is unknown, but an autoimmune basis is suspected. It may occur with other autoimmune disorders such as adrenal insufficiency, hypothyroidism, diabetes mellitus, pernicious anemia, and vitiligo.

Hypomagnesemia (decreased serum magnesium levels) may also cause hypoparathyroidism. Hypomagnesemia is seen in alcoholics and in patients with malabsorption syndromes, chronic kidney disease, and malnutrition. It causes impairment of PTH secretion and may interfere with the effects of PTH on the bones, kidneys, and calcium regulation.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Ask about any head or neck surgery or radiation therapy because these treatments may damage the parathyroid glands and cause hypoparathyroidism. Also determine whether the neck has ever sustained a serious injury in a car crash or by strangulation. Assess whether the patient has any manifestations of hypoparathyroidism, which may range from mild tingling and numbness to muscle tetany. Tingling and

numbness around the mouth or in the hands and feet reflect mild to moderate hypocalcemia. Severe muscle cramps, spasms of the hands and feet, and seizures (with no loss of consciousness or incontinence) reflect a more severe hypocalcemia. The patient or family may notice mental changes ranging from irritability to psychosis.

The physical assessment may show excessive or inappropriate muscle contractions that cause finger, hand, and elbow flexion. This can signal an impending attack of tetany. Check for Chvostek's sign and Trousseau's sign; positive responses indicate potential tetany (see [Chapter 13](#)). Bands or pits may encircle the crowns of the teeth, which indicates a loss of calcium from the teeth with enamel loss.

Diagnostic tests for hypoparathyroidism include electroencephalography (EEG), blood tests, and CT scans. EEG changes revert to normal with correction of hypocalcemia. Serum calcium, phosphate, magnesium, vitamin D, and urine cyclic adenosine monophosphate (cAMP) levels may be used in the diagnostic workup for hypoparathyroidism (see [Chart 66-10](#)). The CT scan can show brain calcifications, which indicate chronic hypocalcemia.

INTERVENTIONS

Nonsurgical management of hypoparathyroidism focuses on correcting hypocalcemia, vitamin D deficiency, and hypomagnesemia. For patients with acute and severe hypocalcemia, IV calcium is given as a 10% solution of calcium chloride or calcium gluconate over 10 to 15 minutes. Acute vitamin D deficiency is treated with calcitriol (Rocaltrol), 0.5 to 2 mg daily. Acute hypomagnesemia is corrected with 50% magnesium sulfate in 2-mL doses (up to 4 g daily) either IM or IV. Long-term oral therapy for hypocalcemia involves the intake of calcium, 0.5 to 2 g daily, in divided doses.

Long-term therapy for vitamin D deficiency is 50,000 to 400,000 units of ergocalciferol daily. The dosage is adjusted to keep the patient's calcium level in the low-normal range (slightly hypocalcemic), enough to prevent symptoms of hypocalcemia. It must also be low enough to prevent increased urine calcium levels, which can lead to stone formation.

Nursing management includes teaching about the drug regimen and interventions to reduce anxiety. Teach the patient to eat foods high in calcium but low in phosphorus. Milk, yogurt, and processed cheeses are avoided because of their high phosphorus content. *Stress that therapy for hypocalcemia is lifelong.* Advise the patient to wear a medical alert bracelet. With adherence to the prescribed drug and diet regimen, the calcium level usually remains high enough to prevent a hypocalcemic crisis.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Keep the environment of a patient at risk for thyroid storm cool, dark, and quiet.

- Keep emergency suctioning and tracheostomy equipment in the room of a patient who has had thyroid or parathyroid surgery.
- Use a lift sheet to move or reposition a patient with hypocalcemia.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd**Health Promotion and Maintenance**

- Teach all patients to take antithyroid drugs or thyroid hormone replacement therapy as prescribed.
- Include the person who prepares the patient's meals when teaching about dietary electrolyte restrictions.
- Collaborate with the dietitian to teach patients about diets that are restricted in calcium or phosphate.

Psychosocial Integrity

- Be accepting of patient behavior.
- Remind patients and family members that changes in cognition and behavior related to thyroid problems are usually temporary.

- Encourage the patient who has a permanent change in appearance (e.g., exophthalmia) to mourn the change.

Physiological Integrity

- Monitor the hydration status of patients who have hypercalcemia.
- Teach patients that hormone replacement therapy for hypothyroidism is lifelong.
- Teach patients to use clinical manifestations (e.g., the number of bowel movements per day, the ability to sleep) as indicators of therapy effectiveness and when the dose of thyroid hormone replacement may need to be adjusted.

CHAPTER

67

Care of Patients with Diabetes Mellitus

Margaret Elaine McLeod

Concept Map: Diabetes Mellitus—Type 2

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Assess the person who has diabetes for specific current and ongoing factors that pose threats to safety.
2. Administer insulin and other antidiabetic agents in a safe and accurate manner.
3. Apply the principles of infection control in the care of patients with diabetes.
4. Individualize patient teaching methods for diabetes management.
5. Teach patients and families the safe use of insulin injection equipment and glucose monitoring equipment.
6. Teach patients with peripheral neuropathy how to avoid injury.

Health Promotion and Maintenance

7. Encourage everyone to prevent type 2 diabetes by achieving and maintaining ideal weight and participating in regular exercise.
8. Teach all patients with diabetes how to self-manage their disease.
9. Teach the patient and family about the manifestations and emergency treatment of hypoglycemia and hyperglycemia.

Psychosocial Integrity

10. Allow the patient the opportunity to express concerns regarding the diagnosis of diabetes or the treatment regimen.
11. Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
12. Refer patients newly diagnosed with diabetes to local resources and support groups.

Physiological Integrity

13. Compare the risk factors, age of onset, manifestations, and pathologic mechanisms of type 1 and type 2 diabetes mellitus.
14. Explain the effects of insulin on carbohydrate, protein, and fat metabolism.
15. Explain how to mix different kinds of insulin together.
16. Evaluate laboratory data to determine effectiveness of the prescribed dietary, drug, and exercise therapies for diabetes.
17. Explain how to perform foot assessment and foot care for the patient with diabetes.
18. Collaborate with members of the health care team to provide care for patients with diabetic ketoacidosis (DKA) or hyperglycemic-hyperosmolar state (HHS).

Diabetes mellitus (DM) is a chronic metabolic disease that requires lifelong behavioral and lifestyle changes. A collaborative approach helps the patient successfully manage the disease. As part of the team, you will plan, organize, and coordinate care with other health care team members to

provide care and education and promote the patient's health and well-being.

Diabetes is a major public health problem, and its complications, especially hypertension and **hyperlipidemia** (high blood lipid levels), cause many serious health problems. In

the United States, diabetes mellitus (DM) is a leading cause of blindness, end-stage kidney disease, and foot or leg amputations. Many people have undiagnosed diabetes and, among those who are diagnosed, many have continuous high blood glucose levels. The complications of DM can be greatly reduced with **glycemic** (blood glucose) control along with management of hypertension and hyperlipidemia. Thus nursing priorities focus on helping the patient with diabetes achieve and maintain lifestyle changes that prevent long-term complications by keeping blood glucose levels and cholesterol levels as close to normal as possible (Young, 2011).

PATHOPHYSIOLOGY

Classification of Diabetes

For all types of diabetes mellitus (DM), the main feature is chronic **hyperglycemia** (high blood glucose level) resulting from problems with insulin secretion, insulin action, or both. The disease is classified by the underlying problem causing a lack of insulin and the severity of the insulin deficiency. Table 67-1 outlines the types of DM.

The Endocrine Pancreas

The pancreas has mostly exocrine functions that are related to digestion and endocrine functions that are related to blood glucose control. The endocrine portion of the pancreas has about 1 million small glands, the *islets of Langerhans*, scattered through the organ. The two types of islet cells

important to glucose control are the *alpha cells*, which secrete glucagon, and the *beta cells*, which produce insulin and amylin. **Glucagon** is a “counterregulatory” hormone that has actions opposite those of insulin. It prevents *hypoglycemia* (low blood glucose levels) by triggering the release of glucose from cell storage sites. Insulin prevents hyperglycemia by allowing body cells to take up, use, and store carbohydrate, fat, and protein.

Active insulin is a protein made up of 51 amino acids. It is initially produced as inactive *proinsulin*, a prohormone that contains an additional amino acid chain (the C-peptide chain). Proinsulin is converted into active insulin by removal of the C-peptide (Fig. 67-1).

About 40 to 50 units of insulin is secreted daily directly into liver circulation in a two-step manner. It is secreted at low levels during fasting (**basal insulin secretion**) and at increased levels after eating (**prandial**). An early burst of insulin secretion occurs within 10 minutes of eating. This is followed by an increasing release that lasts until the blood glucose level is normal.

Glucose Homeostasis

Glucose is the main fuel for central nervous system (CNS) cells. Because the brain cannot produce or store much glucose, it needs a continuous supply from circulation to prevent

TABLE 67-1 CLASSIFICATION OF DIABETES MELLITUS

Type 1 Diabetes

- Beta-cell destruction leading to absolute insulin deficiency
- Autoimmune
- Idiopathic

Type 2 Diabetes

- Ranges from insulin resistance with relative insulin deficiency to secretory deficit with insulin resistance

Other Specific Conditions Resulting in Hyperglycemia

- Genetic defects of beta-cell function
- Genetic defects in insulin action
- Diseases of the exocrine pancreas: pancreatitis, trauma, neoplasia, cystic fibrosis, hemochromatosis
- Endocrinopathies: acromegaly, Cushing's disease, glucagonoma, pheochromocytoma, hyperthyroidism, aldosteronism
- Drug or chemical-induced conditions (from use of pentamidine, nicotinic acid, glucocorticoids, thyroid hormone, diazoxide, beta-adrenergic agents, thiazides, phenytoin, interferon-alpha, other drugs)
- Infections: congenital rubella, cytomegalovirus, human immune deficiency virus
- Uncommon forms of immune-related diabetes
- Other genetic syndromes associated with diabetes: Down syndrome, Klinefelter syndrome, Turner's syndrome, Huntington disease, and others

Gestational Diabetes Mellitus (GDM)

- Glucose intolerance with onset or first recognition during pregnancy

FIG. 67-1 Proinsulin, secreted by and stored in the beta cells of the islets of Langerhans in the pancreas, is transformed by the liver into active insulin. Insulin attaches to receptors on target cells, where it promotes glucose transport into the cells through the cell membranes.

neuronal dysfunction and cell death. Other organs can use both glucose and fatty acids to generate energy. Glucose is stored inside cells as glycogen in the liver and muscles, and free fatty acids are stored as triglyceride in fat cells. Fat is the most efficient means of storing energy. Fat has 9 calories of stored energy per gram. Protein and carbohydrate have only 4 calories per gram. During a prolonged fast or after illness or injury, proteins are broken down and some of the amino acids are converted into glucose.

Several organs and hormones play a role in maintaining glucose homeostasis. During the fasting state, when the stomach is empty, blood glucose is maintained between 60 and 150 mg/dL (3.3 and 8.3 mmol/L) by a balance between glucose uptake by cells and glucose production by the liver. Insulin plays a pivotal role in this process.

Movement of glucose into some cells requires the presence of specific carrier proteins, glucose transport (GLUT) proteins and insulin. Insulin is like a “key” that opens “locked” membranes to glucose, allowing glucose in the blood to move into cells to generate energy. Insulin starts this action by binding to insulin receptors on the cell membranes, which changes membrane permeability to glucose.

Insulin exerts many effects on metabolism and cellular processes in different body tissues and organs. The main metabolic effects of insulin are to stimulate glucose uptake in skeletal muscle and heart muscle and to suppress liver production of glucose and very-low-density lipoprotein (VLDL). In the liver, insulin promotes the production and storage of glycogen (**glycogenesis**) at the same time that it inhibits glycogen breakdown into glucose (**glycogenolysis**). It increases protein and lipid (fat) synthesis and inhibits **ketogenesis** (conversion of fats to acids) and **gluconeogenesis** (conversion of proteins to glucose). In muscle, insulin promotes protein and glycogen synthesis. In fat cells, it promotes triglyceride storage. Overall, insulin keeps blood glucose levels from becoming too high and helps keep blood lipid levels in the normal range.

In the *fasting state* (not eating for 8 hours), insulin secretion is suppressed, which leads to increased gluconeogenesis in the liver and kidneys, along with increased glucose generation by the breakdown of liver glycogen. In the fed state, insulin released from pancreatic beta cells reverses this process. Instead, glycogen breakdown and gluconeogenesis are inhibited. At the same time, insulin also enhances glucose uptake and use by cells and reduces both fat breakdown (**lipolysis**) and protein breakdown (**proteolysis**). When more glucose is present in liver cells than can be metabolized for energy or stored as glycogen, insulin causes the excess glucose to be converted to free fatty acids (FFAs). These extra FFAs are deposited as fat in fat cells.

Glucose in the blood after a meal is controlled by the emptying rate of the stomach and delivery of nutrients to the small intestine where they are absorbed into circulation. Incretin hormones (e.g., GLP-1), secreted in response to the presence of food in the stomach, have several actions. They increase insulin secretion, inhibit glucagon secretion, and slow the rate of gastric emptying, thereby preventing hyperglycemia after meals.

Counterregulatory hormones increase blood glucose by actions opposite those of insulin when more energy is needed. Glucagon is the main counterregulatory hormone. Other hormones that increase blood glucose levels are epinephrine,

TABLE 67-2 PHYSIOLOGIC RESPONSE TO INSUFFICIENT INSULIN

- Decreased glycogenesis (conversion of glucose to glycogen)
- Increased glycogenolysis (conversion of glycogen to glucose)
- Increased gluconeogenesis (formation of glucose from non-carbohydrate sources, such as amino acids and lactate)
- Increased lipolysis (breakdown of triglycerides to glycerol and free fatty acids)
- Increased ketogenesis (formation of ketones from free fatty acids)
- Proteolysis (breakdown of protein with amino acid release in muscles)

norepinephrine, growth hormone, and cortisol. The combined actions of insulin and counterregulatory hormones (discussed in the next section) keep blood glucose levels in the range of 60 to 100 mg/dL (3.3 to 5.6 mmol/L) to support brain functions. When glucose levels fall, insulin secretion stops and glucagon is released. Glucagon causes the release of glucose from the liver. Liver glucose is made through breakdown of glycogen to glucose (glycogenolysis) and conversion of amino acids into glucose (gluconeogenesis). When liver glucose is unavailable, the breakdown of fat (lipolysis) and the breakdown of proteins (proteolysis) provide fuel for energy.

Absence of Insulin

Insulin is needed to move glucose into most body tissues. The lack of insulin in diabetes, from either a lack of production or a problem with insulin use at its cell receptor, prevents some cells from using glucose for energy. The body then breaks down fat and protein in an attempt to provide energy and also increases the levels of counterregulatory hormones in an attempt to make glucose from other sources. **Table 67-2** outlines the body's response to insufficient insulin.

Without insulin, glucose builds up in the blood, causing **hyperglycemia**, which is high blood glucose levels. Hyperglycemia causes fluid and electrolyte imbalances, leading to the classic symptoms of diabetes: polyuria, polydipsia, and polyphagia.

Polyuria is frequent and excessive urination and results from an osmotic diuresis caused by excess glucose in the urine. As a result of diuresis, sodium, chloride, and potassium are excreted in the urine and water loss is severe. Dehydration results, and **polydipsia** (excessive thirst) occurs. Because the cells receive no glucose, cell starvation triggers **polyphagia** (excessive eating). Despite eating vast amounts of food, the person remains in starvation until insulin is available to move glucose into the cells.

With insulin deficiency, fats break down, releasing free fatty acids. Conversion of fatty acids to **ketone bodies** (small acids) provides a backup energy source. Because ketone bodies, or “ketones,” are abnormal breakdown products of fatty acids, they collect in the blood when insulin is not available, leading to metabolic acidosis.

The dehydration that occurs with diabetes leads to **hemoconcentration** (an increased blood concentration), **hypovolemia** (a decreased blood volume), **hyperviscosity** (thick, concentrated blood), poor tissue perfusion, and **hypoxia** (poor tissue oxygenation), especially to the brain. Hypoxic

cells do not metabolize glucose efficiently, the Krebs' cycle is blocked, and lactic acid increases, causing more acidosis.

The excess acids caused by absence of insulin increase hydrogen ion (H^+) and carbon dioxide (CO_2) levels in the blood, causing metabolic acidosis. These products trigger the respiratory centers of the brain to increase the rate and depth of respiration in an attempt to excrete more carbon dioxide and acid. This type of breathing is known as **Kussmaul respiration**. Acetone is exhaled, giving the breath a "fruity" odor. When the lungs can no longer offset acidosis, the blood pH drops. Arterial blood gas studies show a metabolic acidosis (decreased pH with decreased arterial bicarbonate [HCO_3^-] levels) and compensatory respiratory alkalosis (decreased partial pressure of arterial carbon dioxide [$Paco_2$]).

Insulin lack initially causes potassium depletion. With the increased fluid loss from hyperglycemia, excessive potassium is excreted in the urine, leading to low serum potassium levels. High serum potassium levels may occur in acidosis because of the shift of potassium from inside the cells to the blood. Serum potassium levels in DM, then, may be low (**hypokalemia**), high (**hyperkalemia**), or normal, depending on hydration, the severity of acidosis, and the patient's response to treatment. Chapter 14 discusses acid-base balance and acidosis in more detail.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

The client newly diagnosed with diabetes asks why he is always so thirsty. What is the nurse's best response?

- "The extra glucose in the blood increases the blood sodium level, which increases your sense of thirst."
- "Without insulin, glucose is excreted rather than used in the cells. The loss of glucose directly triggers thirst, especially for sugared drinks."
- "The extra glucose in the blood makes the blood thicker, which then triggers thirst so that the water you drink will dilute the blood glucose level."
- "Without insulin, glucose combines with blood cholesterol, which damages the kidneys, making you feel thirsty even when no water has been lost."

Acute Complications of Diabetes

Three glucose-related emergencies can occur in patients with diabetes:

- Diabetic ketoacidosis (DKA) caused by lack of insulin and ketosis
- Hyperglycemic-hyperosmolar state (HHS) caused by insulin deficiency and profound dehydration
- Hypoglycemia from too much insulin or too little glucose

All three problems require emergency treatment and can be fatal if treatment is delayed or incorrect. These problems and their interventions are described later.

Chronic Complications of Diabetes

Diabetes mellitus (DM) can lead to health problems and early death because of changes in large blood vessels (**macrovascular**) and small blood vessels (**microvascular**) in tissues and organs. Complications result from poor tissue circulation and cell death. Macrovascular complications, including coronary heart disease, cerebrovascular disease, and peripheral

vascular disease, lead to increased early death. Microvascular complications of blood vessel structure and function lead to **nephropathy** (kidney dysfunction), **neuropathy** (nerve dysfunction), and **retinopathy** (vision problems). Explanations for these diabetic vascular complications include:

- Chronic hyperglycemia thickens basement membranes, which causes organ damage.
- Glucose toxicity directly or indirectly affects functional cell integrity.
- Chronic ischemia in small blood vessels causes connective tissue hypoxia and microischemia.

Chronic high blood glucose levels are the main cause of microvascular complications and allow premature development of macrovascular complications. Additional risk factors that contribute to poor health outcomes for people with DM include smoking, physical inactivity, increased body weight, hypertension, and excessive blood levels of cholesterol and other fats. Many of these factors can be modified to reduced complications related to DM.

The Diabetes Control and Complications Trial (DCCT) showed that hyperglycemia is a critical factor for long-term complications in patients with type 1 DM. Intensive therapy aiming for blood glucose levels as close to normal as possible delays the onset and progression of retinopathy, nephropathy, neuropathy, and macrovascular disease. Additional studies show that intensive therapy with lowered blood glucose levels delays the onset of retinopathy, nephropathy, and neuropathy in patients with type 2 DM. A strong relationship exists between microvascular complications and blood glucose levels. For every percentage point decrease in **HbA_{1c}** (hemoglobin A_{1c}), a 35% reduction in the risk for kidney and eye complications has been shown.

Macrovascular Complications

Cardiovascular Disease. Diabetes mellitus (DM) is associated with a reduced life span, largely as a result of cardiovascular disease (CVD). Most patients with DM die as a result of a thrombotic event, usually myocardial infarction (MI). DM also affects the heart muscle, causing both systolic and diastolic heart failure. Left ventricular dysfunction with heart failure and fatal cardiac dysrhythmias are more common after MI in patients with DM.

Patients with diabetes, those with prediabetes, and those with metabolic syndrome are at increased risk for CVD. This excess risk affects women to a greater degree than men and is influenced by the patient's ethnic group. The Adult Treatment Panel III of the National Cholesterol Education Program recommends that diabetes be considered a "coronary heart disease risk equivalent" and a target for aggressive reduction of risk factors.

Patients with DM often also have the traditional cardiovascular risk factors of obesity, hypertension, dyslipidemia, and sedentary lifestyle. Cigarette smoking and a positive family history greatly increase risk for CVD. Kidney disease, indicated by **albuminuria** (presence of albumin in the urine), increases the risk for coronary heart disease and mortality from MI. Patients with DM often have higher levels of C-reactive protein (CRP), an acute-phase inflammatory marker associated with increased risk for cardiovascular problems and death.

Cardiovascular complication rates can be reduced through aggressive management of hyperglycemia, hypertension, and

hyperlipidemia. The American Diabetes Association (ADA) recommends that blood pressure be maintained below 130/80 mm Hg and that low-density lipoprotein (LDL) cholesterol remain below 100 mg/dL (2.60 mmol/L) for patients without manifestations of CVD and to less than 70 mg/dL (1.8 mmol/L) for patients with manifestations of CVD (ADA, 2010b). Diets high in saturated fat raise total cholesterol and LDL cholesterol levels, which increase the risk for coronary artery disease. Lifestyle modifications that focus on reducing saturated fat, *trans* fat, and cholesterol intake; increasing intake of omega-3 fatty acids, fiber, and plant sterols; weight loss (if indicated); and increasing physical activity are recommended to improve the lipid profile for patients with DM (ADA, 2010b).

Priority nursing actions focus on interventions to reduce modifiable risk factors associated with CVD, such as smoking cessation, diet, exercise, blood pressure control, maintenance of prescribed aspirin use, and maintenance of prescribed lipid-lowering drug therapy.

Cerebrovascular Disease. The risk for stroke is 2 to 4 times higher in people with DM compared with those who do not have the disease. Diabetes also increases the likelihood of severe carotid atherosclerosis. Hypertension, hyperlipidemia, nephropathy, peripheral vascular disease, and alcohol and tobacco use further increase the risk for stroke in people with DM.

DM affects stroke outcomes as well. Patients with DM are likely to suffer irreversible brain damage with carotid emboli that produce only transient ischemic attacks in people without DM. Elevated blood glucose levels at the time of the stroke may lead to greater brain injury and higher mortality.

In addition, chronic hyperglycemia with microvascular disease may contribute to neuronal damage, brain atrophy, and cognitive impairment. These problems are more frequent and more severe in patients who have longer-duration DM and an increase in the complications of neuropathy and retinopathy (Roberts et al., 2008).

Microvascular Complications

Eye and Vision Complications. Legal blindness (a corrected visual acuity of 20/200 or less) is 25 times more common in patients with diabetes. Diabetic retinopathy (DR) is strongly related to the duration of diabetes. After 20 years of DM, nearly all patients with type 1 disease and most with type 2 disease have some degree of retinopathy. Unfortunately, DR has few manifestations until vision loss occurs.

The cause and progression of DR are related to problems that block retinal blood vessels and cause them to leak, leading to retinal hypoxia. **Nonproliferative diabetic retinopathy** (Fig. 67-2) causes structural problems in retinal vessels, including areas of poor retinal circulation, edema, hard fatty deposits in the eye, and retinal hemorrhages. Microaneurysms are small capillary wall dilations in retinal vessels that form throughout the eye and leak fluid and blood into the retina. This leakage causes retinal edema and hard exudates.

Other retinal problems include retinal hemorrhages, optic nerve atrophy from hypoxia, and venous beading. **Venous beading** is the abnormal appearance of retinal veins in which areas of swelling and constriction along a segment of vein resemble links of sausage. It occurs in areas of retinal ischemia. Nonproliferative diabetic retinopathies develop slowly and rarely cause reduced vision to the point of blindness.

FIG. 67-2 Select ophthalmic changes seen in nonproliferative diabetic retinopathy.

FIG. 67-3 Ophthalmic hemorrhage that is possible with proliferative diabetic retinopathy.

Proliferative diabetic retinopathy is the growth of new retinal blood vessels, also known as *neovascularization*. When retinal blood flow is poor and hypoxia develops, retinal cells secrete growth factors that stimulate formation of new blood vessels in the eye. These new vessels are thin, fragile, and bleed easily, leading to eye hemorrhage and vision loss (Fig. 67-3).

Vision loss from DR has several mechanisms. Central vision may be impaired by macular edema, which can occur at any stage of DR. Diabetic macular edema is characterized by increased blood vessel permeability and deposits of hard exudates at the center of the retina. This problem is the main cause of vision loss in the person with DM. Vision loss also occurs from macular degeneration, corneal scarring, and changes in lens shape or clarity.

Hyperglycemia may cause blurred vision, even with eyeglasses. Hypoglycemia may cause double vision. Cataracts occur at a younger age and progress faster among patients with DM. Open-angle glaucoma also is more common in patients with DM. The management of cataracts and glaucoma is the same as for patients who do not have diabetes (see Chapter 49).

Control of blood glucose, blood pressure, and blood lipid level is important in preventing DR. Thus patients with DM

TABLE 67-3 FEATURES OF DIABETIC NEUROPATHY

COMPLICATION		MANIFESTATION
Diffuse Neuropathies		
Distal symmetric polyneuropathy	Sensory alterations	Paresthesias: burning/tingling sensations, starting in toes and moving up legs Dysesthesias: burning, stinging, or stabbing pain Anesthesia: loss of sensation
	Motor alterations in intrinsic muscles of foot	Foot deformities: high arch, claw toes, hammertoes; shift of weight-bearing to metatarsal heads and tips of toes
Autonomic neuropathy	Anhidrosis	Drying, cracking of skin
	Gastrointestinal	Delayed gastric emptying, gastric retention, early satiety, bloating, nausea, vomiting, anorexia, constipation, diarrhea
	Neurogenic bladder	Atonic bladder, urinary retention
	Impotence	Erectile dysfunction
	Cardiovascular autonomic neuropathy	Early fatigue, weakness with exercise, orthostatic hypotension
	Defective counterregulation	Loss of warning signs of hypoglycemia
Focal Neuropathies		
Focal ischemia	Thoracolumbar radiculopathy with sensory and reflex loss	Pain radiating across back, side, and front of chest or abdomen
	Cranial nerve palsies, third and sixth nerves	Sudden diplopia or ptosis; eye pain
	Amyotrophy	Pain; asymmetric weakness; wasting of iliopsoas, quadriceps, and adductor muscles
Entrapment neuropathies	Median nerve	Carpal tunnel syndrome
	Popliteal nerve/knee	Footdrop
	Posterior tibial nerve at tarsal tunnel	Tarsal tunnel syndrome: sensory impairment in sole of foot; weakness of intrinsic muscles of foot; burning pain and paresthesias at ankle and plantar surface

should have routine ophthalmic evaluations to detect vision problems early before vision loss occurs.

CONSIDERATIONS FOR OLDER ADULTS

The older patient with diabetic retinopathy also has visual changes from aging. As a result, the patient's ability to perform self-care may be seriously affected. The patient with retinopathy may have blurred vision, distorted central vision, fluctuating vision, loss of color perception, and mobility problems resulting from loss of depth perception. It is especially important to assess the patient's ability to measure and inject insulin and to monitor blood glucose levels to determine if adaptive devices are needed to assist in self-management activities.

Diabetic Neuropathy. Neuropathy is a progressive deterioration of nerves that results in loss of nerve function. It is a common complication of DM and often involves all parts of the body. Damage to sensory nerve fibers results in either pain or loss of sensation. Damage to motor nerve fibers results in muscle weakness. Damage to nerve fibers in the autonomic nervous system can cause dysfunction in every part of the body. This combination of factors leads to the nerve damage in diabetic neuropathy (Bedlack, 2009):

- Metabolic factors of hyperglycemia, long duration of DM, hyperlipidemia, low insulin levels
- Damaged blood vessels leading to reduced neuronal oxygen and other nutrients
- Autoimmune neuronal inflammation
- Increased genetic susceptibility to nerve damage
- Smoking and alcohol use

Hyperglycemia leads to neuropathy through blood vessel changes that cause nerve hypoxia. Both the axon and its myelin sheath are damaged by reduced blood flow, resulting

in blocked nerve impulse transmission. Excessive glucose is converted to sorbitol, which collects in nerves. The increased sorbitol also impairs motor nerve conduction. Common diabetic neuropathies are listed in Table 67-3. Autonomic nervous system neuropathy leads to problems in cardiovascular, GI, and urinary function. Keeping blood glucose levels in the normal range can slow the development and progression of diabetic neuropathies.

Diabetic neuropathy can be focal or diffuse, each with different causes and rates of progression. *Diffuse neuropathies* are the most common neuropathies in DM and involve widespread nerve function loss. They have a slow onset, affect both sides of the body, involve motor and sensory nerves, progress slowly, are permanent, and include autonomic nerve dysfunction. Late complications include foot ulcers and deformities.

Focal neuropathies affect a single nerve or nerve group and usually are caused by an acute ischemic event or by nerve trapping. Both problems lead to nerve damage or nerve death. Ischemic neuropathies occur when the blood supply to a nerve or nerve group is disrupted. The symptoms begin suddenly, affect only one side of the body area, and are self-limiting. Recovery time varies. The most common neuropathies affect the nerves that control the eye muscles. Manifestations begin with pain on one side of the face near the affected eye. The eye muscles become paralyzed, resulting in double vision. The problem usually resolves in 2 to 3 months.

Entrapment neuropathies stem from trapping and compressing a nerve in a body compartment or between tissues. Symptoms begin gradually and can occur anywhere. They may be bilateral, having a waxing and waning course without spontaneous recovery. An example of focal entrapment neuropathy is carpal tunnel syndrome.

Cardiovascular autonomic neuropathy (CAN) affects sympathetic and parasympathetic nerves of the heart and blood vessels. This problem contributes to left ventricular dysfunction, painless myocardial infarctions, and exercise intolerance. Most often, CAN leads to **orthostatic** (postural) hypotension and **syncope** (brief loss of consciousness on standing). These problems are due to failure of the heart and arteries to adjust to position changes by increasing heart rate and vascular tone. As a result, blood flow to the brain is interrupted briefly. Orthostatic hypotension and syncope increase the risk for falls, especially among older adults.

Autonomic neuropathy can affect the entire GI system. Common GI problems from diabetic neuropathy include gastroesophageal reflux, delayed gastric emptying and gastric retention, early satiety, heartburn, nausea, vomiting, and anorexia. Sluggish movement of the small intestine can lead to bacterial overgrowth, which causes bloating, gas, and diarrhea. Diarrhea caused by diabetes is chronic, may be severe, and often occurs at night. Constipation, the most common GI problem with DM, is intermittent and may alternate with bouts of diarrhea. **Gastroparesis** (delay in gastric emptying) is a cause of hypoglycemia.

Urinary problems from neuropathy results in incomplete emptying and urine retention, which leads to urinary infection and kidney problems. Manifestations include frequency, urgency, and incontinence.

Diabetic Nephropathy. **Nephropathy** is a pathologic change in the kidney that reduces kidney function and leads to kidney failure. Diabetes is the leading cause of end-stage kidney disease (ESKD) and kidney failure in the United States. Risk factors for nephropathy include a 10- to 15-year history of DM, diabetic retinopathy, poor blood glucose control, uncontrolled hypertension, and genetic predisposition. Studies have shown that the onset of diabetic kidney disease may be prevented and the progression to ESKD can be delayed by maintaining optimum blood glucose control, keeping blood pressure within the normal ranges, and using drug therapy to protect the kidneys (*American Association of Diabetic Educators [AADE], 2009a*). Drugs that protect the kidneys are the angiotensin-converting enzyme (ACE) inhibitors and the angiotensin receptor blockers (ARBs).

Kidney disease causes progressive albumin excretion and a declining glomerular filtration rate (GFR). The earliest manifestation of nephropathy is **microalbuminuria** (small amounts of albumin in the urine). Annual testing for microalbuminuria is recommended for patients who have had type 1 DM for at least 5 years and in everyone with type 2 DM (*ADA, 2010b*).

Chronic high blood glucose levels cause hypertension in kidney blood vessels and excess kidney perfusion. The increased pressure damages the kidney in many ways. The blood vessels become leakier, especially in the glomerulus. This leakiness allows filtration of larger particles (including albumin and other proteins), which then form deposits in the kidney tissue and blood vessels. Blood vessels narrow, decreasing kidney oxygenation and leading to kidney cell hypoxia and cell death. These processes worsen over time, with scarring of glomerular blood vessels and loss of urine filtration ability, leading to kidney failure.

Kidney damage is also related to hypertension for patients with DM and cardiovascular disease. Both systolic and

diastolic hypertension speed the progression of diabetic nephropathy.

Male Erectile Dysfunction. Erectile dysfunction (ED) is the inability to achieve or maintain a penile erection sufficient for satisfactory sexual performance. ED occurs at a higher rate (about 50%) and an earlier age among men with DM as compared with the general population. This occurs 10 to 15 years earlier than in the general population and increases with age. It is related to poor blood glucose control, obesity, hypertension, heavy cigarette smoking, and the presence of other chronic vascular complications. *Chapter 75* discusses erectile function problems in depth.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Why is controlling blood glucose levels important?

- A. High blood glucose levels increase the risk for heart disease, strokes, blindness, and kidney failure.
- B. High blood glucose levels increase the risk for seizure disorders, arthritis, osteoporosis, and bone fractures.
- C. Low blood glucose levels increase the risk for peripheral neuropathy, Alzheimer's disease, and premature aging.
- D. Low blood glucose levels increase the risk for obesity, pancreatitis, dehydration, and certain types of cancer.

Etiology and Genetic Risk

Type 1 Diabetes

Type 1 diabetes mellitus (DM) is an autoimmune disorder in which beta cells are destroyed in a genetically susceptible person (*Table 67-4*). The immune system fails to recognize normal body cells as “self” and takes destructive actions against them. In type 1 DM, immune system cells, mediators, and antibodies attack and destroy insulin-secreting cells in the islets. Although the exact cause of why normal cells are attacked by immune system cells is not known, people with certain tissue types are more likely to develop autoimmune diseases, including type 1 DM. Specifically, patients who have the tissue types *HLA-DR* or *HLA-DQ* are at an increased risk for type 1 DM. Certain viral infections, such as mumps and coxsackievirus infection, appear to trigger autoimmune destruction of pancreatic beta cells (*McCance et al., 2010*).

Indicators or markers of immune damage to insulin-producing cells (a key feature of type 1 DM) are the presence of blood antibodies directed against the beta cells themselves or against substances made by beta cells. Most patients with type 1 diabetes have islet cell antibodies (ICAs), insulin

GENETIC/GENOMIC CONSIDERATIONS

Risk for type 1 diabetes is determined by inheritance of genes coding for the *HLA-DR* and *HLA-DQ* tissue types. However, although inheritance of these genes increases the risk, most people with these genes do not develop type 1 diabetes. Development of the disease is an interactive effect of genetic predisposition and exposure to certain environmental factors. The risk for type 1 diabetes in the general population ranges from 1 in 400 to 1 in 1000. The risk greatly increases for those who have at least one parent with diabetes (from 1 in 20 to 1 in 50) (*Nussbaum et al., 2007*). It is unclear why some genetically susceptible people develop diabetes and others do not.

TABLE 67-4 DIFFERENTIATION OF TYPE 1 AND TYPE 2 DIABETES

FEATURES	TYPE 1	TYPE 2
Former names	Juvenile-onset diabetes Ketosis-prone diabetes Insulin-dependent diabetes mellitus (IDDM)	Adult-onset diabetes Ketosis-resistant diabetes Non–insulin-dependent diabetes mellitus (NIDDM)
Age at onset	Usually younger than 30 yr, occurs at any age	Peaks in 50s; may occur earlier
Symptoms	Abrupt onset, thirst, hunger, increased urine output, weight loss	Frequently none; thirst, fatigue, blurred vision, vascular or neural complications
Etiology	Viral infection	Not known
Pathology	Pancreatic beta-cell destruction	Insulin resistance Dysfunctional pancreatic beta cell
Antigen patterns	<i>HLA-DR, HLA-DQ</i>	None
Antibodies	ICAs present at diagnosis	None
Endogenous insulin and C-peptide	None	Low, normal, or high
Inheritance	Complex	Dominant, multifactorial
Nutritional status	Usually nonobese	60% to 80% obese
Insulin	All dependent on insulin	Required for 20% to 30%
Medical nutrition therapy	Mandatory	Mandatory

ICAs, Islet cell antibodies.

autoantibodies (IAAs), autoantibodies to glutamic acid decarboxylase (GAD), or autoantibodies to tyrosine phosphates. Circulating ICA and IAA may be present before manifestations of type 1 DM develop.

Type 2 Diabetes and Metabolic Syndrome

Type 2 DM is a progressive disorder in which the person has a combination of insulin resistance and decreased secretion of insulin by pancreatic beta cells. Insulin resistance (a reduced ability of cells to respond to insulin) develops from obesity and physical inactivity in a genetically susceptible person. Insulin resistance occurs before the onset of type 2 DM and often is accompanied by other cardiovascular risk factors of hyperlipidemia, hypertension, and increased clot formation. Most patients with type 2 DM are obese. With the increased rate of obesity occurring in younger people, the age of onset for type 2 DM is also decreasing. The specific causes of type 2 DM are not known, although insulin resistance and beta-cell failure have many genetic and nongenetic causes. Heredity plays a major role in the development of type 2 DM. Offspring of patients with type 2 DM have a 15% chance for developing the disease and a 30% risk for having impaired glucose tolerance. Specific gene defects have been identified in certain groups with high incidence rates of type 2 DM (Nussbaum et al., 2007).

Metabolic syndrome, also called *syndrome X*, is the simultaneous presence of metabolic factors known to increase risk for developing type 2 DM and cardiovascular disease. Features of the syndrome include:

- Abdominal obesity: waist circumference of 40 inches (100 cm) or more for men and 35 inches (88 cm) or more for women
- Hyperglycemia: fasting blood glucose level of 100 mg/dL or more or on drug treatment for elevated glucose
- Hypertension: systolic BP of 130 mm Hg or more or diastolic BP of 85 mm Hg or more or on drug treatment for hypertension
- Hyperlipidemia: triglyceride level of 150 mg/dL or more or on drug treatment for elevated triglycerides; high-density lipoprotein (HDL) cholesterol less than 40 mg/dL for men or less than 50 mg/dL for women

Any one of these health problems increases the rate of atherosclerosis and the risk for stroke, coronary heart disease, and early death. Teach patients about the lifestyle changes that can improve health. Reducing weight to within 20% of ideal or body mass index to less than 25 kg/m² by modifying diet and exercising more will reduce cardiovascular risk. Drug therapy may be required to achieve desired lipid and blood pressure outcomes.

Incidence/Prevalence

More than 57 million American adults have **prediabetes**, defined as impaired fasting glucose (IFG) or impaired glucose tolerance (IGT). IFG (fasting plasma glucose levels of 100 mg/dL [5.6 mmol/L] to 125 mg/dL [6.9 mmol/L]) and IGT (2-hr oral glucose tolerance values of 140 mg/dL [7.8 mmol/L] to 199 mg/dL [11.0 mmol/L]) are considered risk factors for diabetes and for cardiovascular disease. Over a 3- to 5-year period, people with prediabetes have a fivefold to fifteenfold higher risk for developing type 2 DM than do those with normal blood glucose levels. IFG and IGT are associated with obesity (especially abdominal or central obesity), dyslipidemia with high triglycerides and/or low HDL cholesterol, and hypertension (AADE, 2009b).

The Diabetes Prevention Trial demonstrated that changes in physical activity and eating habits (primarily reduced calories from fat) resulting in weight loss were associated with reduced diabetes risk. Encourage the person with prediabetes to adopt healthy eating habits that limit caloric and fat intake sufficient for weight reduction and to participate in physical activity in order to sustain weight loss.

Diabetes is the seventh leading cause of death in the United States, where it affects 25.8 million people, or 8.3% of the population. An additional 7.0 million people are unaware they have the disease (ADA, 2011).

About 90% of people with diabetes have type 2 DM. It is diagnosed most often among middle-aged and older adults, affecting about 9.6% of patients ages 20 to 59 years and 20.9% of patients ages 60 years or older. The prevalence of diabetes is higher for men than for women (ADA, 2011).

Although type 2 diabetes is a disease of middle-aged and older adults, recent surveys show an increase of the disorder in childhood and adolescence as a result of obesity. Because the prevalence of obesity is rising in North America, diabetes will become even more common. Obesity and a higher-than-normal body mass index (BMI) greatly increase the risk for diabetes.

HEALTH PROMOTION AND MAINTENANCE

Diabetes is a common disorder causing many preventable but devastating complications and is a major public health problem. Control of diabetes and its complications is a major focus for health promotion activities. No interventions are successful in preventing type 1 DM. Health promotion for patients with type 1 DM focuses on controlling hyperglycemia to reduce its long-term complications.

Adopting a low-calorie diet that results in weight loss and increasing physical activity have been shown to improve metabolic and cardiac risk factors. These improvements include reducing hypertension, increasing heart rate variability between resting rate and exercise rate, lowering triglyceride levels, increasing high-density lipoprotein cholesterol (the “good” cholesterol) levels, and reducing low-density lipoprotein cholesterol (the “bad” cholesterol) levels. These changes reduce the incidence of type 2 DM in older adults by 58% (Mozaffarian et al., 2009).

Teach all patients with DM that tight control of blood glucose levels can prevent many complications. Urge all patients with DM to regularly follow up with their health care provider or endocrinologist, to have their eyes and vision tested yearly by an ophthalmologist, and to have urine microalbumin levels assessed yearly. Early detection of changes in the eye or kidney permits adjustments in treatment regimens that can slow or halt progression of retinopathy and

CULTURAL AWARENESS

Diabetes is a significant health problem for African Americans, American Indians, and Mexican Americans. The increase in obesity and sedentary lifestyles in the U.S. population is the probable cause of this growing problem. The ADA has identified patients who should be tested for diabetes in [Table 67-5](#).

Racial and ethnic differences affect clinical outcomes for patients with diabetes. The prevalence of hypertension in patients with diabetes is at least twice the rate of patients who do not have diabetes, with non-Hispanic whites and African Americans having the highest prevalence. Microvascular complications of the eyes, nerves, and kidneys are more common in African Americans and American Indians with diabetes than in non-Hispanic whites with diabetes. Possible factors for these differences include lack of access to health care, lifestyle issues, mistrust of the health care system, reduced financial resources, and lack of knowledge about the relationship between glucose control and complications.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

The client newly diagnosed with type 2 diabetes asks how diabetes type 1 and diabetes type 2 are different. What is the nurse's best response?

- “Diabetes type 1 develops in people younger than 40 years and diabetes type 2 develops only in older people.”
- “Diabetes type 2 develops in people younger than 40 years and diabetes type 1 develops only in older people.”
- “Patients with type 1 diabetes are at higher risk for obesity and heart disease, whereas patients with type 2 diabetes are at higher risk for strokes.”
- “Patients with type 1 diabetes produce no insulin and patients with type 2 diabetes produce insulin but their insulin receptors are not very sensitive to it.”

TABLE 67-5 INDICATIONS FOR TESTING INDIVIDUALS FOR TYPE 2 DIABETES

- Testing for diabetes should be considered in people 45 years of age and older, particularly in those with a BMI greater than 25 kg/m². If normal, it should be repeated at 3-year intervals.
- Testing should be considered at a younger age or be carried out more frequently in people who are overweight (BMI >25 kg/m²) and have these additional associated factors:
 - Have a first-degree relative with diabetes
 - Are habitually physically inactive
 - Are members of a high-risk ethnic population (e.g., African American, Hispanic American, American Indian, Asian American, or Pacific Islander)
- Deliver a baby weighing more than 9 pounds or have been diagnosed with GDM
- Are hypertensive (>140/90 mm Hg)
- Have a high-density lipoprotein (HDL) cholesterol level less than 35 mg/dL (0.90 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.82 mmol/L)
- Have polycystic ovary syndrome
- Have IFG or IGT on previous testing
- Have a history of vascular disease

Data from American Diabetes Association (ADA). (2010a). Position statement: Diagnosis and classification of diabetes mellitus. *Diabetes Care*, 33(Suppl. 1), 14. BMI, Body mass index; GDM, gestational diabetes mellitus; IFG, impaired fasting glucose; IGT, impaired glucose tolerance.

nephropathy. Encourage all people to maintain weight within an appropriate range for height and body build and to engage in physical activity at least three times per week.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Ask questions about risk factors and symptoms related to diabetes. Age is important because type 2 diabetes mellitus (DM) is more common in older patients, especially among African Americans and Mexican Americans. Ask women how large their children were at birth, because many women who develop type 2 DM had gestational diabetes or were glucose intolerant during pregnancy. These women often have given birth to infants weighing 9 pounds or more.

Assessing weight and weight change is important, because excess weight and obesity are risk factors for type 2 DM. The patient with type 1 DM often has weight loss with increased appetite during the weeks before diagnosis. For both types of DM, patients usually have fatigue, polyuria, and polydipsia. Ask about recent major or minor infections. In particular, ask women about frequent vaginal yeast infections. Ask all patients whether they have noticed that small skin injuries become infected more easily or take longer to heal. Also ask whether they have noticed any changes in vision or in the sense of touch.

Laboratory Assessment

Diagnosis of Diabetes. Diabetes can be diagnosed by assessing blood glucose levels. The ADA defines normal blood glucose values in [Chart 67-1](#). ADA criteria for the diagnosis of type 2 DM are outlined in [Table 67-6](#). A test result

CHART 67-1 LABORATORY PROFILE

Blood Glucose Values

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL RESULTS
Fasting blood glucose test	<100 mg/dL (5.6 mmol/L) Older adults: Levels rise 1 mg/dL per decade of age	Levels >100 mg/dL (5.6 mmol/L) but <126 mg/dL (7.0 mmol/L) indicate impaired fasting glucose (IFG). Levels >126 mg/dL (7.0 mmol/L) obtained on at least two occasions are diagnostic of diabetes, even in older adults.
Glucose tolerance test (2-hr post-load result)	<140 mg/dL (7.8 mmol/L)	Levels >140 mg/dL (7.8 mmol/L) and <200 mg/dL (11.1 mmol/L) indicate impaired glucose tolerance (IGT). Levels >200 mg/dL (11.1 mmol/L) indicate provisional diagnosis of diabetes.
Glycosylated hemoglobin (hemoglobin A _{1c} [HbA _{1c}]) test	4%-6%	Levels >8% indicate poor diabetic control and need for adherence to regimen or changes in therapy.

Data from American Diabetes Association (ADA). (2010a). Position statement: Diagnosis and classification of diabetes mellitus. *Diabetes Care*, 33(Suppl. 1), 42-47; American Diabetes Association (ADA). (2010b). Position statement: Standards of medical care in diabetes—2010. *Diabetes Care*, 33(Suppl. 1), 11-61.

TABLE 67-6 CRITERIA FOR THE DIAGNOSIS OF TYPE 2 DIABETES

A_{1c} 6.5%. The test should be performed in a laboratory using a method that is NGSP certified and standardized to the DCCT assay.
Or
Fasting plasma glucose greater than 126 mg/dL (7.0 mmol/L).
Fasting is defined as no caloric intake for at least 8 hr.
Or
2-hr plasma glucose greater than 200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test. The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.
Or
In a patient with classic manifestations of hyperglycemia or hyperglycemic crisis, a casual blood glucose concentration greater than 200 mg/dL (11.1 mmol/L). *Casual* is defined as any time of the day without regard to time since last meal. The classic manifestations of diabetes include polyuria, polydipsia, and unexplained weight loss.

NOTE: In the absence of unequivocal hyperglycemia, the first three criteria should be confirmed by repeat testing.

Data from American Diabetes Association (ADA). (2010a). Position statement: Diagnosis and classification of diabetes mellitus. *Diabetes Care*, 33(Suppl. 1), 14. NGSP, National Glycohemoglobin Standardization Program; DCCT, Diabetes Control and Complications Trial.

CHART 67-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Blood Glucose Testing**Fasting Blood Glucose**

- Do not eat any food or drink any liquid except water for at least 8 hours before the test.

Oral Glucose Tolerance Test

- Eat a balanced diet with carbohydrate intake of at least 150 g for a minimum of 3 days before the test while maintaining normal physical activity.
- Carbohydrate restriction, bedrest, acute illness, and certain drugs interfere with the test. Phenytoin (Dilantin), anovulatory drugs, diuretics, nicotinic acid, and glucocorticoids adversely affect results.
- The test is performed in the morning after a 10- to 12-hour fast.
- A fasting blood sample is obtained.
- You will be asked to drink 300 mL of a flavored beverage containing 75 g of glucose within 5 minutes of the fasting blood sample.
- Blood samples are drawn at 30-minute intervals for 2 hours.
- During the test, you will remain at rest and not be able to smoke or drink liquids.

diagnostic of DM should be repeated to rule out laboratory error unless classic manifestations of hyperglycemia or hyperglycemic crisis are also present.

The diagnosis of diabetes mellitus has recently changed to include elevated glycosylated hemoglobin levels. This test was not previously recommended for diagnosing diabetes because of a lack of assay standardization. **Glycosylated hemoglobin A_{1c} (HbA_{1c})** is a test that measures how much glucose permanently attaches to a specific area of the hemoglobin molecule. Because glucose binds to a variety of proteins (including hemoglobin) through a process called *glycosylation*, the higher the blood glucose level is over time, the more glycosylated hemoglobin becomes. HbA_{1c} testing is now highly standardized for accuracy and precision. The ADA defines HbA_{1c} levels greater than 6.5% as diagnostic of DM (ADA, 2009).

Fasting plasma glucose (FPG) is used to diagnose diabetes in nonpregnant adults. The patient should have no caloric intake for at least 8 hours (water is permitted). The blood sample needs to be obtained before insulin or oral antidiabetic agents have been taken. A diagnosis of diabetes is made with two separate test results greater than 126 mg/dL (7 mmol/L) (ADA, 2010a). Patient and family education about blood glucose testing is presented in [Chart 67-2](#). *Random or casual plasma glucose* greater than 200 mg/dL (7.0 mmol/L) is used to diagnose diabetes in patients with severe classic hyperglycemia or hyperglycemic crisis.

Oral glucose tolerance testing (OGTT) is the most sensitive test for the diagnosis of DM. However, it is not routinely used in the diagnosis because it is inconvenient to patients, costly, and time consuming compared with fasting blood glucose measures. The diagnosis of gestational diabetes mellitus (GDM) is based on the oral glucose tolerance test (75-g glucose load, 2-hr test or 100-g glucose load, 3-hr test). Before the test, review instructions from [Chart 67-2](#) with the patient. He or she drinks a beverage containing a glucose load, and blood samples are collected at hourly intervals. Two or more

of the plasma levels must be met or exceeded for a diagnosis of DM (ADA, 2010a).

Other blood tests for diabetes can help determine whether a patient has type 1 or type 2 DM, although they are not commonly used. Type 1 DM is an autoimmune disease with the presence of autoantibodies to proteins. The presence of islet cell antibodies (ICAs) is an indicator for type 1 DM. Measurement of C-peptide levels indicates beta secretory function of the pancreas. C-peptide levels correlate well with insulin levels and are used to diagnose type 1 DM.

Screening for Diabetes. Evidence from type 1 DM prevention studies suggests that measurement of islet cell antibodies identifies people who are at risk for developing type 1 DM. Testing to detect prediabetes and type 2 DM should be considered in patients older than 45 years and those defined as overweight (BMI greater than 25 kg/m²). Testing is considered for patients who are younger than 45 years and are overweight if they have additional risk factors for diabetes or have other health problems associated with diabetes. Screening for diabetes is done with hemoglobin A_{1c} levels or either fasting plasma glucose levels or the 2-hour OGTT (75-g glucose load) (ADA, 2010a; ADA, 2010b).

Ongoing Assessment. Glucose can bind to a variety of structures, including proteins, through a process called *glycosylation*. *Glycosylated hemoglobin assays* are useful because blood glucose permanently attaches to hemoglobin. The higher the blood glucose level is over time, the more glycosylated hemoglobin becomes. Thus glycosylated HbA_{1c} is a good indicator of the average blood glucose levels. Measurement of A_{1c} shows the average blood glucose level during the previous 120 days—the life span of red blood cells. HbA_{1c} testing is used to assess long-term glycemic control, as well as to predict the risk for complications. *Unlike the fasting blood glucose test, HbA_{1c} test results are not altered by eating habits the day before the test.* This testing is performed at diagnosis and at specific intervals to evaluate the treatment plan. Hemolysis, blood loss, and pregnancy all increase red blood cell turnover and reduce HbA_{1c} levels. Triglycerides and bilirubin interfere with the assay, leading to overestimation of A_{1c} levels in patients with hypertriglyceridemia. HbA_{1c} testing is recommended at least twice yearly in patients who are meeting expected treatment outcomes and have stable blood glucose control. Quarterly assessment is recommended for patients whose therapy has changed or who are not meeting prescribed glycemic levels (ADA, 2010a). Table 67-7 shows the correlation between HbA_{1c} and mean blood glucose levels.

When glucose binds to amino groups on serum proteins, especially albumin, the glycosylated protein product is called *fructosamine*. This product increases with elevated blood glucose levels in the same way as hemoglobin does. However, because serum proteins and albumin turn over in 14 days, compared with 120 days for red blood cells, these proteins can indicate blood glucose control over a shorter period. These measures are useful when tight control of blood glucose is necessary (e.g., pregnancy), in short-term follow-up of treatment changes, or in patients with hemoglobin abnormalities in which HbA_{1c} is not an accurate reflection of glucose control. Available tests are called *glycosylated serum albumin* (GSA), *glycosylated serum protein* (GSP), and *fructosamine*.

Urine Tests. *Ketone bodies* are a product of fat metabolism. The presence of moderate to high urine ketones (hyperketonuria) indicates a severe lack of insulin. Hyperketonuria

TABLE 67-7 CORRELATION BETWEEN HBA_{1c} LEVEL AND MEAN PLASMA GLUCOSE LEVELS

HBA _{1c} (%)	MEAN PLASMA GLUCOSE	
	MG/DL	MMOL/L
6	126	7.0
7	154	8.6
8	183	10.2
9	212	11.8
10	240	13.4
11	269	14.9
12	298	16.5

Data from American Diabetes Association (ADA). (2010b). Position statement: Standards of medical care in diabetes—2010. *Diabetes Care*, 33(Suppl. 1), 19. HbA_{1c}, Hemoglobin A_{1c}.

in the presence of hyperglycemia is a medical emergency that, when detected early, can be treated with insulin and careful monitoring. Urine testing for ketones should be performed during acute illness or stress, when blood glucose levels consistently exceed 300 mg/dL (16.7 mmol/L), during pregnancy, or when any symptoms of ketoacidosis are present. Ketone testing also is recommended for patients with diabetes participating in a weight-loss program. Hyperketonuria without hyperglycemia suggests that weight loss is occurring without disrupting blood glucose control.

Ketone bodies include beta-hydroxybutyric acid, acetoacetic acid, and acetone. They appear in urine in the same proportion as they do in blood but are affected by urine volume and concentration. Ketones are variably reabsorbed by the kidney tubules and may be present in urine long after blood levels have returned to normal. For these reasons, urine ketone bodies are not used to evaluate the effectiveness of treatment for ketoacidosis.

Tests for kidney function are important because the presence of urine protein without kidney symptoms may indicate microvascular changes in the kidney. Urine albumin excretion rates of 20 to 200 g/min (30 to 300 mg/hr) indicate microalbuminuria. Even minor elevations of albumin are associated with increased mortality.

Once clinical proteinuria has been detected, kidney function (e.g., glomerular filtration rate) is assessed by creatinine clearance tests (see Chapter 68). In patients with nephropathy, a rise in serum creatinine level is related to both poor blood glucose control and hypertension.

Urine glucose testing is an indirect measurement of blood glucose and is much less precise than blood glucose testing. Fluid intake, urine elimination patterns, and certain drugs affect the results. This test may be appropriate for a quick screening but should not be used for monitoring diabetes management.

ANALYSIS

Priority problems for patients with diabetes are:

1. Potential for injury related to hyperglycemia
2. Potential for impaired wound healing related to endocrine and vascular effects of diabetes
3. Potential for injury related to diabetic neuropathy
4. Pain related to diabetic neuropathy

5. Potential for injury related to diabetic retinopathy–induced reduced vision
6. Potential for kidney disease related to impaired renal circulation
7. Potential for hypoglycemia
8. Potential for diabetic ketoacidosis
9. Potential for hyperglycemic-hyperosmolar state and coma

PLANNING AND IMPLEMENTATION

The management of diabetes mellitus (DM) is complex and involves extensive patient education. The Concept Map on p. 1422 highlights care issues for the patient with type 2 DM.

Preventing Injury from Hyperglycemia

Planning: Expected Outcomes. The patient with diabetes is expected to manage DM and prevent disease progression by maintaining blood glucose levels in the expected range. Indicators are that the patient consistently demonstrates these behaviors:

- Performs treatment regimen as prescribed
- Follows recommended diet
- Monitors blood glucose using correct testing procedures
- Manages symptoms of hyperglycemia
- Seeks health care if blood glucose levels fluctuate outside of recommended parameters
- Meets recommended activity levels
- Uses drugs as prescribed
- Maintains optimum weight
- Problem-solves about barriers to self-management

Interventions

Nonsurgical Management. Nonsurgical management of diabetes mellitus (DM) involves nutritional interventions, blood glucose monitoring, a planned exercise program, and in some instances, drugs to lower blood glucose levels. The nurse, together with the patient, physician, dietitian, pharmacist, case manager, and in some cases, physical therapist, plans, coordinates, and delivers care.

The American Diabetes Association (ADA) has proposed these treatment outcomes for glycosylated hemoglobin (HbA_{1c}) and blood glucose levels (ADA, 2010a):

- HbA_{1c} levels are maintained at 7% or below.
- The majority of premeal (preprandial) blood glucose levels are 70 to 130 mg/dL (3.9 to 7.2 mmol/L).
- Peak after-meal (postprandial) blood glucose levels are less than 180 mg/dL (<10.0 mmol/L).

Drug Therapy. Drug therapy is indicated when a patient with type 2 DM does not achieve blood glucose control with diet changes, regular exercise, and stress management. Several categories of drugs are available to lower blood glucose levels. Patients with type 1 DM require insulin therapy for blood glucose control.

Drugs are started at the lowest effective dose and increased every 1 to 2 weeks until the patient reaches desired blood glucose control or the maximum dosage. If the maximum dosage of one agent does not control blood glucose levels, a second agent with a different mechanism of action may be added. Insulin therapy is indicated for the patient with type 2 DM when blood glucose cannot be controlled with the use of two or three different antidiabetic agents.

Antidiabetic drugs are not a substitute for dietary modification and exercise. Teach the patient about the need for

continuing dietary restrictions and regular exercise while taking antidiabetic drugs.

NURSING SAFETY PRIORITY

Drug Alert

To avoid adverse drug interactions, teach the patient who is taking an antidiabetic drug to consult with his or her primary care provider or pharmacist before using *any* over-the-counter drugs.

Drug Selection. The choice of antidiabetic drug is based on cost, the patient's ability to manage multiple drug dosages, age, and response to the drugs. Shorter-acting drugs (e.g., glipizide) are preferred for older patients, those with irregular eating schedules, and those with liver, kidney, or cardiac function problems. Longer-acting drugs (e.g., glyburide, glimepiride) with once-daily dosing are better for adherence. Beta-cell function in type 2 DM often declines over time, reducing the effectiveness of some drugs. The treatment regimen for a patient with type 2 DM may eventually require insulin therapy either alone or with oral drugs.

Antidiabetic Drugs. Drug therapy is prescribed when dietary control has proven insufficient or if the patient is highly symptomatic. Some antidiabetic drugs are oral agents and others require subcutaneous injection.

Insulin Secretagogues. Insulin secretagogues stimulate insulin release from pancreatic beta cells and are used for patients who are still able to produce insulin. These drugs work by blocking potassium in pancreatic beta cells, which increases the time the beta cells spend in the calcium-release stage of cell signaling. This extra time allows for a higher intracellular calcium level, which then signals each beta cell to release more insulin.

Sulfonylurea Agents. Sulfonylurea agents lower fasting plasma glucose levels by triggering the release of insulin from beta cells. Drugs in this class differ in strength, overall effects, metabolism, and risk for complications (Chart 67-3). First-generation sulfonylurea drugs are seldom used.

Side effects of sulfonylurea agents include weight gain and hypoglycemia. Underweight older adults with cardiovascular, liver, or kidney impairment are more susceptible to hypoglycemia. Many drugs interact with sulfonylureas (Table 67-8).

Meglitinide Analogs. Meglitinide analogs are classified as insulin secretagogues and have actions and adverse effects similar to those of sulfonylureas. Repaglinide (Prandin) and Nateglinide (Starlix) were designed to increase meal-related insulin secretion. They are rapidly absorbed and have a short duration of action. Meglitinide analogs lower HbA_{1c} levels by an average of 1.5 percentage points.

Repaglinide (Prandin) is taken before meals, has a rapid onset with a limited duration of action, and is used to treat both fasting and after-meal hyperglycemia. Adverse effects include hypoglycemia, GI disturbances, upper respiratory infections, joint and back pain, and headache.

Nateglinide (Starlix) is rapidly absorbed and stimulates insulin secretion within 20 minutes of ingestion. It is taken just before meals to control mealtime hyperglycemia and improves overall glycemic control in patients with type 2 DM. The major adverse effect is hypoglycemia. Teach patients who skip meals to also skip their scheduled dose of Starlix to reduce the risk for hypoglycemia.

Text continued on page 1428.

Concept Map: Diabetes Mellitus — Type 2

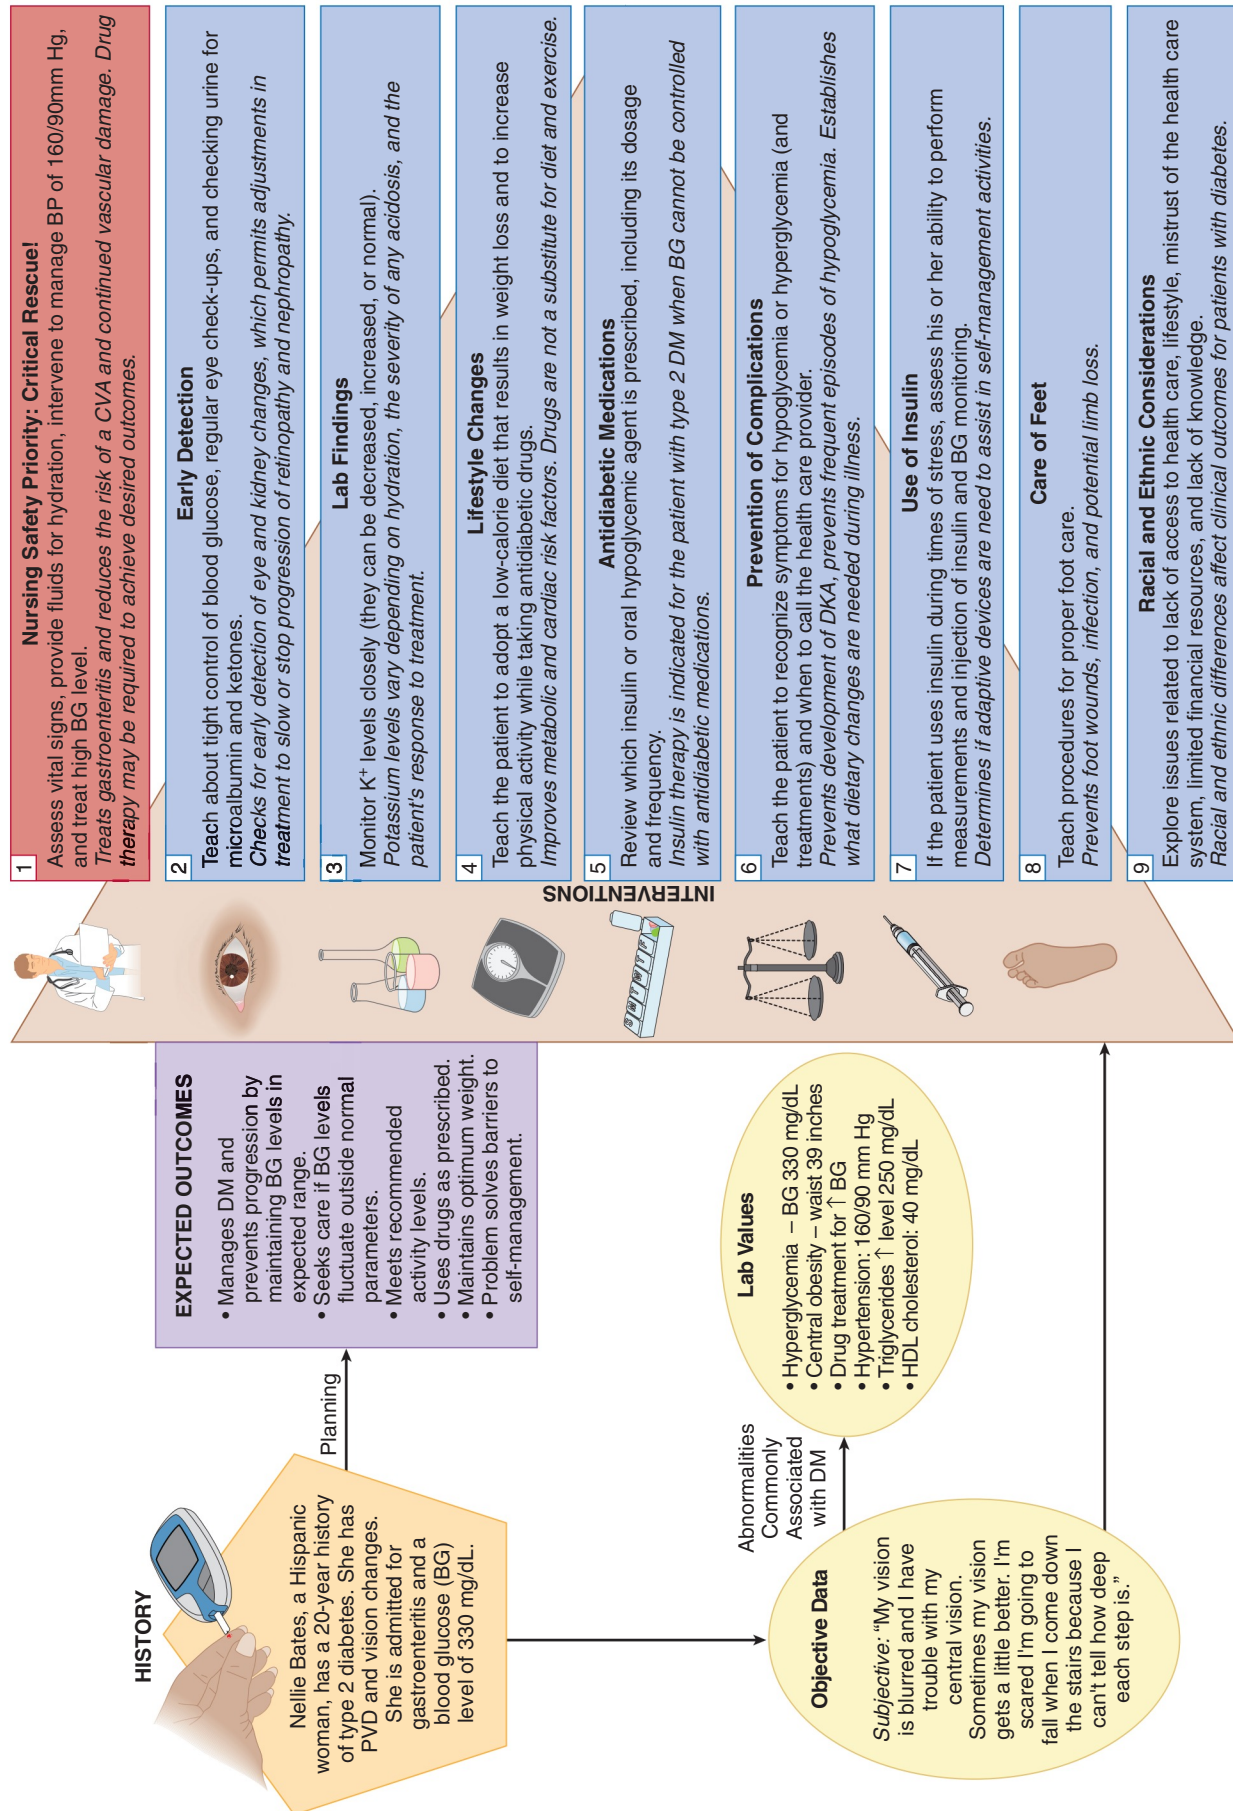

CHART 67-3 COMMON EXAMPLES OF DRUG THERAPY

Diabetes Mellitus

USE IN DIABETES	NURSING INTERVENTIONS	RATIONALES
Secretagogues		
Second-Generation Sulfonylurea Agents		
Glipizide (Glucotrol) Usual dose: 5-10 mg every 12 hr Glucotrol XL (Extended-release form) 5-20 mg orally once daily	Teach patients to take the drug 30 min before meals. Teach patients how to prevent and treat hypoglycemia. Monitor patients with impaired kidney function carefully for hypoglycemia. Instruct patients to swallow the extended-release form of the drug whole and not divided, chewed, or crushed.	Taking the drug 30 min before a meal achieves the best after-meal blood glucose concentration. Because the drug induces insulin secretion, hypoglycemia is possible. The drug is eliminated by the kidney. Patients with impaired kidney function have higher blood levels of the drug and are at risk for hypoglycemia. Damaging the extended-release form of the drug causes the rapid release of the entire dose and can cause hypoglycemia.
Glimepiride (Amaryl) Initial dose: 1-2 mg orally once daily Maintenance dose: 1-4 mg orally once daily Maximum dose: 8 mg daily	Used as single therapy or in combination with metformin or insulin in treatment of type 2 diabetes.	Debilitated or malnourished patients or those with impaired kidney or liver function are more sensitive to blood glucose-lowering effects of glimepiride.
Meglitinide Analogs		
Repaglinide (Prandin) Usual dose: 0.5-4 mg orally daily	Increase insulin secretion in the treatment of type 2 diabetes. Short-acting agent used to prevent postmeal blood glucose elevation.	Drug is most effective when administered with or just before eating a meal. Hypoglycemia may occur shortly after dosing when the meal is delayed or omitted.
Nateglinide (Starlix) Usual dose: 60-120 mg orally before meals	Increase insulin secretion in the treatment of type 2 diabetes. Short-acting agent used to prevent postmeal blood glucose elevation.	Drug is most effective when administered with or just before eating a meal. Hypoglycemia may occur shortly after dosing when the meal is delayed or omitted.
Biguanides		
Metformin (Glucophage) Usual dose: 850 mg orally twice daily with the morning and evening meals (Glucophage XL) Usual dose: 500-2000 mg orally daily before breakfast	Lowers both basal and postmeal blood glucose levels in patients with type 2 diabetes by reducing hepatic glucose production and tissue sensitivity to insulin. Monitor liver and kidney function before starting metformin and periodically thereafter. Monitor cardiopulmonary status throughout therapy. Monitor for conditions that increase risk for lactic acidosis. Instruct patients taking metformin to report symptoms of lactic acidosis: malaise, unusual muscle pain, respiratory distress, increasing somnolence, and abdominal distress.	Adverse GI side effects such as diarrhea, nausea, vomiting, flatulence, indigestion, and abdominal discomfort are common. Taking the drug with food reduces these effects. Metformin should be used with caution in older patients since aging is associated with reduced kidney function. Metformin is contraindicated in people with serum creatinine in males >1.5 mg/dL (132.6 $\mu\text{mol/L}$), and in females >1.4 mg/dL (123.8 $\mu\text{mol/L}$). Metformin should not be used in patients with congestive heart failure requiring drug therapy. These patients are at risk for hypoperfusion and hypoxemia, conditions which increase the risk for lactic acidosis. Metformin is contraindicated in people with risk factors for lactic acidosis: reduced kidney function, liver impairment, respiratory insufficiency, severe infection, alcohol abuse. Onset of lactic acidosis is subtle and accompanied by nonspecific symptoms.

Continued

CHART 67-3 COMMON EXAMPLES OF DRUG THERAPY

Diabetes Mellitus—cont'd

USE IN DIABETES	NURSING INTERVENTIONS	RATIONALES
Metformin—cont'd	Instruct patients taking metformin to report any illness that causes severe vomiting, diarrhea, or fever. Withhold metformin for 48 hr before use of iodinated contrast materials used in certain radiographic studies. Instruct patients taking Glucophage XL that tablets must be swallowed whole and never crushed or chewed.	Precipitating events for lactic acidosis include hypoxemia, dehydration, and sepsis. Iodinated contrast materials can alter kidney function and increase the risk for lactic acidosis. Metformin therapy is restarted when kidney function has returned to normal. Damaging the extended-release form of the drug causes the rapid release of the entire dose and can cause hypoglycemia.
Alpha-Glucosidase Inhibitors	Acarbose (Precose) Usual dose: 50-100 mg orally three times daily Used to prevent postmeal blood glucose elevation in the treatment of type 2 diabetes.	Acarbose must be taken at the beginning of a meal to be fully effective. Acarbose works only when taken at the beginning of a meal. If it is not taken at that time, it should not be taken until the next meal.
	Monitor for abdominal pain, diarrhea, and flatulence. Teach patients about dietary habits to decrease GI discomfort.	GI side effects are very common. Symptoms can be reduced by slow titration of dose. Avoiding foods that will increase GI discomfort such as rich foods, sauces, beverages including beer and carbonated soft drinks, gas-producing foods such as beans, nuts, bran cereals, broccoli, and cabbage reduce the GI side effects of the drug. Meals and snacks should be low in fat. Drinking plenty of water, especially in the early part of the day, and avoiding overeating also reduce symptoms.
Monitor kidney function.	Monitor liver function tests. Emphasize the need to report symptoms of unexplained nausea, vomiting, abdominal pain, fatigue, anorexia, or dark urine.	Drug may accumulate in patients with kidney dysfunction; drug not recommended for patients with serum creatinine >2 mg/dL (176.8 µmol/L).
	Instruct patients receiving acarbose to treat hypoglycemia with glucose tablets, glucose gel, or low-fat milk.	Acarbose is associated with elevation in serum transaminase levels. Doses >150 mg/day associated with increases in ALT and AST (SGOT). ALT should be checked every 3 months for first year and periodically thereafter. Acarbose does not cause hypoglycemia when given alone. Hypoglycemia caused by other agents should be treated with oral dextrose. Sucrose (table sugar or candy bars) will not reverse symptoms of hypoglycemia due to acarbose. Remove from wrapper immediately before taking the drug to prevent deterioration of acarbose.
Miglitol (Glyset) Usual dose: 50 mg orally three times daily Used to prevent postmeal blood glucose elevation in the treatment of type 2 diabetes.	Teach patients to store the drug according to manufacturer's directions. Instruct patients to take the drug with the first bite of each main meal. Monitor kidney function.	Miglitol must be taken at the beginning of a meal to be fully effective. Drug may accumulate in patients with kidney dysfunction; drug not recommended for patients with serum creatinine >2 mg/dL.
Monitor for abdominal pain, diarrhea, and flatulence.	Monitor liver function tests.	GI side effects are very common. Symptoms can be reduced by slow titration of dose. Miglitol is associated with elevation in serum transaminase levels.
Emphasize the need to report symptoms of unexplained nausea, vomiting, abdominal pain, fatigue, anorexia, or dark urine.		These manifestations are associated with reduced liver function.

Thiazolidinediones

Pioglitazone (Actos)

Usual dose: 15 mg or 30 mg once orally daily without regard to meals

Improves tissue sensitivity to insulin in the treatment of type 2 diabetes.

Teach patients taking miglitol to treat hypoglycemia with glucose tablets, glucose gel, or low-fat milk.

Miglitol does not cause hypoglycemia when given alone. Hypoglycemia caused by other agents should be treated with oral dextrose. Sucrose (table sugar or candy bars) will not reverse symptoms of hypoglycemia due to acarbose.

Emphasize the need for liver function tests as recommended. Instruct patients to report symptoms of unexplained nausea, vomiting, abdominal pain, fatigue, anorexia, or dark urine.

Rare cases of liver failure have occurred with pioglitazone. Liver function tests are measured at the start of therapy and at regular intervals thereafter. Not recommended for moderate to severe liver impairment (ALT >2.5 upper limit of normal or active liver disease) or in patients with jaundice.

Advise women of the need for effective contraception during therapy.

Administration of pioglitazone with certain oral contraceptives may reduce the plasma concentration of the oral contraceptive. Postmenopausal women with insulin resistance may resume ovulation during therapy. Fluid retention can lead to weight gain and can cause or exacerbate congestive heart failure.

Monitor weight; assess for edema and shortness of breath.

Stress importance of continuing therapy even if a response is not evident within 2 weeks.

Full therapeutic response may not be evident for 8-12 weeks after initiation of therapy.

Rosiglitazone (Avandia)

Usual dose: 4 mg orally daily in the morning, or 2 mg twice daily in the morning and evening without regard to food

Improves tissue sensitivity to insulin in the treatment of type 2 diabetes.

Emphasize the need for liver function tests as recommended. Instruct the patient to report symptoms of unexplained nausea, vomiting, abdominal pain, fatigue, anorexia, or dark urine.

Rare cases of liver failure have occurred with rosiglitazone. Liver function tests are measured at the start of therapy and at regular intervals thereafter. Not recommended for moderate to severe liver impairment (ALT >2.5 upper limit of normal or active liver disease) or in patients with jaundice.

Advise women of the need for effective contraception during therapy.

Administration of rosiglitazone with certain oral contraceptives may reduce the plasma concentration of the oral contraceptive. Postmenopausal women with insulin resistance may resume ovulation during therapy. Fluid retention can lead to weight gain and can cause or exacerbate congestive heart failure.

Monitor weight; assess for edema and shortness of breath.

Stress importance of continuing therapy even if a response is not evident within 2 weeks.

Full therapeutic response may not be evident for 2-3 months after initiation of therapy.

Fixed Combinations

Actoplus Met (pioglitazone/metformin)

Usual doses:

15 mg/500 mg or

15 mg/850 mg

orally once or twice daily

Pioglitazone added to regimen when blood glucose is inadequately controlled on metformin therapy alone.

Instruct patients in measures to prevent and treat hypoglycemia.

Hypoglycemia may occur when metformin is given in combination with thiazolidinedione agent. Refer to Nursing Interventions and Rationales listed for pioglitazone and metformin.

Avandamet (rosiglitazone/metformin)

Usual oral doses:

1 mg/500 mg

2 mg/500 mg

4 mg/500 mg

Maximum dose: 8 mg/2000 mg daily

Rosiglitazone added to regimen when blood glucose is inadequately controlled on metformin therapy alone.

Teach patients to take the drug in divided doses with meals. Teach patients how to prevent and treat hypoglycemia.

Hypoglycemia may occur when metformin is given in combination with thiazolidinedione agent. Refer to Nursing Interventions and Rationales listed for metformin and rosiglitazone.

Continued

CHART 67-3 COMMON EXAMPLES OF DRUG THERAPY

Diabetes Mellitus—cont'd

	USE IN DIABETES	NURSING INTERVENTIONS	RATIONALES
Avandaryl (glimepiride/ rosiglitazone) Usual oral doses: 1 mg/4 mg 2 mg/4 mg 4 mg/4 mg Maximum dose: 4 mg/8 mg daily	Rosiglitazone added to regimen when blood glucose is inadequately controlled on glimepiride therapy alone.	Teach patients how to prevent and treat hypoglycemia.	Hypoglycemia may occur when glimepiride is given in combination with thiazolidinedione agent. Refer to Nursing Interventions and Rationales listed for rosiglitazone and glimepiride.
Duetact (glimepiride/ pioglitazone) Usual once daily doses: 2 mg/30 mg 4 mg/30 mg	Pioglitazone added to regimen when blood glucose is inadequately controlled on glimepiride therapy alone.	Teach patients how to prevent and treat hypoglycemia.	Hypoglycemia may occur when glimepiride is given in combination with thiazolidinedione agent. Refer to Nursing Interventions and Rationales listed for pioglitazone and glimepiride.
Glucovance (glyburide/ metformin) Usual oral twice-daily doses: 1.25 mg/250 mg 2.5 mg/500 mg 5 mg/500 mg	Metformin added to regimen when blood glucose is inadequately controlled on glyburide therapy alone.	Teach patients how to prevent and treat hypoglycemia.	Hypoglycemia may occur when metformin is given in combination with sulfonylurea agent. Refer to Nursing Interventions and Rationales listed for metformin and glyburide.
Janumet (sitagliptin/metformin) Usual oral twice-daily doses: 100 mg/1000 mg 100 mg/2000 mg Maximum dose: 100 mg/2000 mg	Sitagliptin added to regimen when blood glucose is inadequately controlled on metformin therapy alone.	Teach patients to take the drug twice daily with meals.	Refer to Nursing Interventions and Rationales listed for sitagliptin and metformin.
Metaglip (glipizide/ metformin) Usual oral twice-daily doses: 2.5 mg/250 mg 2.5 mg/500 mg 5 mg/500 mg	Metformin added to regimen when blood glucose is inadequately controlled on glipizide therapy alone.	Teach patients to take the drug with meals. Teach patients how to prevent and treat hypoglycemia.	Hypoglycemia may occur when metformin is given in combination with sulfonylurea agent. Refer to Nursing Interventions and Rationales listed for metformin and glipizide.
PrandiMet (repaglinide /metformin) Usual oral doses taken two or three times daily: 1 mg/500 mg 2 mg/500 mg Maximum dose: 10 mg/2500 mg	Repaglinide added to regimen when blood glucose is inadequately controlled on metformin therapy alone.	Instruct patients in measures to prevent and treat hypoglycemia.	Hypoglycemia may occur when metformin is given in combination with repaglinide. Refer to Nursing Interventions and Rationales listed for repaglinide and metformin.
Amylin Analog Pramlintide (Symlin) Initial subcutaneous dose immediately before each meal: 15 mcg Maintenance dose: 30 mcg or 60 mcg	Used for people with type 1 or type 2 diabetes who have not received desired glucose control with optimal insulin therapy.	Teach the patient to prepare and self-administer pramlintide. Instruct the patient in measures to prevent and treat hypoglycemia. Instruct the patient to eat at least 250 calories or 30 g of carbohydrate after taking pramlintide.	A U-100 insulin syringe is used to administer pramlintide. It is necessary to convert the microgram dosage to insulin syringe unit increments. Pramlintide carries a Black Box Warning for severe insulin-induced hypoglycemia. The risk for hypoglycemia is greatest within 3 hours of injection.

Pramlintide and insulin are not compatible when mixed together.	Instruct the patient in measures to avoid drug incompatibilities: Do not mix pramlintide and insulin together in the same syringe. Inject pramlintide into an anatomical site distant from the insulin injection site.	
Incretin Mimetics (GLP-1 agonist) Exenatide (Byetta) Initial subcutaneous dose: 5 mcg twice daily Maintenance dose: 10 mcg twice daily	Exenatide is used as monotherapy or as part of 2- or 3-drug regimen for patients with type 2 diabetes.	Teach the patient to prepare and self-administer exenatide. Instruct patients to administer as subcutaneous injection within 60 minutes before morning and evening meals (or two main meals of the day). Teach patients the actions to take for missed doses of the drug. Instruct the patient in measures to prevent and treat hypoglycemia. Instruct patient to discontinue use of the drug and to report symptoms of unexplained persistent severe abdominal pain with or without nausea and vomiting. Teach patients to discontinue use of the drug and to report symptoms of hypersensitive reactions to their provider.
Exenatide is available in a prefilled pen containing 60 doses for 30 days of use. Patient education in use of the pen is necessary to ensure that the patient receives the correct dose of the drug. Instruct patients to take the missed dose at the next meal. Exenatide is not given after a meal. Hypoglycemia has been reported when exenatide is given in combination with a sulfonylurea agent. Acute pancreatitis, including both fatal and nonfatal hemorrhagic or necrotizing pancreatitis, has been reported in patients taking exenatide. Hypersensitive reactions including exfoliative dermatitis, urticaria, skin rash, and Stevens-Johnson syndrome have been reported in patients taking exenatide.	Liraglutide is available in a prefilled multi-dose pen. Patient education in use of the pen is necessary to ensure that the patient receives the correct dose of the drug. Side effects tend to be dose-related and lessen over time. Hypoglycemia may occur when liraglutide is given in combination with a sulfonylurea agent. Pancreatitis has been reported in patients taking liraglutide.	Liraglutide (Victoza) Initiate at 0.6 mg per day for 1 week Increase to 1.2 mg after 1 week Maximum once daily subcutaneous dose: 1.8 mg
Liraglutide is available in a prefilled multi-dose pen. Patient education in use of the pen is necessary to ensure that the patient receives the correct dose of the drug. Side effects tend to be dose-related and lessen over time. Hypoglycemia may occur when liraglutide is given in combination with a sulfonylurea agent. Pancreatitis has been reported in patients taking liraglutide.	Instruct patients to administer once daily, at any time of the day, independent of meals. Inject subcutaneously in abdomen, thigh, or upper arm. Monitor for nausea, vomiting, diarrhea, dyspepsia, and constipation. Instruct patients in measures to prevent and treat hypoglycemia. Observe and report symptoms of pancreatitis: persistent severe abdominal pain with or without nausea and vomiting.	DPP-4 Inhibitors Sitagliptin (Januvia) Recommended dose: 100 mg orally once daily
Drug is effective with or without food and does not increase the risk for hypoglycemia. Acute pancreatitis, including both fatal and nonfatal hemorrhagic or necrotizing pancreatitis, has been reported in patients taking sitagliptin. Drug is effective with or without food and does not increase the risk for hypoglycemia. Hypoglycemia may occur when saxagliptin is given in combination with glyburide.	Instruct patients to administer once daily, with or without food. Instruct patient to discontinue use of the drug and to report symptoms of unexplained persistent severe abdominal pain with or without nausea and vomiting. Instruct patients to administer once daily, with or without food. Instruct patients in measures to prevent and treat hypoglycemia.	Saxagliptin (Onglyza) Recommended dose: 2.5 mg or 5 mg orally once daily

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; SGOT, serum glutamate oxaloacetate transaminase.

TABLE 67-8 DRUG INTERACTIONS WITH SULFONYLUREA AGENTS

POTENTIATE HYPOGLYCEMIA	WORSEN HYPERGLYCEMIA
Angiotensin-converting agents (captopril [Capoten], enalapril [Vasotec])	Adrenalin
Alcohol	Calcium channel blocking agents (diltiazem [Cardizem], nifedipine [Procardia])
Allopurinol (Zyloprim)	Corticosteroids (prednisone)
Analgesics (azapropazone, phenylbutazone, salicylates)	Diazoxide (Proglycem [oral], Hyperstat [IV])
Antifungal azoles (fluconazole [Diflucan], ketoconazole [Nizoral], miconazole [Monistat])	Estrogen (Estrace, Premarin)
Beta-adrenergic blocking agents (atenolol, [Tenormin], propranolol [Inderal])	Estrogen-progesterone-containing oral contraceptives (Brevicon, Depo-Provera, Estrostep)
Chloramphenicol (Chloromycetin)	Furosemide (Lasix)
Clofibrate (Atromid-S)	Isoniazid (INH)
Warfarin (Coumadin)	Nicotinic acid (Nicolar)
Fluoroquinolones (ciprofloxacin [Cipro], gatifloxacin [Tequin], levofloxacin [Levaquin])	Phenothiazines (chlorpromazine [Thorazine], prochlorperazine [Compazine], trifluoperazine [Stelazine])
Heparin	Phenytoin (Dilantin)
Histamine H ₂ antagonists (cimetidine [Tagamet], ranitidine [Zantac])	Rifampin (Rifadin)
Monoamine oxidase (MAO) inhibitors (phenelzine [Nardil])	Sympathomimetics
NSAIDs (indomethacin [Indocin], ibuprofen [Advil])	Thiazide diuretics (hydrochlorothiazide [HydroDIURIL], chlorothiazide [Diuril])
Octreotide (Sandostatin)	
Probenecid (Benemid, Probalan)	
Sulfinpyrazone (Anturane)	
Sulfonamides (trimethoprim/sulfamethoxazole [Bactrim], sulfisoxazole [Gantrisin])	
Tricyclic antidepressants (amitriptyline hydrochloride, desipramine hydrochloride [Norpramin], doxepin hydrochloride [Sinequan])	

Data from *AHFS Drug Information*. (2009). Bethesda, MD: American Society of Health-System Pharmacists.

Insulin Sensitizers. Insulin sensitizers include biguanides (metformin) and thiazolidinediones (TZDs). Metformin (Glucophage) does not increase insulin secretion. It decreases liver glucose production, thereby reducing fasting plasma glucose release, and improves insulin receptor sensitivity. TZDs bind to a regulatory protein, peroxisome proliferator-activated receptor (PPAR), that controls expression of genes that regulate glucose and fat metabolism. TZDs increase cellular utilization of glucose, which lowers blood glucose levels.

The ADA recommends metformin as initial therapy for type 2 DM because the drug does not induce weight gain or hypoglycemia and has a relatively low cost and few adverse

effects. It should not be given to anyone with kidney disease and elevated blood creatinine levels. The drug should be withheld for 48 hours before and after using contrast material and surgical procedures requiring anesthesia. Metformin lowers HbA_{1c} levels by an average of 1.5 percentage points.

The most common side effects are abdominal discomfort and diarrhea. Metformin can cause lactic acidosis in patients with kidney problems and should not be used in conditions that decrease drug clearance, such as liver disease, alcoholism, or severe congestive heart failure or in patients older than 80 years. Hypoxemia, dehydration, and sepsis also increase the risk for lactic acidosis. Symptoms of lactic acidosis can be subtle. Teach the patient to report symptoms of fatigue, unusual muscle pain, difficulty breathing, unusual or unexpected stomach discomfort, dizziness, lightheadedness, or irregular heartbeats to the primary care provider. Instruct patients to take metformin with meals to reduce GI effects. Caution against excessive alcohol intake because alcohol increases the risk for lactic acidosis.

! NURSING SAFETY PRIORITY

Drug Alert

Metformin can cause lactic acidosis in patients with renal insufficiency and should not be used by anyone with kidney disease. To prevent kidney damage, the drug should be withheld after using contrast material or any surgical procedure requiring anesthesia until adequate kidney function is established.

Thiazolidinediones (TZDs) improve insulin sensitivity and reduce liver glucose production. TZDs also improve insulin action in muscle, fat, and liver tissue. The two drugs in this class are rosiglitazone (Avandia) and pioglitazone (Actos).

! NURSING SAFETY PRIORITY

Drug Alert

Do not confuse Actos with Actonel. Actos is an oral antidiabetic drug from the thiazolidinedione class, and Actonel is a drug that prevents calcium loss from bones.

All drugs in this class reduce blood lipid levels. Major side effects of TZD treatment are an increase in adipose tissue and fluid retention. Some patients taking these drugs gain weight. Edema, with development of congestive heart failure, is possible but rare. Other side effects include infection, headache, peripheral edema, and pain. Patients taking these drugs should have periodic liver function studies because of the potential for liver damage. There is an increased incidence of fractures of the upper arms, hands, and feet in women using rosiglitazone and pioglitazone. TZDs lower HbA_{1c} levels by an average of 0.5 to 1.4 percentage points.

Rosiglitazone has been associated with an increased risk for heart-related deaths, bone fracture, and macular edema. In May 2011, the FDA issued prescribing information, which includes this black box warning:

- Prescription of rosiglitazone, either as a single drug or combined with other drugs, is limited to only those

patients who are already using the drug and whose disease cannot be adequately controlled by other drugs or a combination of drugs. It is absolutely contraindicated in patients with any symptomatic heart failure.

- Rosiglitazone causes or exacerbates congestive heart failure in some patients. Monitor for signs and symptoms of heart failure (excessive rapid weight gain, difficulty breathing and/or swelling) after starting treatment or after increases in dosage of rosiglitazone. If heart failure signs and symptoms occur, the heart failure should be managed appropriately and discontinuation of rosiglitazone must be considered.
- Rosiglitazone is available only through pharmacies that are certified by the Avandia-Rosiglitazone Medicines Access Programs.

(A **Black Box Warning** is a government designation indicating that a drug has at least one serious side effect and must be used with caution.)

Alpha-Glucosidase Inhibitors. Alpha-glucosidase inhibitors prevent after-meal hyperglycemia by delaying absorption of carbohydrate from the small intestine. These drugs inhibit enzymes in the intestinal tract, reducing the rate of digestion of starches and the absorption of glucose. This action prevents a sudden blood glucose surge after meals. Acarbose *delays* rather than prevents glucose absorption and does not cause weight loss. Alpha-glucosidase inhibitors lower HbA_{1c} levels by an average of 0.5 to 0.8 percentage points.

The most common side effects are flatulence, diarrhea, and abdominal discomfort. There are two drugs in this class. Acarbose (Precose, Prandase ) is well tolerated when started at a low dose (25 mg once daily to three times daily with meals) and increased slowly. At higher doses, poor carbohydrate absorption occurs. Miglitol (Glyset) should be taken three times daily with the first bite of each main meal.

These drugs do not cause hypoglycemia unless given with sulfonylureas or insulin. Because alpha-glucosidase inhibitors delay carbohydrate absorption and interfere with the conversion of complex sugars to glucose, many of the standard products used to manage hypoglycemia have a slower onset of action. These drugs do not inhibit absorption of glucose or lactose. Teach patients to use oral glucose tablets, glucose gel, or low-fat milk to manage hypoglycemia. Severe hypoglycemia may require glucose infusion or glucagon injection.

Incretin Mimetics. Incretin mimetics are natural “gut” hormones that, along with insulin, also lower plasma glucose levels. These agents include glucagon-like peptide-1 (GLP-1) and glucose-dependent insulintropic polypeptide (GIP) that are released by the intestine throughout the day in response to food intake (Appel, 2011). GLP-1 has effects on the stomach, liver, pancreas, and brain to work together to regulate blood glucose. It lowers glucagon secretion from the pancreas, leading to reduced liver glucose production. It also delays gastric emptying, slows the rate of nutrient absorption into the blood, and reduces food intake, all of which lower blood glucose levels. GLP and GIP are rapidly metabolized by an enzyme known as DPP-4, which inactivates their effects. Patients with type 2 DM have a reduced incretin effect, indicating that they have either a decreased level of incretin hormones or a resistance to their effects. Two incretin agents are approved for use in patients with type 2 DM—exenatide (Byetta) and liraglutide (Victoza). Incretin

agents lower HbA_{1c} levels by an average of 0.5 to 1.0 percentage points.

Exenatide (Byetta) is a GLP-1 agonist. It mimics the actions of GLP-1, stimulating insulin secretion only when blood glucose is high. This action restores “first phase” insulin release and improves blood glucose control by lowering both after-meal and fasting blood glucose levels. The drug is approved for use as a single agent or in combination with a sulfonylurea, metformin, or thiazolidinedione in patients with type 2 DM.

The main side effect of exenatide is nausea. Most patients lose weight as a result of the anorexic effect of the drug. It stimulates insulin secretion and may cause hypoglycemia when given with sulfonylurea drugs (which also stimulate insulin secretion) but not with metformin alone. Exenatide should not be used for patients with end-stage kidney disease or those with kidney impairment that reduces glomerular filtration to less than 30 mL/min.

Exenatide is available as a fixed-dose prefilled pen injector delivering either 5 mcg or 10 mcg of drug per dose. It is injected subcutaneously in thigh, abdomen, or upper arm within 60 minutes *before* the morning and evening meals or before the two main meals of the day. Teach patients not to administer exenatide *after* a meal. Unopened prefilled pens are stored in a refrigerator between 36° F and 46° F (2° C and 8° C). Opened pen injectors can be stored for up to 30 days at room temperature in a closed container protected from heat and light. Instruct the patient to discard an open pen after 30 days even if it is not empty.

Liraglutide (Victoza) is a glucagon-like peptide-1 (GLP-1) agonist approved as an addition to diet and exercise to improve glycemic control in adults with type 2 DM. It enhances glucose-dependent insulin secretion from the pancreas, suppresses excess glucagon secretion, delays gastric emptying, reduces appetite, and preserves beta-cell mass and function.

The most common adverse effects are GI related and included nausea, vomiting, diarrhea, dyspepsia and constipation. The frequency of effects tends to be dose-related and decreased over time. Hypoglycemia is uncommon, and occurs more often in combination with a sulfonylurea agent. Liraglutide carries a black box warning for thyroid tumors and is not to be used by patients with a history of medullary thyroid carcinoma (Appel, 2011).

Liraglutide is available as a solution for subcutaneous injection in a prefilled multi-dose pen. It is administered once daily at any time of the day, independent of meals. Each pen delivers doses of 0.6 mg, 1.2 mg, or 1.8 mg. Unopened prefilled pens should be stored under refrigeration between 36° F and 46° F (2° C and 8° C). Opened pens can be stored for up to 30 days at controlled room temperature between 59° F and 86° F (15° C and 30° C) or in a refrigerator. Pens need to be protected from excessive heat and sunlight. Therapy with liraglutide begins at 0.6 daily mg for 1 week. This dose is intended to reduce GI symptoms during initial titration. After 1 week, the dose is increased to 1.2 mg daily and to 1.8 mg daily, if needed.

Monitor patients taking incretin mimetics for symptoms of pancreatitis. Teach patients to discontinue use of the drug and to report symptoms of unexplained, persistent severe abdominal pain with or without nausea and vomiting to their primary care provider as soon as possible.

DPP-4 Inhibitors. DPP-4 inhibitors work by inhibiting the enzyme that inactivates the incretin hormones (Martin, 2010). As a result, more natural incretin hormones (GLP-1 and GIP) are available to regulate blood glucose. Glucagon levels are decreased, and insulin secretion from pancreatic beta cells is increased. The two DPP-4 inhibitors approved for use in patients with type 2 DM are sitagliptin (Januvia) and saxagliptin (Onglyza). DPP-4 inhibitors lower HbA_{1c} levels by an average of 0.6 to 0.9 percentage points.

Sitagliptin increases the body's active incretin hormone levels, reducing both before-meal and after-meal blood glucose levels. It works only when blood glucose is elevated. Sitagliptin is approved as single agent therapy for patients with type 2 DM unable to manage the disease with diet and exercise alone and as add-on therapy for those patients with inadequate blood glucose control who are also taking a sulfonylurea, metformin, or thiazolidinediones. The recommended dose is 100 mg orally, once daily, with or without food. Dosage adjustment is needed for patients with moderate to severe kidney impairment.

Side effects include stuffy or runny nose, sore throat, upper respiratory infection, and GI effects of abdominal pain, nausea, and diarrhea. Monitor for symptoms of kidney impairment. Hypersensitivity reactions including exfoliative dermatitis, urticaria, skin rash, and Stevens-Johnson syndrome have been reported. Teach patients to discontinue use of the drug and to report symptoms of hypersensitive reactions to their health care provider.

Patients taking sitagliptin (Januvia) should be monitored for symptoms of pancreatitis. Acute pancreatitis, including both fatal and nonfatal hemorrhagic or necrotizing pancreatitis, has been reported in patients who received sitagliptin therapy. Teach patients to discontinue use of the drug and to report symptoms of unexplained, persistent severe abdominal pain with or without nausea and vomiting to their health care provider as soon as possible.

Saxagliptin (Onglyza) lowers HbA_{1c} levels in patients with type 2 diabetes when used alone or in combination with metformin, sulfonylurea, or thiazolidinediones (TZDs). Common adverse effects include nasopharyngitis, headache, diarrhea, upper respiratory infection, urinary tract infection, and peripheral edema. Hypoglycemia was reported, particularly when saxagliptin was given in combination with glyburide.

Amylin Analogs. Amylin analogs are drugs similar to amylin, a naturally occurring hormone produced by beta cells in the pancreas that works with and is co-secreted with insulin in response to blood glucose elevation. Amylin levels are deficient in patients with type 1 DM who are also deficient in insulin. Pramlintide (Symlin), an analog of amylin, is approved for patients with either type 1 or type 2 DM treated with insulin. It is indicated as adjunct therapy for patients who use mealtime insulin delivery and have not achieved desirable glucose control despite optimum insulin therapy.

Pramlintide works by three mechanisms: delayed gastric emptying, reducing after-meal blood glucose levels, and triggering satiety (in the brain). (Satiety leads to decreased caloric intake and eventual weight loss.) The initial dose of pramlintide is 15 mcg subcutaneously before meals with at least 250 calories or 30 g of carbohydrate. It can be given up to 4 times per day. Dosage is increased in 15-mcg increments to a target dose of 30 mcg or 60 mcg. Pramlintide alters gastric

uptake. Therefore instruct patients to take oral drugs in which rapid onset of action is important (e.g., analgesics) either 1 hour before or 2 hours after eating.

Teach the patient to prepare and self-administer pramlintide. A U-100 syringe is used to administer the drug. However, it is necessary to convert the microgram dosage to insulin syringe unit increments (e.g., 15 mcg is equal to 2.5 units on a U-100 insulin syringe). Teach the patient to inject pramlintide into a site different from where insulin is injected.

! NURSING SAFETY PRIORITY

Drug Alert

Do not mix pramlintide and insulin in the same syringe because the pH of the two drugs is not compatible.

Nausea, vomiting, and anorexia are common side effects of pramlintide therapy. It should not be used for patients with symptomatic gastroparesis. Pramlintide carries a black box warning for insulin-induced severe hypoglycemia. The hypoglycemic risk is higher in patients with type 1 DM and usually occurs within 3 hours of injection. The black box also warns about the risk for hypoglycemia during driving or operating heavy equipment.

Combination Agents. Combination agents combine drugs with different mechanisms of action. Glucovance, for example, combines glyburide with metformin. Combining drugs with different mechanisms of action may be highly effective in maintaining desired blood glucose control. Some patients may need a combination of oral agents and insulin to control blood glucose levels.

? NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A client with type 2 diabetes who also has heart failure is prescribed metformin extended-release (Glucophage XR) once daily. On assessment, the nurse finds that the client now has muscle aches, drowsiness, low blood pressure, and a slow, irregular heartbeat. What is the nurse's best action?

- A. Assess the client's blood glucose level and prepare to administer IV glucose.
- B. Reassure the client that these symptoms are normal effects of this drug.
- C. Hold the dose and notify the prescriber immediately.
- D. Administer the drug at bedtime to prevent falls.

Insulin Therapy. Insulin therapy is needed for type 1 DM and also may be used for type 2 DM. The safety of insulin therapy in older patients may be affected by reduced vision, mobility and coordination problems, and decreased memory. There are many types of insulin and regimens that have the purpose of achieving normal blood glucose levels. Because insulin is a small protein that is quickly digested and inactivated in the GI tract, it must be administered as an injection or by another route that bypasses the GI tract.

Types of Insulin. Insulin is manufactured using DNA technology to synthesize pure human insulin. Insulin analogs are synthetic human insulins in which the structure of the insulin molecule is altered to change the rate of absorption and duration of action within the body. One example is Lispro insulin, a rapid-acting insulin analog that is created by switching the

TABLE 67-9 TIME ACTIVITY OF PHARMACEUTICAL INSULIN

Insulin glargine injection	Lantus	2-4	None	24

positions of lysine and proline in one area of the insulin molecule.

Rapid-, short-, intermediate-, and long-acting forms of insulin can be injected separately, and some can be mixed in the same syringe. Insulin is available in concentrations of 100 units/mL (U-100) or 500 units/mL (U-500). U-500 is used only in rare cases of insulin resistance.

Teach the patient that the insulin types, the injection technique, the site of injection, and the patient response can all affect the absorption, onset, degree, and duration of insulin activity. Reinforce that changing insulins may affect blood glucose control and should be done only under supervision of the health care provider. Table 67-9 outlines the time activity of human insulin.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

The client newly diagnosed with type 1 diabetes asks why insulin is given only by injection and not as an oral drug. What is the nurse's best response?

- Injected insulin works faster than oral drugs to lower blood glucose levels."
- "Oral insulin is so weak that it would require very high dosages to be effective."
- "Insulin is a small protein that is destroyed by stomach acids and intestinal enzymes."
- "Insulin is a "high alert drug" and could more easily be abused if it were available as an oral agent."

Insulin Regimens. Insulin regimens try to duplicate the normal insulin release pattern from the pancreas. The pancreas produces a constant (*basal*) amount of insulin that balances liver glucose production with glucose use and maintains normal blood glucose levels between meals. The pancreas also produces additional (*prandial*) insulin to prevent blood glucose elevation after meals. The insulin dose required for blood glucose control varies among patients. A usual starting dose is between 0.5 and 1 unit/kg of body weight per day. For multiple-dose regimens or continuous subcutaneous insulin infusion (CSII), basal insulin makes up about 40% to 50% of the total daily dosage, with the remainder divided into premeal doses of rapid-acting insulin analogs or regular insulin. Basal insulin coverage is provided by NPH insulin or by intermediate-acting and long-acting insulin analogs, insulin glargine (Lantus) or insulin detemir (Levemir). Because the rate of absorption is slowed by increasing the dosage, adjustments in dosage should be made no more than every 3 to 4 days. Dosage adjustments are based on the results of blood glucose monitoring.

Single daily injection protocols require insulin injection only once daily. This protocol may include one injection of intermediate- or long-acting insulin or a combination of short- and intermediate-acting insulin. Many patients with type 2 diabetes combine once-daily insulin injection with oral agent therapy.

Multiple-component insulin therapy combines short- and intermediate-acting insulin injected twice daily. Two thirds of the daily dose is given before breakfast and one third before

the evening meal. Ratios of intermediate-acting and regular insulin are based on results of blood glucose monitoring.

Intensified regimens include a basal dose of intermediate- or long-acting insulin and a bolus dose of short- or rapid-acting insulin designed to bring the next blood glucose value into the target range. Blood glucose elevations above the target range are treated with “correction” doses of short- or rapid-acting insulin. The patient’s blood glucose patterns determine insulin dosage. Frequency of blood glucose monitoring is based on the timed action of short- and intermediate- or long-acting insulins and may occur as often as eight times daily. Blood glucose testing 1 to 2 hours after meals and within 10 minutes before the next meal helps determine the adequacy of the bolus dose. The patient determines the effects of basal insulin by monitoring blood glucose levels before breakfast (fasting) and before the evening meal.

Patients on intensified insulin regimens need extensive education to achieve target blood glucose values. They need to know how to adjust insulin doses and understand nutrition therapy to maintain dietary flexibility and target blood glucose values. Patients must also be able to accurately monitor blood glucose levels so that therapy decisions can be based on accurate data.

Regardless of the specific insulin regimen, adherence to insulin injection schedules is critical in achieving glycemic control and maintaining HbA_{1c} levels below the 7% needed to reduce long-term complications. At times, skipping an occasional insulin dose may be related to an unusual meal pattern for a day or a change in exercise. However, many patients continue to “skip” insulin doses regularly, which increases their overall risk for serious health problems and early death. Determining what factors are associated with this behavior can help nurses and other health care professionals provide an individualized approach to assisting the patient with DM to understand the benefits of insulin therapy adherence (Peyrot et al., 2010). (See the Evidence-Based Practice box at right.)

Factors Influencing Insulin Absorption. Many factors affect insulin absorption and availability, including injection site; timing, type, or dose of insulin used; and physical activity.

Injection site area affects the speed of insulin absorption. Fig. 67-4 shows common insulin injection areas. Absorption is fastest in the abdomen, followed by the deltoid, thigh, and buttocks. Rotating injection site areas prevents lipohypertrophy (increased fat deposits in the skin) and lipoatrophy (loss of fatty tissue, leaving an uneven appearance). Rotation *within* one anatomic site is preferred to rotation from one area to another to prevent day-to-day changes in absorption. The abdomen (except for a 2-inch radius around the navel) is the preferred injection site area because it provides the most rapid insulin absorption.

Absorption rate is determined by insulin properties. The longer the duration of action, the more unpredictable is absorption. Larger doses of insulin also prolong the absorption. Factors that increase blood flow from the injection site, such as local application of heat, massage of the area, and exercise of the injected area, increase insulin absorption. Scarred sites often become favorite injection sites because they are less sensitive to pain, but these areas usually slow the rate of insulin absorption.

Injection depth changes insulin absorption. Usually, injections are made into the subcutaneous tissue. Most patients

EVIDENCE-BASED PRACTICE

Why Do Adults with Diabetes Omit Prescribed Insulin Doses?

Peyrot, M., Rubin, R., Kruger, D., & Travis, L. (2010). Correlates of insulin injection omission. *Diabetes Care*, 33(2), 240-245.

Both type 1 and type 2 diabetes mellitus (DM) result in severe and life-shortening complications when blood glucose levels are not controlled. Extensive research has shown that maintaining hemoglobin A_{1c} levels below 7% dramatically reduces or delays these complications. For people with type 1 DM, insulin therapy is required for blood glucose control. For many people with type 2 DM, insulin therapy is needed when other drug therapies are no longer effective. Intentional omission of insulin has been identified as a relatively common behavior in adolescents with DM. This study sought to determine to what degree intentional insulin omission occurs in adults with DM and what personal factors are associated with this behavior.

A total of 502 adults with diabetes were recruited into this online survey-based descriptive study, all of whom were prescribed insulin therapy. The majority, 77%, had type 2 DM and 23% had type 1 DM. Of these 502 subjects, 57% reported having intentionally omitted an insulin dose on occasion; however, 20% reported intentionally omitting insulin doses regularly. The incidence was highest among those with type 2 DM. Other variables that correlated with the behavior of regularly omitting insulin doses were lower socioeconomic level, not having followed a healthy diet, and having a prescribed insulin regimen that required more frequent daily injections. Insulin injection factors that correlated with omitting doses included the perception that injections were painful and embarrassing and that insulin scheduling interfered with the life activities of eating, exercising, and working. Some of the factors that either did not correlate with omitting insulin doses or had only minimal influence were race/ethnicity, education level, and the presence of depressive symptoms.

Level of Evidence: 4

Although very large, the study was descriptive in nature without randomization of subject selection or assignment. The information collected relied on subject self-report. The methods of statistical analysis were appropriate for the research questions posed.

Commentary: Implications for Practice and Research

The results of this study indicate that insulin omission is more common among people with type 2 DM. The researchers postulated that perhaps this group may view their disease as less serious than type 1 DM, especially if they retain any beta-cell function. These subjects also viewed the use of insulin to be more burdensome, painful, and embarrassing than did those with type 1 DM.

Because the overall damage caused by hyperglycemia is the same regardless of the category of DM, it is imperative that patients with type 2 DM understand the relationship between poor blood glucose control and development of complications. Nurses and other members of the health care team must convey the benefits of tight glycemic control that insulin therapy provides, as well as the benefits of a healthy diet. One factor possibly contributing to this problem is a lack of continuing access to support from health care professionals, especially diabetes educators. Assisting the patient to access local and online information and support services may help increase understanding about the disease and its effective therapy.

Some of the issues regarding the “pain” of injections can be reduced by teaching patients about the use of smaller needles, as well as injection into body areas with less sensitivity. Nurses can help patients identify ways and means to self-inject insulin without drawing undue attention and to disguise injection site bruising.

FIG. 67-4 Common insulin injection areas and sites.

lightly grasp a fold of skin and inject at a 90-degree angle. Aspiration for blood is not needed. A thin patient may need to pinch the skin and inject at a 45-degree angle to avoid IM injection. IM injection has a faster absorption and is not used for routine insulin use. Assess the older patient's ability to inject insulin, and arrange for assistance when self-care is no longer possible.

Timing of injection affects blood glucose levels. The interval between premeal injections and eating, known as "lag time," affects blood glucose levels after meals. Insulin lispro, insulin aspart, and insulin glulisine have rapid onsets of action and should be given within 10 minutes before mealtime when blood glucose is in the target range. If hyperglycemia or hypoglycemia is not present, these insulins can be given at any time from 10 minutes before mealtime to just before eating or even immediately after eating. Regular insulin should be given at least 20 to 30 minutes before eating when glucose levels are within the target range. When blood glucose levels are above the target range, the lag time should be increased to permit insulin to begin to have an effect sooner. Rapid-acting insulin analogs can be given 15 minutes before and regular insulin 30 to 60 minutes before eating a meal. When blood glucose levels are below the target range, injection of regular insulin should be delayed until immediately before eating and injection of rapid-acting insulin should be delayed until sometime after eating the meal.

Mixing insulins can change the time of peak action. Mixtures of short- and intermediate-acting insulins produce a more normal blood glucose response in some patients than does a single dose. The patient's response to mixed insulin may differ from the response to the same insulins given separately.

When rapid-acting (Humalog or NovoLog) or short-acting (regular) insulin is mixed with a longer-acting insulin, draw the shorter-acting dose into the syringe first. This action prevents contamination of the shorter-acting insulin vial with the longer-acting insulin. Short-acting and NPH insulins may be used immediately when mixed, or they may be stored. Mixing clouds the solution and makes the onset of action and peak effect time less predictable. Follow American

TABLE 67-10 AMERICAN DIABETES ASSOCIATION GUIDELINES FOR THE MIXING OF INSULINS

- Patients whose condition is well controlled on a particular mixed-insulin regimen should maintain their standard procedure for preparing insulin doses.
- No other drug or diluents should be mixed with any insulin product unless approved by the prescribing health care provider.
- Insulin glargine should not be mixed with any other forms of insulin because of the low pH of its diluent.
- Currently available NPH and short-acting insulin formulations when mixed may be used immediately or stored for future use.
- Rapid-acting insulin can be mixed with NPH insulin.
- When rapid-acting insulin is mixed with either an intermediate-acting or a long-acting insulin, the mixture should be injected within 15 minutes before a meal.
- Insulin formulations may change; therefore manufacturers should be consulted when their recommendations appear to conflict with the American Diabetes Association guidelines.

Data from American Diabetes Association (ADA). (2004). Insulin administration. *Diabetes Care*, 27(Suppl. 1), 106-109.

Diabetes Association (ADA) guidelines for mixing insulins (Table 67-10).

! NURSING SAFETY PRIORITY

Drug Alert

Do not mix any other insulin type with insulin glargine, insulin detemir, or with any of the premixed insulin formulations, such as Humalog Mix 75/25.

Complications of Insulin Therapy. Hypoglycemia from insulin excess has many causes. Its effects and treatment are discussed on pp. 1451-1454 in the Preventing Hypoglycemia section.

Lipoatrophy is a loss of fat tissue in areas of repeated injection that results from an immune reaction to impurities in insulin. Treatment consists of injection of insulin at the edge of the atrophied area. Lipohypertrophy is an increased swelling of fat that occurs at the site of repeated insulin injections. The overlying skin has decreased sensitivity, and the area can become large and unsightly. Treatment consists of rotating the injection site among different body areas. Teach patients who take insulin to rotate injection sites to prevent lipohypertrophy.

Two conditions of fasting hyperglycemia can occur (Fig. 67-5). **Dawn phenomenon** results from a nighttime release of growth hormone that causes blood glucose elevations at about 5 to 6 AM. It is managed by providing more insulin for the overnight period (e.g., giving the evening dose of intermediate-acting insulin at 10 PM). **Somogyi phenomenon** is morning hyperglycemia from the counterregulatory response to nighttime hypoglycemia. It is managed by ensuring adequate dietary intake at bedtime and evaluating the insulin dose and exercise programs to prevent conditions that lead to hypoglycemia. Both problems are diagnosed by blood glucose monitoring during the night. Help identify these problems, and teach the patient and family about management.

Alternative Methods of Insulin Administration. Many methods of insulin delivery are available in addition to traditional subcutaneous injections.

FIG. 67-5 Three blood glucose phenomena in patients with diabetes.

FIG. 67-6 External insulin pump.

Continuous subcutaneous infusion of a basal dose of insulin (CSII) with increases in insulin at mealtimes is more effective in controlling blood glucose levels than a multiple-injection schedule. CSII allows flexibility in meal timing, because if a meal is skipped, the additional mealtime dose of insulin is not given. It is given by an externally worn pump containing a syringe and reservoir with rapid-acting insulin and is connected to the patient by an infusion set. Teach him or her to adjust the amount of insulin based on data from blood glucose monitoring. Rapid-acting insulin analogs are used with insulin infusion pumps (Fig. 67-6).

Problems with CSII include skin infections that can occur when the infusion site is not cleaned or the needle is not changed every 2 to 3 days. When the patient is receiving rapid-acting insulin and has normal blood glucose levels,

stopping the infusion quickly results in hyperglycemia. CSII may lead to more frequent and more severe ketoacidosis than other methods of insulin delivery because of inexperience in pump use, infection, accidental cessation or obstruction of the infusion, or mechanical pump problems. Stress the importance of testing for ketones when blood glucose levels are greater than 300 mg/dL (16.7 mmol/L).

Patients using CSII need intensive education. Because of the risk for hypoglycemia or hyperglycemia, he or she must be able to operate the pump, adjust the settings, and respond appropriately to alarms. Removing the pump for any length of time can result in hyperglycemia. Provide supplemental insulin schedules for times when the pump is not operational. CSII is more costly than traditional insulin injections, and not all costs are covered by insurance.

Injection devices now include a needleless system and a pen-type injector in addition to traditional insulin syringes. With a needleless device, the needle is replaced by an ultra-thin liquid stream of insulin forced through the skin under high pressure. Insulin given by jet injection is absorbed at a faster rate and has a shorter duration of action. Cost is a drawback to this system.

Patient Education: Drugs. Provide specific instructions about insulin therapy, new drug therapies, and self-monitoring of blood glucose levels.

Insulin storage varies by use. Teach patients to refrigerate insulin that is not in use to maintain potency, prevent exposure to sunlight, and inhibit bacterial growth. Insulin in use may be kept at room temperature for up to 28 days to reduce irritation at the injection site caused by cold insulin.

To prevent loss of drug potency, teach the patient to avoid exposing insulin to temperatures below 36° F (2.2° C) or above 86° F (30° C), to avoid excessive shaking, and to protect insulin from direct heat and light. Insulin should not be allowed to freeze. Insulin glargine (Lantus) should be stored in a refrigerator (36° to 46° F [2.2° to 7.8° C]) even when in use. Teach patients to discard any unused insulin after 28 days.

Teach patients to always have a spare bottle of each type of insulin used. A slight loss in potency may occur after the bottle has been in use for more than 30 days, even when the expiration date has not passed. Prefilled syringes are stable up to 30 days when refrigerated. If possible, store prefilled syringes in the upright position, with the needle pointing upward, so that insulin particles do not clog it. Teach patients to roll prefilled syringes between the hands before using. The effect of premixing insulins on blood glucose control is assessed by examining blood glucose levels.

Dose preparation is critical for insulin effectiveness and patient safety. Teach patients that the person giving the insulin needs to inspect the insulin before each use for changes (e.g., clumping, frosting, precipitation, or change in clarity or color) that may indicate loss in potency. Rapid-acting, short-acting, and glargine insulins should be clear, and all other types of insulin should be uniformly cloudy after gently rolling the vial between the hands. If potency is questionable, another vial of the same type of insulin should be used.

Syringes are the most commonly used method to administer insulin. The standard insulin syringes are marked in insulin units. They are available in 1-mL (100-U), ½-mL (50-U), and ⅓-mL (30-U) sizes. The unit scale on the barrel of the syringe differs with the syringe size and manufacturer.

FIG. 67-7 Reuse of an insulin needle. **A**, A new needle. **B**, A needle that has been used once. **C**, A needle that has been used twice. **D**, A needle that has been used six times.

CHART 67-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Subcutaneous Insulin Administration

- Wash your hands.
- Inspect the bottle for the type of insulin and the expiration date.
- Gently roll the bottle of intermediate-acting insulin in the palms of your hands to mix the insulin.
- Clean the rubber stopper with an alcohol swab.
- Remove the needle cover, and pull back the plunger to draw air into the syringe. The amount of air should be equal to the insulin dose. Push the needle through the rubber stopper, and inject the air into the insulin bottle.
- Turn the bottle upside down, and draw the insulin dose into the syringe.
- Remove air bubbles in the syringe by tapping on the syringe or injecting air back into the bottle. Redraw the correct amount.
- Make certain the tip of the plunger is on the line for your dose of insulin. Magnifiers are available to assist in measuring accurate doses of insulin.
- Remove the needle from the bottle. Recap the needle if the insulin is not to be given immediately.
- Select a site within your injection area that has not been used in the past month.
- Clean your skin with an alcohol swab. Lightly grasp an area of skin, and insert the needle at a 90-degree angle.
- Push the plunger all the way down. This will push the insulin into your body. Release the pinched skin.
- Pull the needle straight out quickly. Do not rub the place where you gave the shot.
- Dispose of the syringe and needle without recapping in a puncture-proof container.

Insulin syringe needles are measured in 28-, 29-, 30-, and 31-gauge and in lengths of $\frac{1}{2}$ -inch and $\frac{5}{16}$ -inch. Short needles are not used for obese patients because of poor insulin absorption. To ensure accurate insulin measurement, instruct the patient to always buy the same type of syringe. [Charts 67-4 and 67-5](#) review instructions for drawing up a single insulin injection and for mixing regular and NPH insulin in the same syringe.

CHART 67-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

How to Mix a Prescribed Dose of 10 Units of Regular Insulin and 20 Units of NPH Insulin

- Wash your hands.
- Inspect the bottle for the type of insulin and the expiration date.
- Gently roll the bottle of intermediate-acting (NPH) insulin in the palms of your hands to mix the insulin.
- Clean the rubber stopper with an alcohol swab.
- Inject 20 units of air into the NPH insulin bottle. The amount of air should be equal to the dose of insulin needed. Always inject air into the intermediate-acting insulin first. Withdraw the needle.
- Inject 10 units of air into the regular insulin bottle. The amount of air is equal to the dose of insulin desired.
- Withdraw 10 units of regular insulin. Be sure that the syringe is free of air bubbles. Always withdraw the shorter-acting insulin first.
- Withdraw 20 units of NPH insulin with the same syringe, being careful not to inject any short-acting insulin into the bottle. (A total of 30 units should be in the syringe.)

Manufacturers recommend that disposable needles be used only once. Reuse of an insulin syringe and needle can compromise insulin sterility. Most insulins contain products that inhibit growth of bacteria commonly found on the skin; however, most patients with diabetes are at an increased risk for infection. Another reason to not reuse smaller (30- and 31-gauge) needles is that even with one injection, the needle tip can become bent to form a hook, which can lacerate tissue or break off to leave needle fragments in the skin ([Fig. 67-7](#)). Teach the patient to discard the syringe and needle after one use by participating in a community program, such as a drop-off center for household hazardous waste, or in a national disposal program, such as a “sharps” mail-back program (in accordance with The Joint Commission’s National Patient Safety Goals). Information on needle disposal can be obtained at www.safeneedledisposal.org.

Pen-type injectors hold small, lightweight, prefilled insulin cartridges. The injectors are easy to carry and make intensive

therapy with multiple injections easier. These devices allow greater accuracy than traditional insulin syringes, especially when measuring small doses. Discuss proper storage for pre-filled insulin pens or cartridges. More drugs are becoming available in a pre-filled syringe or cartridge. Ensure that the product is appropriate to the patient's unique needs. *Pen-type injectors are not designed for independent use by visually impaired patients or by those with cognitive impairment.* Ensure that the patient has received education on its use. Each syringe or cartridge has specific requirements. Patients using the FlexPen (Novo Nordisk) must be able to attach a needle and to perform an air shot of 2 units to ensure that a dose of insulin is administered. The Institute for Safe Medication Practices (ISMP) and The Joint Commission's National Patient Safety Goals identify insulin as a *High-Alert* drug. (**High-Alert** drugs are those that have an increased risk for causing patient harm if given in error.) The ISMP cautions that digital displays on some of the newer insulin formulations can be misread. If the pen is held upside down, as a left-handed person might do, a dose of 52 units actually appears to be a dose of 25 units, and a dose of 12 units looks like a dose of 21 units.

DECISION-MAKING CHALLENGE

Patient-Centered Care

You are teaching a 22-year-old woman newly diagnosed with type 1 diabetes how to self-administer insulin. This is the second teaching session, and she can draw up the correct amount and maintain sterility. She has not been able to actually inject the needle into her skin, saying "It doesn't hurt but I just can't stand to push that needle in." She has not had any difficulty when her sister or the nurse has injected the insulin.

1. What should your immediate response be?
2. What modifications in your teaching technique can you make?
3. Is it critical that the patient learn to inject herself at this session? Why or why not?
4. Is there any type of adaptation that can help with this problem?

Patient Education: Blood Glucose Monitoring. Self-monitoring of blood glucose (SMBG) levels provides information to assess effectiveness of the management plan. SMBG allows patients and providers to evaluate patient response to therapy and assess whether glycemic targets are being reached. Results of SMBG are useful in preventing hypoglycemia and adjusting drug therapy, nutrition therapy, and physical activity. Assessment of blood glucose levels is very important for these situations:

- Symptoms of hypoglycemia/hyperglycemia
- Hypoglycemic unawareness
- Periods of illness
- Before and after exercise
- Gastroparesis
- Adjustment of diabetes medications
- Evaluation of other drug therapies (e.g., steroids)
- Preconception planning
- Pregnancy

Technique for SMBG follows principles that are the same for most self-monitoring systems. The finger is pricked, a drop of blood flows over or is drawn into a testing strip or disc impregnated with chemicals, and the glucose value is displayed in mg/dL or mmol/L. Most meters display blood glucose results on a screen. For vision-impaired patients,

"talking meters" are available to allow independence in blood glucose monitoring.

Home blood glucose meters measure glucose in whole blood, whereas most laboratory tests measure glucose in plasma, which is generally 10% to 15% higher than glucose measured in whole blood. Many meters currently in use give results as "plasma equivalents" even though they are measuring whole blood. This value is calculated from the whole blood glucose reading using a formula built into the glucose meter. This conversion allows patients to compare their home glucose monitoring results with laboratory measurements of glucose.

Data obtained from SMBG are evaluated along with other measures of blood glucose (e.g., glycosylated hemoglobin, or hemoglobin A_{1c} [HbA_{1c}], values) or periodic laboratory blood glucose tests. Even when SMBG is performed correctly, the results are affected by hematocrit values (anemia falsely elevates glucose values; polycythemia falsely depresses them) and may be unreliable in the hypoglycemic or severe hyperglycemic ranges.

Blood glucose meters must meet the accuracy standards set by the International Organization for Standardization (IOS). According to the IOS, blood glucose meters must provide results that are within 20% of a laboratory standard 90% of the time. The performance of SMBG systems depends on accuracy of the specific blood glucose meter, operator proficiency, and test strip quality. Results are influenced by the size and quality of the blood sample; the meter's calibration to the strip in use; environmental conditions of altitude, temperature, and moisture; and patient-specific conditions of hematocrit level, triglyceride level, high levels of substances such as ascorbic acid in blood, and the presence of hypotension or hypoxia.

Accuracy of the blood glucose monitor is ensured when the manufacturer's directions are followed. The most significant source of error in blood glucose measurement is related to the skill of the user and not to errors of the instrument. Common errors in SMBG involve failure to obtain a sufficient blood drop, poor storage of test strips, using expired strips, and not changing the code number on the meter to match the strip bottle code. Help the patient select a meter based on cost of the meter and strips, ease of use, and availability of repair and servicing. Provide training, explain and demonstrate procedures, assess visual acuity, and check the patient's ability to perform the procedure through a return demonstration. Glucose meters are designed to reduce user error as much as possible. Newer meters no longer require wiping the blood from the strip in timed sequence, include error signals for inadequate sample size, "lock out" if control solutions are not tested, and store hundreds of SMBG results. (See the Consumer Guide published yearly in the January edition of Diabetes Forecast [forecast.diabetes.org] for information to help patients determine which blood glucose meter best meets their needs.)

Even when highly trained personnel tested meters under optimal conditions, accuracy and precision varied widely among capillary blood glucose monitoring devices. Teach patients to properly calibrate the machine. Instruct them to re-check the calibration and re-test if they obtain a test result that is unusual for them and whenever they are in doubt about test accuracy. Continued retraining of patients performing SMBG helps ensure accurate results because

performance accuracy deteriorates over time. Laboratory glucose determinations are more accurate than SMBG.

Frequency of testing varies with the complexity of the drug schedules and the patient's prescribed therapy target outcomes. The ADA recommends that patients taking multiple insulin injections or using insulin pump therapy monitor glucose levels three or more times daily. For patients taking less-frequent injections of insulin, non-insulin therapy, or nutrition therapy alone, SMBG is useful for evaluation of therapy.

Blood glucose therapy target goals are set individually for each patient. The entire health care team works with him or her to reach target blood glucose levels. The ADA recommends that patients with type 1 diabetes aim for HbA_{1c} values less than 7%, premeal glucose levels of 70 to 130 mg/dL (3.9 to 7.2 mmol/L), and postmeal glucose levels less than 180 mg/dL (10.0 mmol/L) (ADA, 2010b).

Infection control measures are needed for SMBG. Teach the patient to follow Centers for Disease Control and Prevention (CDC) guidelines for infection control during SMBG. The chance of becoming infected from blood glucose monitoring processes is reduced by handwashing before monitoring and by not reusing lancets. *Instruct patients to not share their blood glucose monitoring equipment.* Hepatitis B virus can survive in a dried state for at least 1 week. Infection can be spread by the lancet holder even when the lancet itself has been changed. Small particles of blood can stick to the device and infect multiple users. Regular cleaning of the meter is critical for infection control. Remind health care staff who perform blood glucose testing and family members who help with testing to wear gloves.

Many meters have sophisticated data-handling capabilities. Many can be downloaded by a cable or by infrared technology to a computer that has diabetes management software. Some meters allow entry of additional data such as insulin dose, amounts of carbohydrate eaten, or exercise. A radio link to an insulin pump allows automatic transfer of glucose readings to a calculator that assists the patient in deciding on an appropriate insulin dose.

! NURSING SAFETY PRIORITY

Action Alert

Prevent hypoglycemia by ensuring that appropriate blood glucose testing products are used for patients receiving parenteral maltose, parenteral galactose, and oral xylose products.

The U.S. Food and Drug Administration issued an Important Safety Information Notice about blood glucose measurement following use of parenteral maltose, parenteral galactose, and oral xylose-containing products.

When patients receive icodextrin (EXTRANEAL) peritoneal dialysis solution, blood glucose values obtained using point-of-care blood glucose monitors may be falsely elevated. Icodextrin is metabolized to maltose, and the presence of maltose in blood can cause readings to be falsely elevated when using some, but not all, portable glucose monitors. Insulin therapy based on falsely elevated blood glucose values has caused hypoglycemia, coma, and death. Products containing maltose, galactose, and xylose also cause blood glucose readings to be falsely elevated. Maltose is found in immune globulin intravenous (Octagam 5%, Gamimune N 5%),

rho(D) immune globulin (WinRho SDF), and vaccinia immune globulin (VIG-IV). Galactose and xylose are found in some foods, herbs, and dietary supplements; they are also used in diagnostic tests.

Portable glucose monitors using test strips with glucose dehydrogenase pyrroloquinoline quinone (GDH-PQQ) or glucose-dye-oxidoreductase (GDO) reagents cannot distinguish between glucose, maltose, and other sugars and will provide falsely elevated "glucose" readings in the presence of these sugars. The GDH-PQQ and GDO reagent-based glucose monitors are widely available and commonly used in hospital settings to provide point-of-care blood glucose testing. Various manufacturers, including Abbott, Bayer, Roche, CH Diagnostics, and Home Diagnostics, have glucose strips that use GDH-PQQ technology.

It is important that staff understand the potential for hypoglycemia when patients are admitted to the hospital. In that instance, it is safest to monitor blood glucose patterns by laboratory methods. Blood glucose monitoring needs to be performed with a system whose test strips use a different enzyme technology. The best resource for guidance in selecting a glucose monitoring system that is not reactive to maltose interference is the manufacturer of the test strip. Some manufacturers produce test strips that use more than one type of enzyme technology.

Alternate site testing allows patients to obtain blood from sites other than the fingertip and is available on many meters. However, use caution when interpreting results obtained from alternate sites. These results are not necessarily the same as those from the fingertip when tested at the same time. Comparison studies have shown wide variation between fingertip and alternate sites, and the variation is most evident during times when blood glucose levels are rapidly changing. Teach patients that there is a lag time for blood glucose levels between the fingertip and other sites when blood glucose levels are changing rapidly and that the fingertip reading is the only safe choice at those times.

! NURSING SAFETY PRIORITY

Critical Rescue

Teach patients with a history of hypoglycemic unawareness not to test at alternative sites.

Continuous blood glucose monitoring (CGM) systems monitor glucose levels in interstitial fluid. The system consists of three parts: a disposable sensor that measures glucose levels, a transmitter that is attached to the sensor, and a receiver that displays and stores glucose information. A thin plastic sensor is inserted into subcutaneous tissue. Electrodes measure interstitial glucose concentrations and convert these values to blood glucose levels. The transmitter attached to the sensor uses radiofrequency communication to send information to the receiver, which provides real-time glucose information to the user. After an initiation or warm-up period, the sensor gives glucose values every 1 to 5 minutes. Sensors are approved for 3- to 7-day use, depending on the manufacturer. CGM provides information about the current blood glucose level, provides short-term feedback about results of treatment, and provides warnings when glucose readings become dangerously high or low. Most available sensors require at least two capillary glucose readings per day for calibration of

FIG. 67-8 The MiniMed Paradigm® REAL-Time Insulin Pump and Continuous Glucose Monitoring System. **A**, Pump. **B**, Injection cannula. **C**, Glucose sensor. **D**, Data transmitter.

the sensor. Sensor accuracy depends on these calibrations. There may be a lag time between the capillary glucose measurement and the glucose sensor value. If the blood glucose value is changing rapidly, the time between capillary and interstitial glucose values may be as long as 30 minutes. For this reason, capillary glucose readings need to be checked on all extreme values and before any corrective treatment is given.

Fig. 67-8 shows this type of system. The costs for CGM systems are substantial. The initial device varies from \$400 to more than \$2000. An additional monthly charge of at least \$300 includes the cost of disposable sensors, which last between 3 to 7 days, and additional glucose test strips used to calibrate the sensors and perform FDA-required capillary glucose testing before treatment decisions are made.

Continuous glucose monitoring is meant to supplement, not replace, finger stick tests. Insulin should be given only after confirming the results of any of the continuous glucose monitoring systems.

Nutrition Therapy. Effective self-management of diabetes requires that the meal plan, education, and counseling programs be “patientized” for each patient. A dietitian should be a member of the treatment team. The nurse, dietitian, patient, and family work together on all aspects of the meal plan, which must be realistic and as flexible as possible. Plans that consider the patient’s cultural background, financial status, and lifestyle are more likely to be successful.

Desired Outcomes of Nutrition Therapy. The ADA (2008) advocates that nutrition therapy focuses on these outcomes:

- Achieving and maintaining blood glucose levels in the normal range or as close to normal as is safely possible
- Achieving and maintaining a blood lipid profile that reduces the risk for vascular disease
- Achieving blood pressure levels in the normal range or as close to normal as is safely possible
- Preventing or slowing the rate of development of the chronic complications of diabetes by modifying nutrient intake and lifestyle

- Addressing patient nutrition needs taking into account personal and cultural preferences and willingness to change
- Maintaining the pleasure of eating by limiting food choices only when indicated by scientific evidence
- Meeting the nutritional needs of unique times of the life cycle, particularly for pregnant and lactating women and for older adults with diabetes
- Providing self-management training for patients treated with insulin or insulin secretagogues for exercising safely, including the prevention and treatment of hypoglycemia, and managing diabetes during acute illness

Principles of Nutrition in Diabetes. The dietitian develops a meal plan based on the patient’s usual food intake, weight-management expectations, and lipid and blood glucose patterns. Day-to-day consistency in the timing and amount of food eaten helps control blood glucose. Patients receiving insulin therapy need to eat at times that are coordinated with the timed action of insulin. Teach patients using intense insulin therapy to adjust premeal insulin to allow for timing and quantity changes in their meal plan.

Carbohydrate recommendation for the patient with diabetes is a diet containing 45% to 65% of calories from carbohydrate, with a minimum intake of 130 g carbohydrate/day. The diet should include carbohydrate from fruit, vegetables, whole grains, legumes, and low-fat milk. Diets restricting total carbohydrate to less than 130 g/day are not recommended in the management of diabetes (ADA, 2008).

Food choices that prevent after-meal (*postprandial*) blood glucose elevation are important in achieving blood glucose control. The amount and types of carbohydrate consumed have the greatest impact on after-meal blood glucose levels.

The percentage of calories from carbohydrates is determined for each patient. Various starches have different blood glucose responses. Place the emphasis on the *total amount* of carbohydrate consumed each day rather than the source of the carbohydrate. Little evidence supports the assumption that sugars are more rapidly absorbed than starches and cause blood glucose values to increase more rapidly.

Dietary fat and cholesterol intake for people with diabetes focuses on limiting saturated fatty acids, *trans* fatty acids, and cholesterol to reduce the risk for cardiovascular disease. Current recommendations from the ADA (2008, 2010b) for patients with diabetes are:

- Limiting saturated fatty intake to less than 7% of total calories
- Minimizing intake of *trans* fat
- Limiting dietary cholesterol to less than 200 mg/day
- Having two or more servings of fish per week (with the exception of commercially fried fish) to provide n-3 polyunsaturated fatty acids

Trans fatty acids raise low-density lipoprotein (LDL) cholesterol and lower high-density lipoprotein (HDL) cholesterol; both actions increase the risk for cardiovascular disease. *Trans* fatty acids are found in hard margarine and in foods prepared with or fried in hydrogenated and partly hydrogenated oils. Teach the patient to restrict intake of *trans* fatty acids by limiting the amount of commercially fried foods and bakery goods eaten.

Further dietary fat restrictions for patients with diabetes are determined by a dietitian based on specific lipid levels.

Adults with diabetes should be tested annually for abnormalities of fasting serum cholesterol, triglyceride, HDL cholesterol, and calculated LDL cholesterol levels (ADA, 2008).

Protein intake of 15% to 20% of total daily calories is appropriate for patients with diabetes and normal kidney function. In patients with microalbuminuria, reducing protein intake to 10% of calories (0.8-1.0 g/kg) may slow progression of kidney failure. Reducing protein intake to not more than 0.8 g/kg body weight in later stages of chronic kidney disease may improve function (ADA, 2008).

Fiber improves carbohydrate metabolism and lowers cholesterol levels. Taste and texture, limited food choices, and GI side effects make it difficult to achieve a high-fiber intake. Assist the patient to first reach the target of 14 g per 1000 calories. The American Heart Association recommends a fiber intake of 25 g each day. Teach the patient to select a variety of fiber-containing foods such as legumes, fiber-rich cereals (more than 5 g fiber/serving), fruits, vegetables, and whole-grain products because they provide vitamins, minerals, and other substances important for good health.

Teach the patient that adding high-fiber foods to the diet gradually can reduce abdominal cramping, loose stools, and flatulence. An increase in fluid intake should accompany increased fiber intake. The nurse and the patient should pay careful attention to blood glucose levels because hypoglycemia can result when dietary fiber intake increases significantly.

Sweeteners include sucrose and a variety of nonnutritive substances. Dietary sucrose does not increase blood glucose more than equal amounts of other starches. Intake of sucrose and sucrose-containing foods by patients with diabetes does not need to be restricted out of a concern for causing hyperglycemia. Sucrose can be included in the meal plan as long as it is adequately covered with insulin or other glucose-lowering agents.

The use of products to enhance the taste of food while not disturbing blood glucose control is desirable. The FDA has approved five nonnutritive sweeteners: saccharin, aspartame, acesulfame, neotame, and sucralose.

Alcohol consumption can affect blood glucose levels. Levels are not affected by *moderate* use of alcohol when diabetes is well controlled. Teach patients with diabetes that two alcoholic beverages for men and one for women can be ingested with, and in addition to, the usual meal plan. (One alcoholic beverage equals 12 ounces of beer, 5 ounces of wine, or 1 and ½ ounces of distilled spirits.) Alcohol raises plasma triglycerides. Thus reducing or abstaining from alcohol is important for patients with hyperlipidemia. One alcoholic beverage is substituted for two fat exchanges when calculating caloric intake (ADA, 2008).

! NURSING SAFETY PRIORITY

Action Alert

Because of the potential for alcohol-induced hypoglycemia, instruct the patient with diabetes to ingest alcohol only with or shortly after meals.

Patient Education: Prescribed Nutrition Plan. No one meal plan is right for all patients with diabetes. Each patient's nutrition recommendations are based on blood glucose monitoring results, total blood lipid levels, and glycosylated

hemoglobin (HbA_{1c}). These tests help determine whether current meal and exercise patterns need adjustment or whether present habits need reinforcement. A specific nutritional prescription is developed for each patient.

Reinforce information provided by the dietitian. The patient with DM needs to understand how to adjust food intake during illness, planned exercise, and social occasions (e.g., restaurant meals) when the usual time of eating is delayed. He or she may be unable to follow the prescribed plan because of an inability to see, read, or understand printed materials. Share dietary information with the person who prepares the meals. The dietitian sees each patient at least yearly to identify changes in lifestyle and make appropriate nutrition therapy changes. Some patients, such as those with weight control problems or low incomes, may need more frequent evaluation and counseling.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which statement made by the client during nutritional counseling indicates to the nurse that the client with diabetes type 1 correctly understands his or her nutritional needs?

- A. "If I completely eliminate carbohydrates from my diet, I will not need to take insulin."
- B. "I will make certain that I eat at least 130 g of carbohydrate each day regardless of my activity level."
- C. "My intake of protein in terms of grams and calories should be the same as my intake of carbohydrate."
- D. "My intake of unsaturated fats in terms of grams and calories should be the same as my intake of protein."

Meal Planning Strategies. Many meal planning approaches are available. Each approach emphasizes different aspects of nutrition.

Exchange systems are based on three food groups: carbohydrates, meat and meat substitutes, and fat. The exchange list for meal planning assumes that foods with similar nutrient content affect blood glucose levels similarly. Plans based on the exchange system produce predictable blood glucose responses. The patient's prescription identifies how many items from each food group are to be eaten at a meal or snack. Information can be obtained from the American Dietetic Association at www.eatright.org.

Carbohydrate (CHO) counting is a simple approach to meal planning that uses label information of the nutritional content of packaged food items. Because fat and protein have little effect on after-meal blood glucose levels, CHO counting focuses on the nutrient that has the greatest impact on these levels. It uses total grams of carbohydrate, regardless of the food source. The dietitian determines the number of grams of carbohydrate to be eaten at each meal and snack and helps the patient make appropriate food choices. This method is effective in achieving overall blood glucose control when carbohydrate intake is consistent from day to day.

Patients using intensive insulin or pump therapies can use CHO counting to determine insulin coverage. After the amount of insulin needed to cover the usual meal is determined, insulin may be added or subtracted for changes in carbohydrate intake. An initial formula of 1 unit of rapid-acting insulin for each 15 g of carbohydrate provides flexibility to meal plans. The patient determines the grams of carbohydrate in a specific meal or snack by reading labels or

TABLE 67-11 CARBOHYDRATE COUNTING

MEAL	FOOD SOURCE	GRAMS OF CARBOHYDRATES	TOTAL	INSULIN DOSE* (1:15 RATIO)
Breakfast	2 slices honey grain bread	32		
	¼ cup egg substitute	0		
	½ cup orange juice	15		
	1 tablespoon lower-fat margarine	0	47	3
Lunch	2 oz tuna, canned in water	0		
	1 hamburger bun	30		
	Fat-free Pringles (#15)	15		
	1 tablespoon reduced-fat mayonnaise	0		
	1 tomato and 1 lettuce slice	0		
	1 medium dill pickle	0		
	Sugar-free pudding made with fat-free milk	15	60	4
Supper	3 oz chicken breast, grilled	0		
	1 small (3 oz) baked potato	15		
	1 cup steamed broccoli	10		
	1 French roll	25		
	1 tablespoon lower-fat margarine	0		
	2 tablespoons reduced-fat sour cream	0		
	½ cup canned pineapple (in own juice)	15	65	4

*Insulin dose has been rounded off to the nearest whole unit.

weighing and measuring each item. The total grams of carbohydrate are used to calculate the bolus dose of insulin based on his or her prescribed insulin-to-carbohydrate ratio. See Table 67-11 for an example of carbohydrate counting.

People at high risk for type 2 diabetes are encouraged to achieve moderate weight loss (7% total body weight), participate in regular physical activity (150 minutes per week), and reduce caloric and dietary fat intake. These at-risk people are also encouraged to increase fiber intake to at least 14 g per 1000 calories consumed and to eat foods containing whole grains.

Special considerations for type 1 diabetes include developing insulin regimens that conform to the patient's preferred meal routines, food preferences, and exercise patterns. Patients using rapid-acting insulin by injection or an insulin pump should adjust insulin doses based on the carbohydrate content of the meals and snacks. Insulin-to-carbohydrate ratios are developed and are used to provide mealtime insulin doses. Blood glucose monitoring before and 2 hours after meals determines whether the insulin-to-carbohydrate ratio is correct. For patients who are on fixed insulin regimens and do not adjust premeal insulin dosages, consistency of timing of meals and the amount of CHO eaten at each meal is important to prevent hypoglycemia.

Physical exercise can cause hypoglycemia if insulin is not decreased before activity. For planned exercise, reduction in insulin dosage is the preferred method for hypoglycemia prevention. For unplanned exercise, intake of additional CHO is usually needed. Moderate exercise increases glucose utilization by 2 to 3 mg/kg/min. A 70-kg person would need about 10 to 15 g additional CHO per hour of moderate-intensity physical activity. More CHO is needed for intense activity (ADA, 2008).

It is important for patients with type 1 diabetes to avoid gaining weight. **Hyperinsulinemia** (chronic high blood insulin levels) can occur with intensive treatment schedules and may result in weight gain. These patients may need to manage hyperglycemia by restricting calories rather than

increasing insulin. Weight gain can be minimized by following the prescribed meal plan, getting regular exercise, and avoiding overtreatment of hypoglycemia.

Special considerations for type 2 diabetes focus on lifestyle changes. Many patients with type 2 diabetes are overweight and insulin resistant. Nutrition therapy stresses lifestyle changes that reduce calories eaten and increase calories expended through physical activity. Many patients also have abnormal blood fat levels and hypertension (metabolic syndrome), making reductions of saturated fat, cholesterol, and sodium desirable. A moderate caloric restriction (250 to 500 calories less than average daily intake) and an increase in physical activity improve diabetic control and weight control. Decreases of more than 10% of body weight can result in

CONSIDERATIONS FOR OLDER ADULTS

Older patients are at increased risk for malnutrition, hypoglycemia, and especially dehydration, a factor in the development of hyperglycemic-hyperosmolar state (HHS). Many factors contribute to malnutrition. Nutritional needs of the older adult change as the person's taste, smell, and appetite diminish and his or her ability to obtain and prepare food decreases. Older patients who prepare their own food or have tooth loss or poorly fitting dentures may not eat enough food. Neuropathy with gastric retention or diarrhea compounds poor food intake. Impaired cognition and depression may disrupt self-care. Older patients may have a marginal food supply because of inadequate income, may have poor understanding of meal-planning needs, or may live alone and have reduced incentive to prepare or eat proper meals. They may eat in restaurants or live in situations in which they have little control over meal preparation. Regular visits by home health nurses can assist older patients in following a diabetic meal plan.

A realistic approach to nutrition therapy is essential for the older patient with diabetes. Changing the eating habits of 60 to 70 years is very difficult. The nurse, dietitian, and patient assess the patient's usual eating patterns. Teach the older patient taking antidiabetic drugs about the importance of eating meals and snacks at the same time every day, eating the same amount of food from day to day, and eating all food allowed on the diet.

significant improvement in HbA_{1c}. Decreasing intake of cholesterol-raising fatty acids helps reduce the risk for cardiovascular disease.

When patients with type 2 diabetes need insulin, consistency in timing and carbohydrate content of meals is important. Division of the total daily calories into three meals or into smaller meals and snacks is based on patient preference.

Exercise Therapy. Regular exercise is an essential part of diabetic management. It has beneficial effects on carbohydrate metabolism and insulin sensitivity. Programs of increased physical activity and weight loss reduce the incidence of type 2 diabetes in patients with impaired glucose tolerance (AADE, 2008).

Plasma glucose levels remain stable in physically active patients without diabetes because of the balance between glucose use by exercising muscles and glucose production by the liver. Exercise does not result in hyperglycemia or hypoglycemia. The patient with type 1 DM cannot make the hormonal changes needed to maintain stable blood glucose levels during exercise. Without an adequate insulin supply, cells cannot use glucose. Low insulin levels trigger release of glucagon and epinephrine (counterregulatory hormones) to increase liver glucose production, further raising blood glucose levels. In the absence of insulin, free fatty acids become the source of energy. Exercise in the patient with uncontrolled diabetes results in further hyperglycemia and the formation of ketone bodies. He or she may have prolonged elevated blood glucose levels after vigorous exercise.

Exercise in the person with diabetes can cause hypoglycemia because of increased muscle glucose uptake and inhibited glucose release from the liver. It can occur during exercise and for up to 24 hours after exercise. Replacement of muscle and liver glycogen stores, along with increased insulin sensitivity after exercise, causes insulin requirements to drop.

Benefits of Exercise. Appropriate exercise results in better regulation of blood glucose levels and lowering of insulin requirements for patients with type 1 DM. Exercise also increases insulin sensitivity, which enhances cell uptake of glucose and promotes weight loss.

Regular exercise decreases risk for cardiovascular disease. It decreases most blood lipid levels and increases high-density lipoproteins (HDLs). Exercise decreases blood pressure and improves cardiovascular function. Regular vigorous physical activity prevents or delays type 2 DM by reducing body weight, insulin resistance, and glucose intolerance.

Adjustments for Diabetes Complications. Exercise in the presence of long-term complications of diabetes often requires some adjustment. Vigorous aerobic or resistance exercise may be contraindicated in the presence of proliferative diabetic retinopathy or severe nonproliferative diabetic retinopathy. Teach the patient with retinopathy to avoid the **Valsalva maneuver** (breath holding while bearing down) and activities that increase blood pressure. Heavy lifting, rapid head motion, or jarring activities can cause vitreous hemorrhage or retinal detachment. Decreased pain sensation in the extremities increases the risk for skin breakdown and infection and for joint destruction. Teach patients with peripheral neuropathy to wear proper footwear and to examine their feet daily for lesions. Teach anyone with a foot injury or open sore to engage in non-weight-bearing activities such as swimming, bicycling, or arm exercises. Those with autonomic neuropathy

are at increased risk for exercise-induced injury from impaired temperature control, postural hypotension, and impaired thirst with risk for dehydration. Physical activity also can increase urine protein excretion. Encourage high-risk patients to start with short periods of low-intensity exercise and to increase the intensity and duration slowly (ADA, 2010b).

Safety Assessment. Assessment before initiating an exercise program is necessary to ensure patient safety. Although current ADA guidelines do not recommend routine screening for patients with diabetes who have no manifestations of cardiovascular disease, be alert to conditions that might predispose the patient to injury or that contraindicate certain types of exercise. Regular physical activity increases the risk for both musculoskeletal injury and life-threatening cardiovascular events. The ADA recommends screening when any of these conditions exist (Roelker, 2008):

- Typical or atypical chest pain
- Abnormal electrocardiogram (ECG) suggestive of ischemia or infarction
- Peripheral or carotid occlusive disease
- Age older than 35 years with sedentary lifestyle in a patient who plans a vigorous exercise program
- Two or more risk factors in addition to diabetes, such as dyslipidemia, hypertension, tobacco use
- Family history for premature coronary artery disease, or microalbuminuria or macroalbuminuria of more than 10 years' duration
- Age older than 25 years and type 1 diabetes of more than 15 years' duration
- Severe autonomic neuropathy, severe peripheral neuropathy, history of foot lesions, and unstable proliferative retinopathy

Screening for coronary artery disease before an exercise program is started is recommended for patients with cardiovascular risk factors. The purpose of exercise treadmill testing (ETT) is to determine if a person can exercise to 85% of their predicted heart rate without having ischemic changes. Also, ETT provides information about exercise capacity and functional status. Failure to achieve 85% of the predicted heart rate is associated with increased death from all causes.

Imaging studies provide information regarding the risk for exercise-induced ischemia. Medical stress tests with vasodilator therapy are recommended for patients who are not able to exercise or who have abnormal ECG. Stress echocardiography provides information about left ventricular systolic, left ventricular diastolic, and valvular function, and it assesses for evidence of exercise-induced ischemia. Additional tests may be performed to determine the presence of obstructive lesions in coronary arteries.

The positive benefits of exercise are short term (i.e., triglyceride reduction lasts for up to 72 hours). Advise people with DM to perform at least 150 min/week of moderate-intensity aerobic physical activity, or 75 min/week of vigorous aerobic physical activity or an equivalent combination of the two. In the absence of contraindications, patients with type 2 diabetes are urged to perform resistance exercise 3 times a week, targeting all major muscle groups (ADA 2010b). The effect of a single bout of aerobic exercise on insulin sensitivity lasts 24 to 72 hours, depending on the duration and intensity of the activity. The ADA recommends that there be no more than 2 consecutive days without aerobic physical activity.

A 5- to 10-minute warm-up period with stretching and low-intensity exercise before exercise prepares the skeletal muscles, heart, and lungs for a progressive increase in exercise intensity. After the activity session, a cool-down should be performed similarly to the warm-up. The cool-down should last 5 to 10 minutes and gradually bring the heart rate down to pre-exercise level.

Guidelines for exercise are based on blood glucose levels and urine ketone levels. Recommend that the patient test blood glucose before exercise, at intervals during exercise, and after exercise to determine if it is safe to exercise and to evaluate the effects of exercise. The absence of urine ketones indicates that enough insulin is available for glucose transport and that exercise should be effective in lowering blood glucose levels. *When urine ketones are present, the patient should NOT exercise.* Ketones indicate that current insulin levels are not adequate and that exercise would elevate blood glucose levels. Carbohydrate foods should be ingested to raise blood glucose levels above 100 mg/dL (5.6 mmol/L) before engaging in exercise.

! NURSING SAFETY PRIORITY

Critical Rescue

Teach patients with type 1 diabetes to perform vigorous exercise only when blood glucose levels are 100 to 250 mg/dL (5.6 to 13.8 mmol/L) and no ketones are present in the urine.

Patient Education: Exercise Promotion. Chart 67-6 lists tips to teach the patient and family about self-management and exercise. Instruct the patient to wear shoes with good traction and cushioning and to examine the feet daily and after

CHART 67-6 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Exercise

- Teach the patient about the relationship between regularly scheduled exercise and blood glucose levels, blood lipid levels, and complications of diabetes.
- Reinforce the level of exercise recommended for the patient based on his or her physical health.
- Instruct the patient to wear appropriate footwear designed for exercise.
- Remind the patient to examine his or her feet daily and after exercising.
- Warn the patient not to exercise within 1 hour of insulin injection or near the time of peak insulin action.
- Teach patients how to prevent hypoglycemia during exercise:
 - Do not exercise unless blood glucose level is at least 80 and less than 250 mg/dL.
 - Have a carbohydrate snack before exercising if 1 hour has passed since the last meal or if the planned exercise is high intensity.
 - Carry a simple sugar to eat during exercise if symptoms of hypoglycemia occur.
 - Ensure that identification information about diabetes is carried during exercise.
- Remind the patient to check blood glucose levels more frequently on days in which exercise is performed and that extra carbohydrate and less insulin may be needed during the 24-hour period after extensive exercise.

exercise. Warn him or her to not exercise in extreme heat or cold or during periods of poor blood glucose control. Teach the patient to stay hydrated, especially during and after exercise in a warm environment.

Teach patients not to exercise within 1 hour of insulin injection or at the peak time of insulin action. Exercise can increase absorption of insulin from the injection site, increasing blood insulin levels. The risk for hypoglycemia increases when insulin is injected into an area that is exercised.

Teach patients about the risk for hypoglycemia and its preventive measures. Those taking insulin secretagogues or insulin should monitor blood glucose levels to determine the effects of exercise. Reinforce that snacks containing rapidly absorbable carbohydrate may be eaten before and during exercise to maintain normal blood glucose levels. Extra carbohydrate may be needed for up to 24 hours after exercise to prevent hypoglycemia. The amount of additional carbohydrate is directed by the results of blood glucose monitoring. Teach the patient to decrease insulin dosage before planned exercise as directed.

Advise the nonobese patient who is taking insulin secretagogues or insulin to have a carbohydrate-containing snack before exercise if at least 1 hour has passed since the last food was eaten or if high-intensity exercise is planned. Additional carbohydrate intake is not needed when the blood glucose level exceeds 100 mg/dL (5.6 mmol/L) before exercise and the planned activity is of low intensity and short duration. When vigorous activity of long duration is planned, teach the patient to eat an additional 15 to 30 g of carbohydrate for every 30 to 60 minutes of exercise. Snacks such as fruit, fruit juice, bread products, and whole milk can prevent hypoglycemia. Teach patients to carry a simple sugar (hard candy) to eat if symptoms of hypoglycemia occur. Also instruct them to carry identifying information about having diabetes.

CONSIDERATIONS FOR OLDER ADULTS

With age, the ability of the heart and lungs to deliver oxygen to tissues and organs declines. These changes may be due more to decline in muscle mass than to changes in cardiac output. Aerobic activities are important in maintaining muscle mass. Healthy older adults are able to maintain cardiac output by increasing stroke volume during exercise.

The emphasis for any activity program is on changing sedentary behavior to active behavior at any level. Encourage sedentary older adults to begin with low-intensity physical activity. Start low-intensity activities in short sessions (less than 10 minutes); include warm-up and cool-down components with active stretching. Changes in activity levels should be gradual. Formal evaluation by a physical therapist and/or occupational therapist may be needed.

In the absence of retinopathy-related restrictions, strength (resistance) training for major muscles of the legs, arms, stomach, and trunk, performed two or three times weekly, helps preserve muscle mass and minimizes general functional decline. Examples of specific exercise can be found at www.geri.com.

Blood Glucose Control in Hospitalized Patients. Hyperglycemia in hospitalized patients occurs for many reasons and is associated with poor outcomes. In patients without a previous diagnosis of diabetes, elevated blood glucose may be due to “stress hyperglycemia.” Hyperglycemia may result from decline in basic level of glucose control caused by illness, decreased physical activity, withholding of antidiabetic drugs, administration of drugs that cause hyperglycemia such as

corticosteroids, and initiation of tube feedings or parenteral nutrition.

Hyperglycemia among general medical-surgical patients is linked with higher infection rates, longer hospital stays, increased need for intensive care, and greater mortality. Serum glucose levels greater than 200 mg/mL (11.0 mmol/L) after cardiothoracic surgical procedures are associated with higher rates of wound infection. Admission glucose levels greater than 198 mg/dL (10.9 mmol/L) are associated with greater risk for mortality and complications. Hypoglycemia, defined as blood glucose values lower than 40 mg/dL (2.2 mmol/L), is considered an independent risk factor for mortality.

Current American Association of Clinical Endocrinologists (AACE) and ADA guidelines recommend treatment protocols that maintain blood glucose levels between 140 and 180 mg/dL (7.8 and 10.0 mmol/L) for critically ill patients. For the majority of non-critically ill patients, premeal glucose targets should be lower than 140 mg/dL (7.8 mmol/L) in conjunction with random blood glucose values less than 180 mg/dL (10.0 mmol/L). To prevent hypoglycemia, insulin regimens should be reviewed if blood glucose levels fall below 100 mg/dL (5.6 mmol/L) and should be modified when blood glucose levels are less than 70 mg/dL (3.9 mmol/L) (ADA, 2010b).

Continuous IV insulin solutions are the most effective method for achieving glycemic targets in the intensive care setting. Scheduled subcutaneous injection with basal, meal, and correction elements is the preferred method for achieving and maintaining glucose control in non-critically ill patients. Using correction dose or “supplemental insulin” to correct premeal hyperglycemia in addition to scheduled prandial and basal insulin is recommended. The correction dose is determined by the patient’s insulin sensitivity and current blood glucose level. The health care provider calculates sensitivity by adding up the patient’s total daily insulin requirement and dividing that amount into 1500 (for type 2 DM) or 1700 (for type 1 DM).

Prevention of hypoglycemia is also part of managing blood glucose levels. Causes of inpatient hypoglycemia include an inappropriate insulin type, mismatch between insulin type and/or timing of nutritional intake, and altered nutritional intake without insulin dosage adjustment. Many facilities have protocols for hypoglycemia treatment that direct staff to provide carbohydrate replacement if the patient is alert and able to swallow, or to administer 50% dextrose intravenously or glucagon by subcutaneous injection if the patient cannot swallow.

There is confusion about whether to give or to hold insulin from a patient who is NPO. Administration of rapid-acting or short-acting insulin, as well as amylin and incretin mimetics, will cause hypoglycemia if a patient is not eating. Basal insulin should be administered when the patient is NPO because it treats baseline glucose levels. Insulin mixtures are not administered because they contain some short-acting or rapid-acting insulin and will cause hypoglycemia.

Surgical Management. Surgical interventions for diabetes include transplantation of the pancreas. Successful transplantation improves quality of life by eliminating the need for insulin injections, blood glucose monitoring, and many dietary restrictions. It can eliminate the acute complications related to blood glucose control but is only partially

successful in reversing long-term diabetes complications. Pancreatic transplant is successful when the patient no longer needs insulin therapy and all blood measures of glucose are normal.

Transplantation requires lifelong drug therapy to prevent graft rejection. These drug regimens have toxic side effects that restrict their use to patients who have serious progressive complications of diabetes. In addition, some anti-rejection drugs have the effect of increasing blood glucose levels. Pancreas-alone transplants are considered for patients with severe metabolic complications, clinical and emotional problems with insulin that are so severe as to be incapacitating, and consistent failure of insulin-based therapy to prevent acute complications.

Pancreas transplantation is considered in patients with diabetes and end-stage kidney disease who have had or plan to have a kidney transplant. Normal blood glucose levels after pancreas transplantation improve kidney graft survival. Pancreas graft survival is better when performed at the time of the kidney transplant.

Whole-Pancreas Transplantation. Improved surgical techniques and newer anti-rejection drugs have improved transplantation outcomes. The 1-year survival rate for patients is above 95%, with more than 83% of patients remaining free of insulin injection and diet restrictions after 1 year. The degree of HLA tissue-type matching affects the results.

Pancreatic transplantation is performed in one of three ways: pancreas alone (PTA), pancreas after kidney transplant (PAK), and simultaneous pancreas and kidney transplant (SPK). SPK is the ideal procedure for patients with DM and uremia.

Operative Procedure. Most pancreatic transplants are from cadaver donors using a total pancreas still attached to the exit of the pancreatic duct. Because the pancreas performs important digestive functions, the recipient’s pancreas is left in place and the donated pancreas is placed in the pelvis. The insulin released by the pancreas graft is secreted into the bloodstream. The new pancreas also produces about 800 to 1000 mL of fluid daily, which is diverted to either the bladder or the bowel.

Chronic loss of pancreatic secretions can cause dehydration and electrolyte imbalance, and drainage of these fluids into the urinary bladder causes irritation. When the pancreas is attached to the bladder, the loss of fluid rich in bicarbonate may cause acidosis. Some techniques allow intestinal drainage of pancreatic fluids.

Rejection Management. A combination of drugs and antibodies are used to reverse rejection. (See Chapter 19 for a listing of agents used to prevent or treat transplant rejection.) Patients undergoing anti-rejection therapy first receive drugs to prevent viral, bacterial, and fungal infection because of the risk for opportunistic infections.

In most episodes of rejections, kidney problems occur before pancreatic problems. An increase in serum creatinine indicates rejection of both the transplanted kidney and the pancreas. In patients with bladder drainage of pancreatic hormones, a decrease in the urine amylase level by 25% is an indication to treat rejection. High blood glucose levels are a later marker of rejection and usually indicate irreversible graft failure.

Long-Term Effects. Long-term anti-rejection therapy increases the risk for infection, cancer, and atherosclerosis.

The transplanted pancreas does not duplicate all the functions of a normal pancreas. When insulin drains into systemic rather than portal (liver) circulation, blood insulin levels rise (*hyperinsulinemia*) and increase the risk for hypertension and macrovascular disease.

Complications. Complications are common in patients taking long-term anti-rejection therapy. Monitor laboratory values, fluid and electrolyte status, physical changes, and changes in vital signs to identify possible complications. Early removal of IV and intra-arterial lines, use of sterile technique with dressing changes and catheter irrigations, strict hand-washing by all health care personnel, and good pulmonary hygiene help prevent infection.

Complications immediately after surgery include thrombosis, pancreatitis, anastomosis leak with infection, and rejection of the transplanted pancreas. Pancreatic blood vessel thrombosis occurs in about 30% of patients after transplantation. Observe for and report any sudden drop in urine amylase levels, rapid increases in blood glucose, gross **hematuria** (bloody urine), and tenderness or pain in the graft area (iliac fossa). Pancreatitis in the transplanted organ occurs to some degree in all patients after surgery. Report elevations in serum amylase that persist after 48 to 96 hours.

The most serious complication of enteric-drained pancreas transplantation is leaking and intra-abdominal abscess. Observe for and report elevation in temperature, abdominal discomfort, and elevation in white blood cell (WBC) count. Bladder-drained pancreas transplantation has a lower rate of intra-abdominal abscess formation. However, drainage of bicarbonate-rich fluid with pancreatic enzymes into the urinary bladder can cause urinary tract infections, cystitis, urethritis, and balanitis. Metabolic acidosis occurs from the loss of large amounts of alkaline pancreatic secretions.

Assess for and document manifestations of rejection. In acute rejection, decreased kidney function is indicated by increased serum creatinine, decreased urine output, hypertension, increased weight, graft tenderness, and fever. Proteinuria is often the first indicator of chronic graft rejection. Check for increased blood amylase, lipase, or glucose; decreased urine amylase; graft tenderness; hyperglycemia; and fever. *It is especially important to assess for signs of infection and start appropriate therapy. Fever can indicate both infection and rejection.*

Monitor for side effects of the anti-rejection drugs. Cyclosporine (Neoral) is toxic to the kidney. Signs of toxicity are elevated creatinine and decreased urine output. Monitor WBC counts daily, because azathioprine (Imuran) can suppress bone marrow function. Prednisone has many side effects, including elevated blood glucose levels. Common side effects of tacrolimus (Prograf) are hypertension, kidney toxicity, neurotoxicity, GI toxicity, and glucose intolerance.

The patient's quality of life improves as a result of freedom from the need for insulin, a less restricted lifestyle, and a return to a normal diet. Stress, however, the potential need for insulin injections to treat hyperglycemia caused by anti-rejection drugs.

Islet Cell Transplantation. Islet cell transplantation eliminates the need for insulin and protects against the complications of diabetes. Wider use of this procedure is hindered by the limited supply of beta cells available for transplantation and by issues related to rejection. Islet cells from tissue-typed (HLA-matched) cadaver pancreas glands are injected into the portal vein. The new cells lodge in the liver and begin to

function, secreting insulin and maintaining near-perfect blood glucose control.

Islet cell transplantation may successfully restore long-term endogenous insulin production and glycemic control in patients with type 1 diabetes and unstable baseline control. Currently, most patients undergoing this procedure eventually have a progressive loss of islet cell function over time. Very few islet cell transplant recipients have remained insulin-free for more than 4 years. The reasons for this gradual loss of function are not known and make this procedure a long-term but temporary intervention. It is considered an experimental procedure.

Enhancing Surgical Recovery

Planning: Expected Outcomes. The patient with diabetes undergoing a surgical procedure is expected to recover completely without complications. Indicators include:

- Wound healing
- Absence of infection
- Maintenance of blood glucose levels within expected range
- Discharge readiness

Interventions. Surgery is a physical and emotional stressor, and the patient with diabetes has a higher risk for complications. Anesthesia and surgery cause a stress response with release of counterregulatory hormones that elevate blood glucose. Stress hormones suppress insulin action, increasing the risk for ketoacidosis and metabolic acidosis. Hyperglycemic-hyperosmolar state (HHS) (previously known as *hyperglycemic-hyperosmolar nonketotic syndrome [HHNS]*) is a common complication after major surgery and is associated with increased mortality. Diuresis from hyperglycemia can cause severe dehydration and increase the risk for kidney failure.

Complications of diabetes increase the risk for surgical complications. Patients with DM are at higher risk for hypertension, ischemic heart disease, cerebrovascular disease, MI, and cardiomyopathy. Heart failure is a serious risk factor and must be improved before surgery. Damage to nerves controlling the heart and blood vessels (autonomic neuropathy) may result in sudden tachycardia, bradycardia, or postural hypotension. The patient with DM is at risk for acute kidney injury and urinary retention after surgery, especially if he or she has albumin in the urine (indicator of kidney damage). Nerves to the intestinal wall and sphincters can be impaired, leading to delayed gastric emptying and reflux of gastric acid, which increases the risk for aspiration with anesthesia. Autonomic neuropathy may cause paralytic ileus after surgery.

Preoperative Care. Patients undergoing major surgery should be admitted to the hospital 2 to 3 days before surgery to optimize blood glucose control. Second-generation sulfonylureas are discontinued 1 day before surgery. Metformin (Glucophage) is stopped 48 hours before surgery and restarted only after kidney function is normal. All other oral drugs are stopped the day of surgery. Patients taking long-acting insulin may need to be switched to intermediate-acting insulin forms 1 to 2 days before surgery.

Preoperative blood glucose levels should be less than 200 mg/dL (11.1 mmol/L). Higher levels can cause neutrophil dysfunction and increased infection rates. They also impair wound healing by altering collagen formation, which decreases wound strength.

Plan ahead for pain control after surgery. Pain, a stressor, triggers the release of counterregulatory hormones, increasing blood glucose levels and insulin needs. Opioid analgesics slow GI motility and alter blood glucose levels. The older patient who receives opioids is more at risk for confusion, paralytic ileus, hypoventilation, hypotension, and urinary retention. Patient-controlled analgesia (PCA) systems reduce respiratory complications and confusion. (See [Chapter 5](#) for pain interventions and [Chapter 16](#) for general preoperative care.)

Intraoperative Care. IV infusion of insulin, glucose, and potassium is standard therapy for perioperative management of diabetes. The purpose is to keep the glucose level between 140 and 180 mg/dL (7.8 and 10.0 mmol/L) during surgery to prevent hypoglycemia and reduce risks from hyperglycemia. Levels below 180 mg/dL (10.0 mmol/L) reduce the risk for wound infection. Insulin/glucose infusion rates are based on hourly capillary glucose tests. Higher insulin doses may be needed because stress releases glucagon and epinephrine. Patients with DM should receive about 5 g of glucose per hour during surgery to prevent hypoglycemia, ketosis, and protein breakdown.

Monitor the patient's temperature—it may be lowered deliberately in some surgical procedures and inadvertently in others. Low operating room temperatures and large incisions also lower body temperature. Hypothermia decreases metabolic needs, depresses heart rate and contractility, causes vasoconstriction, and impairs insulin release, resulting in high blood glucose levels. Monitor arterial blood gas values for acidosis.

Postoperative Care. Hyperglycemia is associated with increased mortality and morbidity after surgical procedures. Current AACE and ADA guidelines recommend insulin protocols that maintain blood glucose levels between 140 and 180 mg/dL (7.8 and 10.0 mmol/L) for critically ill patients. Targets less than 110 mg/dL (6.1 mmol/L) are avoided (Moghissi et al., 2009).

Protocols and computer-based programs can be used to determine the insulin infusion rate required to maintain blood glucose levels within a defined target range. Many insulin infusion algorithms are implemented by nursing staff. Continue glucose and insulin infusions as prescribed until the patient is stable and can tolerate oral feedings. Short-term insulin therapy may be needed after surgery for the patient who usually uses oral agents. For those receiving insulin therapy, dosage adjustments may be required until the stress of surgery subsides.

Monitoring. Patients with autonomic neuropathy or vascular disease need close monitoring to avoid hypotension or respiratory arrest. Those who take beta blockers for hypertension need close monitoring for hypoglycemia because these drugs mask symptoms of hypoglycemia. Patients with **azotemia** (increased protein or nitrogen waste products in the blood) may have problems with fluid management. Check central venous pressure or pulmonary artery pressure as needed.

! NURSING SAFETY PRIORITY

Critical Rescue

When a patient who has had reasonably controlled blood glucose levels in the hospital develops an unexpected rise in blood glucose values, check for wound infection.

Glucose levels are a sensitive marker of counterregulatory hormones, which are often activated before patients become febrile. Hyperglycemia often occurs before a fever.

Hyperkalemia (high blood potassium level) is common in patients with mild to moderate kidney failure and can lead to cardiac dysrhythmia. In other patients, **hypokalemia** (low blood potassium level) may occur and be made worse by insulin and glucose given during surgery. Monitor the cardiac rhythm and serum potassium values.

Cardiovascular monitoring using serial electrocardiograms (ECGs) is recommended for older patients with diabetes, those with long-standing type 1 DM, and those with heart disease. Patients with diabetes are at higher risk for MI after surgery with a higher mortality rate. Changes in ECG or in potassium level may indicate a silent MI.

Kidney monitoring, especially observing fluid balance, helps detect acute kidney injury. Diagnosis of kidney impairment may require the use of x-ray studies using dyes, which may be nephrotoxic. Management of infections may require the use of nephrotoxic antibiotics. Ensure adequate hydration when these drugs are used. Check for impending kidney failure by assessing fluid and electrolyte status.

Nutritional Care. Patients requiring clear or full liquid diets should receive about 200 g of carbohydrate daily in equally divided amounts at meals and snack times. Liquids should not be sugar-free. For tube feedings, either a standard formula (50% carbohydrate) or a lower-carbohydrate formula (33%-40% carbohydrate) may be used. Most patients require 25 to 35 calories per kg of body weight every 24 hours. After surgery, food intake is initiated as quickly as possible, and progression from clear liquids to solid foods should be accomplished as rapidly as tolerated (ADA, 2008).

Use of total parenteral nutrition (TPN) in patients with diabetes can cause severe metabolic changes. Anticipate that hyperglycemia will occur with TPN therapy. Monitor blood glucose often to determine the need for supplemental short-acting insulin. Insulin can be added to the TPN infusion or given as a separate IV infusion.

Returning to a normal meal plan as soon as possible after surgery promotes healing and metabolic balance. When oral foods are tolerated, make sure the patient takes at least 150 to 200 g of carbohydrate daily to prevent hypoglycemia.

Preventing Injury from Peripheral Neuropathy

Planning: Expected Outcomes. The patient with diabetes is expected to identify factors that increase the risk for injury, practice proper foot care, and maintain intact skin on the feet. Indicators include that the patient consistently demonstrates these behaviors:

- Follows preventive foot care practices
- Cleanses and inspects the feet daily
- Wears properly fitting shoes
- Avoids walking in bare feet
- Trims toenails properly
- Reports nonhealing breaks in the skin of the feet to the health care provider

Interventions. Patients with DM need intensive teaching about foot care. *Foot injury is the most common complication of diabetes leading to hospitalization.* Studies have shown that patients with DM have up to a 25% lifetime risk for developing a foot ulcer. Once an ulcer has developed, there is an increased risk for wound progression that will eventually lead to amputation. Almost all lower extremity amputations are

FIG. 67-9 A “Charcot foot” type of diabetic foot deformity.

preceded by foot ulcers. The 5-year mortality rate after leg or foot amputation ranges from 39% to 67% ([National Institute of Diabetes and Digestive and Kidney Diseases \[NIDDK\], 2011](#)). Diabetic foot ulcers are the result of a combination of factors. The major causes of diabetic foot ulcers are peripheral neuropathy and ischemia from peripheral vascular disease.

Motor neuropathy results in damage to the nerves of the intrinsic foot muscles that lead to imbalance between flexion and extension of the foot. This imbalance leads to anatomic foot deformities that create abnormal bony prominences and pressure points that gradually cause skin breakdown and ulceration. In claw toe deformity, toes are hyperextended and increase pressure on the metatarsal heads (“ball” of the foot), resulting in ulceration. Thinning or shifting of the fat pad under the metatarsal heads decreases cushioning and increases areas of pressure. These changes predispose the patient to callus formation, ulceration, and infection. The Charcot foot is a type of diabetic foot deformity with multiple anatomic abnormalities, often including a hallux valgus (turning inward of the great toe) ([Fig. 67-9](#)). The foot is warm, swollen, and painful. Walking collapses the arch, shortens the foot, and gives the foot a “rocker bottom” shape.

Autonomic neuropathy causes loss of normal sweating and skin temperature regulation, resulting in dry, thinning skin. Skin cracks and fissures increase the risk for infection. Sensory neuropathy may cause tingling or burning, but more often it produces numbness and reduced sensation. Without sensation, the patient does not notice injuries to the foot and does not treat them. Peripheral arterial disease commonly

affects the tibial and peroneal arteries of the calf, resulting in reduced blood supply to the foot. This problem increases the risk for ulcer formation and reduces ulcer healing ([McCance et al., 2010](#)).

Foot injuries can be caused by walking barefoot, wearing ill-fitting shoes, sustaining thermal injuries from heat (e.g., hot water bottles, heating pads, baths), or receiving caustic burns from over-the-counter corn treatments. Because the blood supply to the diabetic foot is poor, these injuries can lead to amputation.

Ulcers result from continued pressure. Plantar ulcers (on the sole, usually the ball) are from standing or walking. Those on the top or sides of the foot usually are from shoes. The increased pressure causes calluses. Ulcers usually form over or around the great toe, under the metatarsal heads, and on the tops of claw toes.

Broken skin increases the risk for infection. Skin tends to break in areas of pressure. Infection is common in diabetic foot ulcers and, once present, is difficult to treat. Infection also impairs glucose control, leading to higher blood glucose levels and reduced immune defenses, which further increases the risk for infection.

Prevention of High-Risk Conditions. Neuropathy of the feet and legs can be delayed by keeping blood glucose levels as near normal as possible. Poor blood glucose control increases the risk for neuropathy and amputation. Intensive therapy reduces the risk for peripheral sensory neuropathy by 60%. Urge smoking cessation to reduce the risk for vascular complications.

The risk for ulcers or amputation increases with duration of diabetes. Other risk factors are male gender; poor glucose control; and cardiovascular, retinal, or kidney complications. Foot-related risks include poor gait and stepping mechanics, peripheral neuropathy, increased pressure (callus, erythema, hemorrhage under a callus, limited joint mobility, foot deformities, or severe nail pathology), peripheral vascular disease, and a history of ulcers or amputation.

Peripheral Neuropathy Management. The feet should be evaluated closely at least annually. [Chart 67-7](#) lists self-management activities for prevention of injury from peripheral neuropathy, and [Table 67-12](#) lists foot risk categories.

Complete a full foot assessment as outlined in [Chart 67-8](#). Sensory examination with Semmes-Weinstein monofilaments is the most practical measure of the risk for foot ulcers. The nylon monofilament is mounted on a holder standardized to exert a 10-g force. There is no agreement on the exact number of sites to test. A person who cannot feel the 10-g pressure at any point is at increased risk for ulcers. To perform the examination:

- Provide a quiet and relaxed setting. Ask the patient to close his or her eyes during the test.
- Test the monofilament on the patient’s cheek so he or she knows what to expect.
- Test the sites noted in [Fig. 67-10](#).
- Apply the monofilament at a right angle to the skin surface.
- Apply enough force to bend the filament using a smooth, not jabbing, motion ([Fig. 67-11](#)).
- The approach, contact, and removal of the filament at each site should take 1 to 2 seconds.
- Apply the filament along the perimeter and **not** on an ulcer site, callus, scar, or necrotic tissue. Do not slide

CHART 67-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Peripheral Neuropathy and Safety

- Protect feet and other body areas where sensation is reduced (e.g., do not walk around in bare feet or stocking feet; always wear shoes with a protective sole).
- Be sure shoes are long enough and wide enough to prevent creating sores or blisters.
- Provide a long break-in period for new shoes; do not wear new shoes for longer than 2 hours at a time.
- Avoid pointed-toe shoes and shoes with heels higher than 2 inches.
- Inspect your feet daily (with a mirror) for open areas or redness.
- Avoid extremes of temperature; wear warm clothing in the winter, especially over hands, feet, and ears.
- Test water temperature with a thermometer when washing dishes or bathing. Use warm water rather than hot water (less than 110° F).
- Use potholders when cooking.
- Use gloves when washing dishes or gardening.
- Do not eat foods that are “steaming hot,” allow them to cool before placing them in your mouth.
- Eat foods that are high in fiber (e.g., fruit, whole grain cereals, vegetables).
- Drink two to three liters of fluid (nonalcoholic) daily unless your health care provider has told you to restrict fluid intake.
- Get up from a lying or sitting position slowly. If you feel dizzy, sit back down until the dizziness fades before standing and then stand in place for a few seconds before walking or using the stairs.
- Look at your feet and the floor or ground where you are walking to assess how the ground, floor, or step changes to prevent tripping or falling.
- Avoid using area rugs, especially those that slide easily.
- Use handrails when going up or down steps.

the filament across the skin or make repeated contact at the test site.

Randomize the sequence of applying the filament throughout the examination. Have the patient identify where the filament touched rather than asking “Do you feel this?”

Footwear. All patients with any degree of peripheral neuropathy need to wear protective shoes. They should be fitted by an experienced shoe fitter, such as a certified podiatrist. The shoe should be $\frac{1}{2}$ to $\frac{3}{8}$ inch longer than the longest toe. Heels should be less than 2 inches high. Shoes that are too tight damage tissue when worn for 4 hours or longer. Teach the patient to change shoes by midday and again in the evening. Socks or stockings need to fit properly and be appropriate for the planned activity. Socks should feel soft and have no thick seams, creases, or holes. They should pad the foot and absorb excess moisture. Teach patients to avoid tight stockings or those that have constricting bands. Patients with toe deformities should buy custom shoes with high, wide toe boxes and extra depth. Those with severely deformed feet, such as Charcot feet, need specially molded shoes. All new shoes need a long break-in period with frequent inspection for irritation or blistering.

Foot Care. Teach patients about preventive foot care and the need for examination of the feet and legs at each visit to a health care provider. Identify patients with high-risk foot conditions, and teach them about foot care. Explain problems caused by loss of protective sensation, the importance of

TABLE 67-12 FOOT RISK CATEGORIES

Risk Categories

Risk Category 0

- Has disease that leads to insensitivity
- Has protective sensation
- Has not had a plantar ulcer

Risk Category 1

- Does not have protective sensation
- Has not had a plantar ulcer
- Does not have a foot deformity

Risk Category 2

- Does not have protective sensation
- Has not had a plantar ulcer
- Does have a foot deformity

Risk Category 3

- Does not have protective sensation
- Has history of plantar ulcer

Management Categories

Management Category 0

- Examine feet at each visit, at least four times per year
- Foot clinic visit once a year
- Patient education

Management Category 1

- Examine feet at each visit, at least four times per year
- Foot clinic visit every 6 months
- Soft insoles
- Patient education

Management Category 2

- Examine feet at each visit, at least 4 times per year
- Foot clinic visit every 3-4 months
- Custom-molded insoles
- Prescription footwear
- Patient education

Management Category 3

- Examine feet at each visit, at least four times per year
- Foot clinic visit every 1-2 months
- Custom-molded insoles
- Prescription footwear
- Patient education

From Gillis W. Long Hansen's Disease Center Rehabilitation Branch. (1992). *Foot screening: Care of the foot in diabetes—The Carville approach*. Carville, LA: Department of Health and Human Services.

CHART 67-8 FOCUSED ASSESSMENT

The Diabetic Foot

Assess the patient for risk for diabetic foot problems:

- History of previous ulcer
- History of previous amputation

Assess the foot for abnormal skin and nail conditions:

- Dry, cracked, fissured skin
- Ulcers
- Toenails: thickened, long nails; ingrown nails
- Tinea pedis; onychomycosis (mycotic nails)

Assess the foot for status of circulation:

- Symptoms of claudication
- Presence or absence of dorsalis pedis or posterior tibial pulse
- Prolonged capillary filling time (greater than 25 seconds)
- Presence or absence of hair growth on the top of the foot

Assess the foot for evidence of deformity:

- Calluses, corns
- Prominent metatarsal heads (metatarsal head is easily felt under the skin)
- Toe contractures: clawed toes, hammertoes
- Hallux valgus or bunions
- Charcot foot (“rocker bottom”)

Assess the foot for loss of strength:

- Limited ankle joint range of motion
- Limited motion of great toe

Assess the foot for loss of protective sensation:

- Numbness, burning, tingling
- Semmes-Weinstein monofilament testing at 10 points on each foot

FIG. 67-10 Placement sites of monofilaments for testing of protective sensation.

FIG. 67-11 Correct technique for sensation testing with 10-g monofilament. **A**, Apply monofilament to designated areas of the foot sole (intact skin only, see Fig. 67-10). **B**, Apply pressure to the filament until either the patient states he or she can feel the pressure or until the filament bends (see pp. 1446-1447). **C**, Quickly remove the filament without sliding it or touching other areas of the foot.

monitoring the feet daily, proper care of the feet (including nail and skin care), and how to select appropriate footwear. Advise patients with neuropathy to break in new shoes slowly to reduce the risk for blisters.

Teach patients to inspect their feet daily. Assess their ability to inspect all areas of the foot and to perform foot care. Teach family members how to inspect and care for the patient's feet if the patient cannot. Chart 67-9 lists foot care instructions for self-management.

Wound Care. The standards of care for diabetic ulcers are a moist wound environment, débridement of necrotic tissue, and elimination of pressure (*offloading*).

Wound environment is influenced by the dressing. Dressings reduce or prevent infection, allow débridement, reduce

CHART 67-9 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF MANAGEMENT

Foot Care Instructions

- Inspect your feet daily, especially the area between the toes.
- Wash your feet daily with lukewarm water and soap. Dry thoroughly.
- Apply moisturizing cream to your feet after bathing. Do not apply to the area between your toes.
- Change into clean cotton socks every day.
- Do not wear the same pair of shoes 2 days in a row, and wear only shoes made of breathable materials, such as leather or cloth.
- Check your shoes for foreign objects (nails, pebbles) before putting them on. Check inside the shoes for cracks or tears in the lining.
- Purchase shoes that have plenty of room for your toes. Buy shoes later in the day, when feet are normally larger. Break in new shoes gradually.
- Wear socks to keep your feet warm.
- Trim your nails straight across with a nail clipper. Smooth the nails with an emery board.
- See your physician or nurse immediately if you have blisters, sores, or infections. Protect the area with a dry, sterile dressing. Do not use adhesive tape to secure dressing.
- Do not treat blisters, sores, or infections with home remedies.
- Do not smoke.
- Do not step into the bathtub without checking the temperature of the water with your wrist or thermometer. Optimal temperature is 95° F (35° C). Maximum temperature is 110° F (43° C).
- Do not use very hot or cold water. Never use hot water bottles, heating pads, or portable heaters to warm your feet.
- Do not treat corns, blisters, bunions, calluses, or ingrown toenails yourself.
- Do not go barefooted.
- Do not wear sandals with open toes or straps between the toes.
- Do not cross your legs or wear garters or tight stockings that constrict blood flow.
- Do not soak your feet.

wound pain, and stimulate granulation tissue. Many commercial products are available. Antiseptics such as povidone iodine, hydrogen peroxide, and chlorhexidine interfere with wound healing. Dressings that keep the wound moist are essential.

Débridement removes dead tissues that support bacterial growth. Proper débridement is needed to reduce the risk for infection and to reduce pressure around the wound. It is accomplished with surgery, topical débriding agents, and dressings. Mechanical débridement, although helpful, can delay healing by removing newly formed tissue.

Eliminating pressure on an infected area is essential to wound healing. Teach patients with foot ulcers to not wear a shoe on the affected foot while the ulcer is healing. Those with poor sensation may keep walking on an ulcer because it does not hurt. This results in pressure necrosis that delays healing and increases ulcer size. Pressure is reduced by specialized orthotic devices, custom-molded shoe inserts, or shoe adjustments that redistribute weight.

The purpose of offloading is to redistribute force away from ulcer sites and pressure points to wider areas of the foot. Several products are available for offloading, including total-contact casting, half shoes, removable cast walkers, wheelchairs, and crutches. Total-contact casts redistribute pressure over the bottom of the foot. Casting material is molded to the

foot and leg so pressure is spread along the entire surface of contact, thereby reducing vertical force. The almost complete elimination of motion of the total-contact cast reduces plantar shear forces. The cast is removed 24 to 48 hours after application to inspect the foot and the cast fit. The cast is replaced and then removed and reapplied weekly thereafter until the ulcer is healed. *Teach the patient that foot ulcers will recur unless weight is permanently redistributed.*

Growth factors applied to wounds increase healing by stimulating new tissue and enhancing cell growth. This treatment has helped heal foot ulcers present for many months or even years. Because it is costly, this therapy is usually performed in specialized treatment centers.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

The patient, Angelina Lopez, is a 44-year-old woman who was diagnosed with type 2 diabetes on admission for a wound infection of her right foot. She stepped on a piece of a small toy while walking in her bare feet at home. The toy broke the skin of the foot and lodged there, leading to infection. She was unaware of the presence of the toy and sought medical help only when her foot began to drain purulent fluid and smell. Examination of her retinas shows damage indicating she has had diabetes for at least 10 years. She is overweight and hypertensive (for which she has just been prescribed an antihypertensive). She is crying and tells you that her grandmother in Mexico died after an amputation because of diabetes. She says she just doesn't understand how she "caught" diabetes and is worried that she too will die young.

1. What specific risk factors led to the wound infection?
2. What will you tell her about "catching" diabetes?
3. Is she or is she not at risk for dying young? Why or why not?
4. What will you say immediately to address her worry?
5. What are the teaching priorities for this patient?

Managing Pain

Planning: Expected Outcomes. The patient with neuropathic pain is expected to experience relief of pain. Indicators include these consistent behaviors:

- Uses preventive measures
- Uses available resources to increase comfort
- Reports pain controlled

Interventions. Neuropathic pain results from damage anywhere along the nerve. The mechanism for neuropathic pain in the patient with diabetes is unclear. Many patients with diabetes suffer from the painful neuropathy. Common symptoms of diabetic neuropathy include:

- Burning
- Muscle cramps
- Piercing, stabbing, or darting pain
- Metatarsalgia (feeling as if you are walking on marbles)
- Hyperalgesia (exaggerated pain response)
- Allodynia (pain in response to normally nonpainful stimuli)
- Tingling, numbness, and loss of proprioception in lower extremities

Maintaining normal blood glucose levels and avoiding extreme fluctuations prevent neuropathy and relieve symptoms of acute nerve dysfunction. Rapid improvement in blood glucose control may actually trigger acute peripheral neuropathy.

Several pharmacologic agents are used to manage neuropathic pain. The anticonvulsants *gabapentin* (Neurontin) and *pregabalin* (Lyrica) and the serotonin-norepinephrine reuptake inhibitor (SNRI) *duloxetine* (Cymbalta) are approved for management of peripheral neuropathic pain. Tricyclic antidepressants such as amitriptyline hydrochloride (Elavil, Levate ) and nortriptyline (Pamelor) are widely used for neuropathic pain but are not approved for this purpose and have some significant side effects. Their use is contraindicated for older adults and those with cardiovascular disease.

The burning of neuropathy may respond to capsaicin cream 0.075% (Axsain , Zostrix-HP). This drug reduces amounts of substance P, which is involved in pain transmission (see Chapter 5). Teach the patient to apply it four times daily for several weeks. Neuropathic pain may worsen for several days after therapy is started before improving.

Unpleasant symptoms are noted with abrupt discontinuation of many of these drugs. Teach the patient about possible side effects of the drug before its initiation, and warn him or her to avoid abrupt discontinuation. A gradual reduction in the dose rather than abrupt cessation is recommended to prevent side effects.

Provide support and practical information on measures to reduce pain. Simple measures such as a bed cradle to lift bed clothes off hypersensitive skin can be beneficial. Assist the patient to maintain stable glucose control. *All patients with neuropathy are at increased risk for foot ulcers and require more frequent assessment and education in routine foot management.*

Preventing Injury from Reduced Vision

Planning: Expected Outcomes. The patient with diabetes is expected to be free of injury related to reduced vision and to maintain current level of vision. Indicators include:

- No further reduction of visual fields
- No double vision

Interventions

Blood Glucose Control. Poor blood glucose control, proteinuria, diastolic hypertension, and long duration of diabetes are risk factors for diabetic retinopathy and vision loss. Surgical intervention for retinal hemorrhage or new retinal blood vessel growth can reduce vision loss.

Besides regular eye examinations to evaluate retinopathy, urge the patient with impaired vision to have an optometrist or ophthalmologist assess the remaining vision and prescribe appropriate eyewear. A functional vision assessment, performed by a low-vision technician, rehabilitation teacher, or diabetes educator, determines the patient's use of lighting, contrast, non-optical and low-vision devices, large-print options, and use of central or peripheral vision. Low-vision reading aids include products or devices such as closed circuit television systems, handheld magnifiers, desktop systems, portable low-vision aids, talking calculators, talking and large-print books, check-writing guides, and telescopic lenses. The American Foundation for the Blind maintains a list of services for visually impaired people that is organized by type of service and geographic area. More information is available at (800) 232-5463 and www.afb.org.

Environmental Management. Not all visually impaired patients need special devices. Adjustments in lighting, contrast, color, distance, type size of printed materials, and eye movement often improve visual abilities. Instruct the patient

to supplement overhead fluorescent lighting with an incandescent lamp directed toward the workspace. Placing dark equipment against a white or yellow background (or vice versa) provides contrast to enhance vision. Coding objects such as vials of insulin with bright colors or with felt-tipped markers helps identify the correct bottle. Bringing the blood glucose lancet or insulin syringe close to the eye makes it easier to see. Suggest large type or bold print to ease reading. Teach the patient to use peripheral vision.

Prefilled insulin pens are not approved for use by people with severe visual impairment unless they are assisted by a person with good vision who is trained to use the pen correctly. Adaptive devices can help the patient self-administer insulin independently. Some syringes may have a magnifier attached to the syringe. Other devices include preset dose gauges (which measure the space between the end of the syringe barrel and the plunger) to help the patient draw up the correct amount of insulin by feeling this distance. The blind patient can accurately measure insulin by using products such as the Count-A-Dose Insulin Measuring Device. This device is designed to be used with the BD Lo-Dose syringe. It holds two insulin vials and has a slot to direct the syringe needle into the vials' rubber stoppers. The patient draws insulin into the syringe by turning a thumb-wheel, which clicks for each unit (clicks can be both heard and felt). (See the Consumer Guide published yearly in the January edition of Diabetes Forecast [forecast.diabetes.org] for information to help patients determine which adaptive devices best meet their needs.) When teaching the patient to use an adaptive device, stress:

- Differentiating between bottles of fast-acting and slower-acting insulin by wrapping a rubber band around the fast-acting insulin bottle
- Ensuring proper placement of the device on the syringe
- Holding the insulin bottle upright when measuring insulin
- Avoiding air bubbles in the syringe by pulling a small amount of insulin into the syringe, moving the plunger in and out three times, and measuring insulin on the fourth draw

Design a system to determine how many doses can be drawn from a bottle so the patient does not inject air from an empty bottle instead of insulin.

Specialized adaptive equipment also is available to assist with blood glucose monitoring techniques. Assist the patient to select a blood glucose monitoring device best suited to his or her level of visual impairment. For patients with reliable low vision, monitors with large display screens and easy-to-use features may be used. The Prodigy Voice (Diagnostic Devices) is fully audio for patients who are visually impaired. The monitor uses no coding, has automatic turn-on with test strip insertion, and has a button for repeating the last message. Assess the ability of the patient to obtain an adequate blood sample and to apply it to the test strip. Commercially made blood drop guides can assist with this task.

Reducing the Risk for Kidney Disease

Planning: Expected Outcomes. The patient with diabetes is expected to maintain a normal urine elimination pattern. Indicators include:

- Urine protein levels within normal limits
- 24-hour intake and output balance

- Blood urea nitrogen (BUN) and serum creatinine within the normal ranges
- Serum electrolytes within the normal ranges

Interventions

Prevention. Tight control of blood glucose levels may slow kidney disease in patients with type 1 diabetes. Diabetic kidney disease is more likely to develop in those with poor blood glucose control. Progression to end-stage kidney disease can be delayed or prevented by normalizing blood pressure, correcting hyperlipidemia, and restricting dietary protein. Control of hypertension is essential for the reduction of diabetic nephropathy (ADA, 2010c). Both systolic and diastolic hypertension greatly accelerate the progression of diabetic kidney disease.

Stress the need for evaluation of kidney function according to the ADA Standards of Care. Glomerular filtration rate (GFR) is the best overall measure of kidney function. Serum creatinine should be measured at least annually for an estimation of GFR in all patients with diabetes (ADA, 2010b). An annual test for microalbuminuria is performed for patients who have had type 1 DM for over 5 years and in all those with type 2 DM starting at diagnosis and during pregnancy.

After 5 or more years of DM, the earliest change signaling diabetic kidney disease is an excretion of 30 to 299 mg of albumin per day (*microalbuminuria*). When albumin excretion rises above 300 mg per day, it is termed *albuminuria*. Screening for microalbuminuria is performed by three methods: (1) random spot urine collection to measure the albumin-creatinine ratio, (2) 24-hour urine collection to measure creatinine clearance, and (3) timed urine collection (e.g., 4 hours or overnight). Timed urine collections are not reliable in patients with neuropathy and incomplete bladder emptying. The preferred method of screening for microalbuminuria is by measuring the albumin-to-creatinine ratio in a random spot urine collection (ADA, 2010c).

Aggressive control of blood glucose and hypertension in patients without microalbuminuria can avoid nephropathy. Once microalbuminuria develops, management focuses on controlling blood pressure and blood glucose, restricting dietary protein, avoiding nephrotoxic agents, promptly treating urinary tract infections, and preventing dehydration.

Control of blood pressure and blood glucose levels requires the patient's participation and effort. Prescribed drugs must be taken according to schedules, and dietary restriction must be maintained. Teach patients about the roles of blood pressure and blood glucose levels in kidney disease. Help them maintain normal blood glucose levels and blood pressure levels below 130/80 mm Hg. Stress the need for yearly screening for microalbuminuria.

Smoking cessation is important in halting the progression of diabetic kidney disease. Smoking increases the risk for development of microalbuminuria, increases the rate of advancement to proteinuria, and accelerates the rate of progression of kidney disease in patients with either type 1 or type 2 DM. Teach the patient about the risks of smoking, and refer him or her to appropriate resources for assistance in smoking cessation.

Any urinary tract infection (UTI) can lead to kidney infection and further reduce kidney function. Explain the manifestations of UTI. Urge the patient to take antibiotics exactly as prescribed, completing the entire course of treatment.

Reinforce the need for follow-up urine cultures to reduce the risk for kidney damage. Avoid indwelling urinary catheters when possible.

Drugs can affect kidney function either through toxic effects on the kidney or by an acute but reversible reduction in function. The most common nephrotoxic drugs are antifungal agents (amphotericin B) and aminoglycoside antibiotics such as amikacin (Amikin), streptomycin, kanamycin (Kantrex), gentamicin (Garamycin), and tobramycin (Tobrex). Outside the hospital, the leading nephrotoxic agents are NSAIDs such as ibuprofen (Advil) or naproxen (Aleve). To prevent accidental ingestion of nephrotoxic drugs, teach the patient to check with a health care provider before taking over-the-counter drugs or herbal remedies.

Radiocontrast dyes can also affect kidney function, especially in patients with preexisting kidney problems. Monitor IV hydration before and after contrast is used to prevent contrast-induced nephropathy in patients with diabetes.

Drug Therapy. Use of angiotensin-converting enzyme (ACE) inhibitors (ACEIs) or angiotensin receptor blockers (ARBs) is recommended for all patients with microalbuminuria or advanced stages of nephropathy (ADA, 2010c). ACE inhibitors reduce the level of albuminuria and the rate of progression of kidney disease. These drugs have not shown to be effective in primary prevention of microalbuminuria. Monitor serum potassium levels for development of hyperkalemia.

Nutrition Therapy. Patients with nephropathy should restrict dietary protein to 0.8 g/kg of body weight per day. Once the glomerular filtration rate (GFR) starts falling, further reducing protein may slow the decline in kidney function (ADA, 2010c). Because lifelong dietary restrictions are difficult, provide ongoing teaching to encourage adherence.

Fluid and Electrolyte Management. Fluid and electrolyte management can prevent more loss of kidney function. Avoiding dehydration is important for kidney perfusion and function. Assess fluid balance, and use measures to prevent dehydration. The most common cause of dehydration in patients with diabetes is overuse of diuretics. Teach patients to report edema or symptoms of orthostatic hypotension, and provide ongoing education to promote nutrition therapy.

Dialysis for patients with DM and kidney failure is the same as for patients without diabetes (see Chapter 71). The dosage of insulin needs to be adjusted when dialysis starts.

Preventing Hypoglycemia

Hypoglycemia is defined as the presence of Whipple's triad: manifestations consistent with low blood glucose, a low plasma glucose concentration, and resolution of symptoms or signs after plasma glucose concentration is raised. Hypoglycemic symptoms are mediated through both the central and peripheral nervous systems. Once plasma glucose levels fall below 70 mg/dL (3.88 mmol/L), a sequence of events begins with release of counterregulatory hormones, stimulation of the autonomic nervous system, and production of *neurogenic* and *neuroglycopenic* symptoms. Peripheral autonomic symptoms (adrenergic), including sweating, irritability, tremulousness, anxiety, tachycardia, and hunger, serve as an early warning system and occur before the central neuroglycopenic symptoms (confusion, paralysis, seizure, and coma) due to central glucose deprivation. *Neuroglycopenic symptoms* occur when brain glucose *gradually declines* to a

TABLE 67-13 SYMPTOMS OF HYPOGLYCEMIA

Neuroglycopenic Symptoms	Neurogenic Symptoms
• Weakness • Fatigue • Difficulty thinking • Confusion • Behavior changes • Emotional instability • Seizures • Loss of consciousness • Brain damage • Death	• Adrenergic: • Shaky/tremulous • Heart pounding • Nervous/anxious • Cholinergic: • Sweaty • Hungry • Tingling

low level. *Neurologic symptoms* result from autonomic nervous activity triggered by a *rapid decline* in blood glucose (Table 67-13).

Central nervous system (CNS) function depends on a continuous supply of glucose in the blood. The brain cannot make glucose and stores only a few minutes' supply as glycogen. This needed supply is not maintained when the blood glucose level falls below critical levels.

The first defense against falling blood glucose levels in a person who does not have diabetes is decreased insulin secretion, decreased glucose use, and increased glucose production. Normally, insulin secretion decreases when blood glucose levels drop to about 83 mg/dL (4.5 mmol/L). Counterregulatory hormones are activated at about 67 mg/dL (3.7 mmol/L), a level well above the threshold for symptoms of hypoglycemia. The main counterregulatory hormone is glucagon. Epinephrine also becomes important in patients with DM who are deficient in glucagon. Both glucagon and epinephrine raise blood glucose levels by stimulating liver glycogen breakdown and conversion of protein to glucose. Epinephrine also limits insulin secretion. Growth hormone and cortisol also are important during prolonged hypoglycemia. Their effects do not become evident until 4 hours after the onset of hypoglycemia.

Type 1 DM disrupts the body's response to hypoglycemia, a change that occurs within 1 to 5 years of diagnosis. Regulation of circulating insulin levels is lost because insulin comes from an injection rather than from the pancreas. As blood glucose levels fall, insulin levels do not decrease. Over time, the pancreas loses its ability to secrete glucagon in response to hypoglycemia. After a few more years of type 1 DM, the response of epinephrine to falling blood glucose levels is also reduced. It does respond, but it takes a lower blood glucose level to become active. These problems greatly increase the risk for severe hypoglycemia.

A second problem with long-standing type 1 DM is *hypoglycemic unawareness*, in which patients no longer have the warning symptoms of impending hypoglycemia that should prompt them to take preventive action. This problem occurs most often in patients who have had type 1 DM for 30 years or longer.

The blood glucose level at which symptoms of hypoglycemia occur varies among patients. Many have symptoms when blood glucose levels are well above 50 mg/dL (2.8 mmol/L), especially if the level dropped rapidly or they are used to chronic hyperglycemia. Thus clinical criteria used to

TABLE 67-14 DIFFERENTIATION OF HYPOGLYCEMIA AND HYPERGLYCEMIA

FEATURE	HYPOGLYCEMIA	HYPERGLYCEMIA
Skin	Cool, clammy	Warm, moist
Dehydration	Absent	Present
Respirations	No particular or consistent change	Rapid, deep*; Kussmaul type; acetone odor ("fruity" odor) to breath
Mental status	Anxious, nervous,* irritable, mental confusion,* seizures, coma	Varies from alert to stuporous, obtunded, or frank coma
Symptoms	Weakness,* double vision, blurred vision, hunger, tachycardia, palpitations	No specific symptoms for DKA Acidosis; hypercapnia; abdominal cramps, nausea and vomiting Dehydration: decreased neck vein filling, orthostatic hypotension, tachycardia, poor skin turgor
Glucose	<70 mg/dL (3.9 mmol/L)	>250 mg/dL (13.8 mmol/L)
Ketones	Negative	Positive

DKA, Diabetic ketoacidosis.

*Classic symptoms.

categorize hypoglycemia are based on severity rather than blood glucose levels. In mild hypoglycemia, the patient remains alert and able to self-manage symptoms. In severe hypoglycemia, neurologic function is so impaired that he or she needs another person's help to increase blood glucose levels.

Planning: Expected Outcomes. The patient with DM is expected to have decreased episodes of hypoglycemia and remain oriented to person, place, and time, as indicated by a Glasgow Coma Scale score above 7.

Interventions. A blood glucose level below 70 mg/dL (3.9 mmol/L) alerts you to assess for manifestations of hypoglycemia (Table 67-13; see also Table 67-14).

Blood Glucose Management. Monitor blood glucose levels before giving antidiabetic drugs, before meals, before bedtime, and when the patient is symptomatic. All patients who take insulin, those taking long-acting insulin secretagogues (glyburide [glibenclamide]), and those taking metformin in combination with glyburide (Glucovance) are at risk for hypoglycemia. This risk is increased if they are older, have liver or kidney impairment, or are taking drugs that enhance the effects of antidiabetic drugs. Proper patient selection, drug dosage, and instructions are important factors in avoiding severe hypoglycemia. Hypoglycemia may be difficult to recognize in those who take beta-blocking drugs. Symptoms become less intense and less obvious. Manifestations of hypoglycemia in older patients may be mistaken for other conditions.

The most common causes of hypoglycemia are:

- Too much insulin as it relates to food intake and physical activity
- Insulin injected at the wrong time relative to food intake and physical activity
- The wrong type of insulin injected at the wrong time

- Decreased food intake resulting from missed or delayed meals
- Delayed gastric emptying from gastroparesis
- Decrease liver glucose production after alcohol ingestion
- Increased insulin sensitivity as a result of regular exercise and weight loss
- Decreased insulin clearance from progressive kidney failure

Nutrition Therapy. When the patient is hypoglycemic, start carbohydrate replacement per physician prescription or standing protocols. Ingestion of 15 to 20 g of glucose is the preferred treatment for hypoglycemia. If the patient can swallow, give a liquid form of carbohydrate, although any source of carbohydrate can be used to treat hypoglycemia. Ingestion of 15 to 20 g of glucose is the preferred treatment for blood glucose levels less than 70 mg/dL (3.9 mmol/L), repeated in about 15 minutes if manifestations have not improved or if blood glucose levels are still less than 70. The amount of carbohydrate should be increased to 30 g when treating glucose levels less than 50 mg/dL (2.8 mmol/L).

Ten grams of oral glucose raises plasma glucose levels by about 40 mg/dL over 30 minutes, and 20 g of oral glucose raises plasma glucose levels by about 60 mg/dL over 45 minutes. Glucose levels often begin to fall about 60 minutes after glucose ingestion. Specific recommendations are listed in Chart 67-10.

The blood glucose level determines the form and amount of glucose used. The response to treatment of hypoglycemia should be apparent in 10 to 20 minutes; however, test plasma glucose again in about 60 minutes because additional treatment may be needed. Fluid is absorbed much more quickly from the GI tract than are solids. Concentrated sweet fluids, such as juice with sugar added or a soft drink, may slow absorption.

Management of hypoglycemia requires ingestion of glucose or glucose-containing foods. The blood glucose response correlates better with the glucose content rather than the carbohydrate content of the food. Adding protein to carbohydrate does not improve blood glucose response and does not prevent subsequent hypoglycemia. Adding fat may retard and then prolong the blood glucose response, resulting in post-treatment hyperglycemia. Commercially available products provide predictable glucose absorption.

Drug Therapy. Glucagon given subcutaneously or IM and 50% dextrose given IV is used for patients who cannot swallow. Glucagon is the main counterregulatory hormone and is used as therapy for severe hypoglycemia in DM. It converts liver glycogen to glucose but is not effective in starved patients who have little liver glycogen. Take care to prevent aspiration in patients receiving glucagon, because it often causes vomiting. Give 50% dextrose carefully to avoid extravasation because it is hyperosmolar and can damage tissue. The effects of glucagon and dextrose are temporary. After the patient responds and is no longer nauseated, give a simple sugar followed by a small snack or meal. IV glucose is used to maintain mild hyperglycemia. Diazoxide (Proglycem) or octreotide (Sandostatin) may be required to treat sulfonylurea-induced hypoglycemia. Evaluate response by monitoring blood glucose levels for several hours. Symptoms may persist for an hour or more after treatment. A target blood glucose level is 70 to 110 mg/dL (3.9 to 6.2 mmol/L).

CHART 67-10 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Treatment of Hypoglycemia at Home

For *mild* hypoglycemia (hungry, irritable, shaky, weak, headache, fully conscious; blood glucose usually less than 60 mg/dL [3.4 mmol/L]):

- Treat the symptoms of hypoglycemia with 10 to 15 g of carbohydrate. You may use one of the following:
 - Glucose tablets or glucose gel (dosage is printed on the package)
 - $\frac{1}{2}$ cup of fruit juice
 - $\frac{1}{2}$ cup of regular (nondiet) soft drink
 - 8 ounces of skim milk
 - 6 to 10 hard candies
 - 4 cubes of sugar
 - 4 teaspoons of sugar
 - 6 saltines
 - 3 graham crackers
 - 1 tablespoon of honey or syrup
- Re-test blood glucose in 15 minutes.
- Repeat this treatment if symptoms do not resolve.
- Eat a small snack of carbohydrate and protein if your next meal is more than an hour away.

For *moderate* hypoglycemia (cold, clammy skin; pale; rapid pulse; rapid, shallow respirations; marked change in mood; drowsiness; blood glucose usually less than 40 mg/dL [2.2 mmol/L]):

- Treat the symptoms of hypoglycemia with 15 to 30 g of rapidly absorbed carbohydrate.
- Take additional food, such as low-fat milk or cheese, after 10 to 15 minutes.

For *severe* hypoglycemia (unable to swallow; unconsciousness or convulsions; blood glucose usually less than 20 mg/dL [1.0 mmol/L]):

- Treatment administered by family members:
 - Administer 1 mg of glucagon as intramuscular or subcutaneous injection.
 - Administer a second dose in 10 minutes if the person remains unconscious.
 - Notify a primary care provider immediately, and follow instructions.
 - If still unconscious, transport the person to the emergency department.
 - Give a small meal when the person wakes up and is no longer nauseated.

! NURSING SAFETY PRIORITY

Critical Rescue

For the patient with *severe* hypoglycemia (unable to swallow, unconscious or convulsing, blood glucose usually less than 20 mg/dL [1.0 mmol/L]), treat by:

1. Giving glucagon 1 mg subcutaneously or IM
2. Repeating the dose in 10 minutes if the patient remains unconscious
3. Notifying the primary health care provider immediately, and following instructions

Prevention Strategies. Teach the patient how to prevent hypoglycemia by avoiding the four common causes of hypoglycemia. These are (1) excess insulin, (2) deficient intake or absorption of food, (3) exercise, and (4) alcohol intake.

Insulin excess from variable absorption of insulin can cause hypoglycemia even when insulin is injected correctly. This excess also can be caused by lowered insulin resistance,

which occurs with termination of pregnancy or resolution of an infection. Increased insulin sensitivity can occur with weight loss or exercise programs. Differences in insulin formulation can result in hypoglycemia. Teach the patient to not change insulin brands without medical supervision.

Deficient food intake from inadequate or incorrectly timed meals can result in hypoglycemia. Changes in gastric absorption may cause hypoglycemia in patients with delayed gastric emptying. This problem is more common in those with DM of long duration, is more severe with solid than with liquid meals, and is made worse by illness or poor glucose control. Teach the patient about the importance of regularity in timing and quantity of food eaten.

Exercise usually causes blood glucose levels to fall in a patient with type 1 DM. Prolonged exercise increases cellular glucose uptake for several hours after exercise. Teach the patient about blood glucose monitoring and carbohydrate consumption before and during exercise.

Alcohol inhibits liver glucose production and leads to hypoglycemia. It interferes with the counterregulatory response to hypoglycemia and impairs glycogen breakdown, making exercise-induced hypoglycemia more severe. Alcohol is more likely to cause hypoglycemia when the patient does not eat for long periods, when basic nutrition is poor, and when glycogen stores are depleted. Teach him or her to ingest alcohol only with or shortly *after* eating a meal with enough carbohydrate to prevent hypoglycemia. Warn patients to avoid excess alcohol at bedtime to prevent nighttime hypoglycemia.

Patient and Family Education. The cause of hypoglycemia may be subtle. At the onset of menses, a fall in hormone levels decreases insulin needs and contributes to hypoglycemia. When patients switch to a new bottle of insulin, hypoglycemia may occur because the fresh insulin has greater potency. Some patients have hypoglycemia when they change injection sites. Drugs such as propranolol (Inderal, Detensol ) or other beta blockers mask warning signs and thus predispose patients to severe hypoglycemia. Some episodes of hypoglycemia occur without an obvious cause and are due to the erratic absorption of insulin, which can occur in any patient.

Many patients who have been treated in the emergency department for hypoglycemia do not receive adequate instruction on how to prevent another episode and are at continuing risk. Help each patient develop a personal treatment plan for hypoglycemia. Routinely taking 10 to 15 g of carbohydrate results in overtreatment of hypoglycemia in some patients and undertreatment in others. The exact glucose rise from a set amount of carbohydrate varies; however, using the estimate that each 5 g of carbohydrate raises blood glucose about 20 mg/dL is a good starting plan. For example, the patient may be directed to take:

- 20 to 30 g of carbohydrate if the blood glucose level is 50 mg/dL (2.8 mmol/L) or less
- 10 to 15 g of carbohydrate if the blood glucose level is 51 to 70 mg/dL (2.9 to 3.9 mmol/L)

Use blood glucose monitoring results to revise or reinforce this plan.

Encourage the patient to wear a medical alert bracelet, and help him or her obtain one. This bracelet is helpful if the patient becomes hypoglycemic and is unable to provide self-care.

FIG. 67-12 The pathophysiologic mechanism of diabetic ketoacidosis (DKA).

Teach the patient and family about the manifestations of hypoglycemia. Emphasize that delaying a meal for more than 30 minutes raises the risk for hypoglycemia when using some insulin regimens. Instruct him or her to keep a carbohydrate source nearby at all times. Teach the patient and family how to administer glucagon.

CONSIDERATIONS FOR OLDER ADULTS

The risk for severe or fatal hypoglycemia associated with insulin use or other antidiabetic drugs increases dramatically in the older adult with DM. Age-related changes in liver and kidney function slow metabolism of these drugs, predisposing to prolonged and recurrent hypoglycemia. Older patients may have a delayed release of epinephrine, as well as an impaired response of glucagon to falling blood glucose levels. In addition, they often have a reduced awareness of the autonomic manifestations and may not know how to interpret manifestations of hypoglycemia. Older patients have impaired psychomotor performance when their blood sugars are low, preventing them from taking appropriate steps to return their blood sugars to normal. Physical symptoms such as confusion may make the older patient unable to correct hypoglycemia.

Instruct the older patient with DM and the family to check blood glucose values when symptoms such as unsteadiness, lightheadedness, poor concentration, trembling, or sweating occur. Assess eating patterns to make sure he or she is eating sufficient foods at appropriate times. Encourage a patient with a poor appetite to eat a small snack at bedtime to prevent hypoglycemia during the night.

Antidiabetic drugs with low hypoglycemia potential should be selected for older patients. The highest rates of severe and fatal episodes of hypoglycemia are associated with the use of glyburide, and most of these events occurred in patients older than 70 years. Drug regimens that require that meals be eaten on time increase the potential for hypoglycemic reactions.

Hypoglycemia is a major risk for patients receiving intensive insulin protocols who engage in exercise programs. Explain that nightmares or headaches on days after prolonged or severe exercise occur with hypoglycemia.

Establishing Treatment Plans. Blood glucose monitoring directs hypoglycemia treatment. Treatment continues until blood glucose levels reach and stay in the target range. Once blood glucose control is regained, the specific cause of each hypoglycemic episode should be determined and measures taken to prevent recurrence.

Preventing Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is characterized by uncontrolled hyperglycemia, metabolic acidosis, and increased production of ketones. This condition results from the combination of insulin deficiency and an increase in counterregulatory hormone release (Fig. 67-12). Laboratory diagnosis of DKA is shown in Table 67-15. Hormonal changes lead to increased liver and kidney glucose production and decreased glucose use in peripheral tissues. Increased production of counterregulatory hormones leads to the production of ketacids with resultant ketonemia and metabolic acidosis.

DKA occurs most often in patients with type 1 DM but also can occur in those with type 2 DM who are under severe stress (e.g., trauma, surgery, infection). The most common precipitating factor for development of DKA is infection. *Death occurs in up to 10% of these cases even with appropriate treatment.* Mortality is highest for older patients who also have infection, stroke, MI, vascular thrombosis, intestinal obstruction, or pneumonia.

Hyperglycemia leads to osmotic diuresis with dehydration and electrolyte loss. Classic symptoms of DKA include

TABLE 67-15 DIFFERENCES BETWEEN DIABETIC KETOACIDOSIS AND HYPERGLYCEMIC-HYPEROSMOLAR STATE

	DIABETIC KETOACIDOSIS (DKA)	HYPERGLYCEMIC-HYPEROSMOLAR STATE (HHS)
Onset	Sudden	Gradual
Precipitating factors	Infection Other stressors Inadequate insulin dose	Infection Other stressors Poor fluid intake
Manifestations	Ketosis: Kussmaul respiration, "fruity" breath, nausea, abdominal pain Dehydration or electrolyte loss: polyuria, polydipsia, weight loss, dry skin, sunken eyes, soft eyeballs, lethargy, coma	Altered central nervous system function with neurologic symptoms Dehydration or electrolyte loss: same as for DKA
Laboratory Findings		
Serum glucose	>300 mg/dL (16.7 mmol/L)	>600 mg/dL (33.3 mmol/L)
Osmolarity	Variable	>320 mOsm/L
Serum ketones	Positive at 1:2 dilutions	Negative
Serum pH	<7.35	>7.4
Serum HCO ₃ ⁻	<15 mEq/L	>20 mEq/L
Serum Na ⁺	Low, normal, or high	Normal or low
BUN	>30 mg/dL; elevated because of dehydration	Elevated
Creatinine	>1.5 mg/dL; elevated because of dehydration	Elevated
Urine ketones	Positive	Negative

BUN, Blood urea nitrogen; HCO₃⁻, bicarbonate; Na⁺, sodium.

polyuria, polydipsia, polyphagia, weight loss, vomiting, abdominal pain, dehydration, weakness, altered mental status, shock, and coma. Mental status can vary from total alertness to profound coma. As ketone levels rise, the buffering capacity of the body is exceeded, the pH of the blood decreases, and acidosis occurs. **Kussmaul respirations** (very deep and rapid respirations) cause respiratory alkalosis in an attempt to correct metabolic acidosis by exhaling carbon dioxide. Initial serum sodium levels may be low or normal. Initial potassium levels depend on how long DKA lasts before treatment. After therapy starts, serum potassium levels drop quickly.

Planning: Expected Outcomes. The patient is expected to have few episodes of hyperglycemia and avoid diabetic ketoacidosis. Indicators include that the patient consistently demonstrates these behaviors:

- Maintains blood glucose levels within the prescribed target range
- Adjusts insulin doses to match eating patterns and blood glucose levels during illness
- Maintains easily digestible liquid diet containing carbohydrate and salt when nauseated
- Describes correct procedure for urine ketone testing
- Describes when to seek help from health care professional

Interventions

Blood Glucose Management. Monitor for manifestations of DKA (see Table 67-15 and Fig. 67-12). Document and use these findings to determine therapy effectiveness. *First assess the airway, level of consciousness, hydration status, electrolytes, and blood glucose level.* Check the patient's blood pressure, pulse, and respirations every 15 minutes until stable. Record urine output, temperature, and mental status every hour. When a central venous catheter is present, assess central venous pressure every 30 minutes or as prescribed. After treatment starts and these values are stable, monitor and record vital signs every 4 hours. Use blood glucose values to assess therapy effectiveness and determine when to switch from saline to dextrose-containing solutions.

Fluid and Electrolyte Management. *Closely assess the patient's fluid status.* The kidneys are less able to respond to changes in pH or fluid and electrolyte balance, to concentrate urine, or to regulate blood osmolarity. The risk for kidney failure rises with age. Impaired bicarbonate reabsorption and acid excretion in poorly functioning kidney tubules can lead to acidosis. Cardiovascular disease can cause fluid retention. The dehydrated patient's lips and mouth may be dry and the tongue furrowed. Temperature may be elevated. Age-related skin changes, such as loss of elasticity and dryness, make skin turgor an unreliable sign of dehydration in the older patient. In patients with poor kidney function and excess fluid volume, assess for edema around the eyes and in the limbs, increasing abdominal girth, increasing blood pressure and pulse volume, jugular venous distention, and orthostatic hypotension. Edema occurs with excess interstitial fluid and often is not apparent until interstitial volume increases by 2 to 3 L. Daily weights are good indicators of fluid status because 1 kg of body weight equals 1 L of fluid.

Check the clinical indicators of fluid imbalance. Fluid overload can cause hypertension, especially in patients with kidney failure. Jugular venous pressure increases with volume overload. Orthostatic hypotension may indicate volume depletion. In that case, jugular venous pulsation may not be visible at a 45-degree angle. In severe volume depletion, the jugular venous pulsation may not be visible even with the patient lying flat.

The first outcome of fluid therapy is to restore volume and maintain perfusion to the brain, heart, and kidneys. Typically, initial infusion rates are 15 to 20 mL/kg/hr during the first hour (Fowler, 2009).

The second outcome of fluid therapy, replacing total body fluid losses, is achieved more slowly. The choice for fluid replacement depends on hemodynamics (status of blood pressure), the state of hydration, serum electrolyte levels, and urine output. In general, hypotonic fluids are infused at 4 to 14 mL/kg/hr after the initial fluid bolus. When blood glucose levels reach 250 mg/dL (13.8 mmol/L), give 5% dextrose in 0.45% saline. This solution prevents hypoglycemia and cerebral edema, which can occur when serum osmolarity declines too rapidly.

During the first 24 hours of treatment, the patient needs enough fluids to replace the actual volume deficit and ongoing losses. This may be as much as 6 to 10 L. Assess cardiac, kidney, and mental status to avoid fluid overload. Watch for signs of congestive heart failure and pulmonary edema. Central venous pressure may be monitored for older patients and those with myocardial disease. Assess the status of fluid

replacement by monitoring blood pressure and intake and output.

Drug Therapy. The outcome of insulin therapy is to lower serum glucose by about 50 to 75 mg/dL/hr. Unless the episode of DKA is mild, regular insulin by continuous IV infusion is the treatment of choice. Effective blood insulin levels are reached quickly when an IV bolus dose is given at the start of the infusion. An initial IV bolus dose of 0.1 unit/kg is followed by an IV infusion of 0.1 unit/kg/hr. Continuous insulin infusion is used because of the 4-minute half-life of IV insulin and because of the delayed onset of action and prolonged half-life of subcutaneous regular insulin. Subcutaneous insulin is started when the patient can take oral fluids and ketosis has stopped. Criteria for resolution of DKA include blood glucose less than 200 mg/mL along with a serum bicarbonate level higher than 18 mEq/L, venous pH higher than 7.3, and a calculated ion gap of less than 12 mEq/L. Assess therapy effectiveness by hourly blood glucose measurements.

Acidosis Management. The key diagnostic feature of DKA is elevation in circulating total body ketone concentration. The severity of DKA is best assessed by measurements of serum β -hydroxybutyrate. Accumulation of ketoacids results in an increased anion gap metabolic acidosis. The anion gap is calculated by subtracting the sum of chloride and bicarbonate concentration from the sodium concentration. A normal anion gap is between 7 and 9 mEq/L; an anion gap greater than 10 to 12 mEq/L indicates metabolic acidosis.

Despite total-body potassium depletion, mild to moderate hyperkalemia is common in patients with hyperglycemia. Insulin therapy, correction of acidosis, and volume expansion decrease serum potassium concentration. To prevent hypokalemia, potassium replacement is initiated after serum levels fall below normal. *Assess for signs of hypokalemia, including fatigue, malaise, confusion, muscle weakness, shallow respirations, abdominal distention or paralytic ileus, hypotension, and weak pulse.* An ECG shows cardiac conduction changes related to potassium. Hypokalemia is a common cause of death in the treatment of DKA.

! NURSING SAFETY PRIORITY

Critical Rescue

Before giving IV potassium, make sure the patient produces at least 30 mL/hr of urine.

Bicarbonate is used only for severe acidosis because it may reverse acidosis too rapidly and lead to severe hypokalemia, which can cause fatal cardiac dysrhythmias. Rapid correction can worsen the patient's mental status. Acidosis is corrected with fluid replacement and insulin therapy. Sodium bicarbonate, given by slow IV infusion over several hours, is indicated when the arterial pH is 7.0 or less or the serum bicarbonate level is less than 5 mEq/L (5 mmol/L).

After acid-base disturbances are corrected, efforts are directed toward determining the cause of DKA. Infection is the most common cause (see [Table 67-15](#)).

Patient and Family Education. Exploring the factors leading to DKA helps in planning specific educational efforts. Teach the patient and family to check blood glucose levels every 4 to 6 hours as long as symptoms such as anorexia,

CHART 67-11 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Sick-Day Rules

- Notify your health care provider that you are ill.
- Monitor your blood glucose at least every 4 hours.
- Test your urine for ketones when your blood glucose level is greater than 240 mg/dL (13.8 mmol/L).
- Continue to take insulin or oral antidiabetic agents.
- To prevent dehydration, drink 8 to 12 ounces of sugar-free liquids every hour that you are awake. If your blood glucose level is below your target range, drink fluids that contain sugar.
- Continue to eat meals at regular times.
- If unable to tolerate solid food because of nausea, consume more easily tolerated foods or liquids equal to the carbohydrate content of your usual meal.
- Call your primary care provider for any of these danger signals:
 - Persistent nausea and vomiting
 - Moderate or large ketones
 - Blood glucose elevation after two supplemental doses of insulin
 - High (101.5° F [38.6° C]) temperature or increasing fever; fever for more than 24 hours
- Treat symptoms (e.g., diarrhea, nausea, vomiting, fever) as directed by your primary care provider.
- Get plenty of rest.

nausea, and vomiting are present and as long as glucose levels exceed 250 mg/dL (13.8 mmol/L). Teach them to check urine ketone levels when blood glucose levels exceed 300 mg/dL (16.7 mmol/L).

Teach the patient to reduce the risk for dehydration by maintaining food and fluid intake. Unless another health problem is present that requires fluid restriction, suggest that he or she drink at least 3 L of fluid daily and increase this amount when infection is present. When nausea is present, instruct the patient to take liquids containing both glucose and electrolytes (e.g., soda pop, diluted fruit juice, and sports drinks [Gatorade]). Small amounts of fluid may be tolerated even when vomiting is present. When blood glucose levels are normal or elevated, the patient should take 8 to 12 ounces (240 to 360 mL) of calorie-free and caffeine-free liquids every hour while awake to prevent dehydration.

Liquids containing carbohydrate can be taken if the patient with diabetes cannot eat solid food. Ingesting at least 150 g of carbohydrate daily reduces the risk for starvation ketosis. After consulting a primary care provider, urge the patient to take additional rapid-acting (lispro) or short-acting (regular) insulin based on blood glucose levels.

Instruct the patient and family to consult the primary care provider when these problems occur:

- Blood glucose exceeds 250 mg/dL (13.8 mmol/L).
- Ketonuria lasts for more than 24 hours.
- The patient cannot take food or fluids.
- Illness lasts more than 1 to 2 days.

Also instruct them to detect hyperglycemia by monitoring blood glucose whenever the patient is ill. Illness can result in dehydration with DKA, hyperglycemic-hyperosmolar state, or both. The sooner the patient seeks treatment, the less severe the metabolic alteration. He or she should not omit insulin therapy during illness. [Chart 67-11](#) lists guidelines for the ill patient.

FIG. 67-13 The pathophysiologic mechanism of hyperglycemic-hyperosmolar state (HHS). *BUN*, Blood urea nitrogen.

Preventing Hyperglycemic-Hyperosmolar State

Hyperglycemic-hyperosmolar state (HHS), formerly known as *hyperglycemic-hyperosmolar nonketotic syndrome (HHNS)*, is a hyperosmolar (increased blood osmolarity) state caused by hyperglycemia. The processes of HHS are outlined in Fig. 67-13. Both HHS and diabetic ketoacidosis (DKA) are caused by hyperglycemia and dehydration. HHS differs from DKA in that ketone levels are low or absent and blood glucose levels are much higher. Blood glucose levels may exceed 600 mg/dL (33.3 mmol/L), and blood osmolarity may exceed 320 mOsm/L. Other biochemical problems with HHS also are more severe than those with DKA. Table 67-15 lists the differences between DKA and HHS.

HHS is the end result of a sustained osmotic diuresis. Kidney impairment in HHS allows for extremely high blood glucose levels. Glucose impairs the concentrating ability of the kidney. Normally, kidneys act as a safety valve to eliminate glucose above levels around 180 mg/dL (10.0 mmol/L). As serum concentrations of glucose exceed the renal threshold, the kidney's capacity to reabsorb glucose is exceeded.

Decreased blood volume, caused by osmotic diuresis, or underlying kidney disease, common in many older patients with diabetes, results in further deterioration of kidney function. The decreased volume further reduces glomerular filtration rate, causing the glucose level to increase. Decreased kidney perfusion from hypovolemia further impairs kidney function.

Myocardial infarction, sepsis, pancreatitis, stroke, and some drugs (glucocorticoids, diuretics, phenytoin [Dilantin], propranolol [Inderal], and calcium channel blockers) also

CONSIDERATIONS FOR OLDER ADULTS

HHS occurs most often in older patients with type 2 diabetes mellitus, many of whom did not know that they had diabetes. Mortality rates in older patients are as high as 40% to 70%. The onset of HHS is slow and may not be recognized. The older patient often seeks medical attention later and is sicker than the younger patient. HHS does not occur in adequately hydrated patients. Older patients are at greater risk for dehydration and HHS because of age-related changes in thirst perception and poor urine-concentrating abilities.

Many older adults take diuretics, which contributes to dehydration. In the long-term care settings and for home-bound older adults who depend on others for oral intake, many patients do not ingest enough fluids and can more easily become dehydrated. Ensure that older adults with diabetes are weighed every 3 days or weekly to monitor trends and detect dehydration early.

may cause HHS. Central nervous system (CNS) changes range from confusion to complete coma. Unlike DKA, patients with HHS may have seizures, myoclonic jerking, and reversible paralysis. The degree of neurologic impairment is related to serum osmolarity, with coma occurring once serum osmolarity is greater than 350 mOsm/L (350 mmol/L).

The development of HHS rather than DKA is related to residual insulin secretion. In HHS, the patient secretes just enough insulin to prevent ketosis but not enough to prevent hyperglycemia. The hyperglycemia of HHS is more severe than that of DKA, greatly increasing the blood osmolarity and causing profound diuresis. Severe dehydration and electrolyte loss occur, and the patient may lose 15% to 25% of body fluid. When dehydration is severe, glucose is not filtered into the urine, causing even greater hyperglycemia and

hyperosmolarity. Impairment of the thirst center in the brain occurs, making it impossible for the patient to drink enough fluid to prevent dehydration. This problem is worse in the older adult with diabetes because age-related changes in the thirst center reduce the patient's sensation of thirst.

Planning: Expected Outcomes. The patient with DM is expected to have few episodes of hyperglycemia and avoid HHS. Indicators include that the patient consistently demonstrates these behaviors:

- Maintains blood glucose levels within the target range
- Uses antidiabetic drugs appropriately
- Remains well hydrated
- Describes when to seek help from health care professionals

Interventions

Monitoring. Assess for manifestations of HHS. (See Tables 67-14 and 67-15 for symptoms of hyperglycemia.) Continually assess fluid status.

Fluid Therapy. The expected outcome of therapy is to rehydrate the patient and restore normal blood glucose levels within 36 to 72 hours. The choice of fluid replacement and the rate of infusion are critical in managing HHS. The severity of the CNS problems is related to the level of blood hyperosmolarity and cellular dehydration. Re-establishing fluid balance in brain cells is a difficult and slow process, and many patients do not recover baseline CNS function until hours after blood glucose levels have returned to normal.

The *first* priority for fluid replacement in HHS is to increase blood volume. In shock or severe hypotension, give normal saline. Otherwise, use half-normal saline because it more rapidly corrects the water deficit. Infuse fluids at 1 L/hr until central venous pressure or pulmonary capillary wedge pressure begins to rise or until blood pressure and urine output are adequate. The rate is then reduced to 100 to 200 mL/hr. Half of the estimated water deficit is replaced in the first 12 hours, and the rest is given over the next 36 hours. Body weight, urine output, kidney function, and the presence or absence of pulmonary congestion and jugular venous distention determine the rate of fluid infusion. In patients with congestive heart failure, kidney disease, or acute kidney injury (failure), monitor central venous pressure. *Assess the patient hourly for signs of cerebral edema—abrupt changes in mental status, abnormal neurologic signs, and coma.* Lack of improvement in level of consciousness may indicate inadequate rates of fluid replacement or reduction in plasma osmolarity. Regression after initial improvement may indicate a too-rapid reduction in plasma osmolarity. A slow but steady improvement in CNS function is the best evidence that fluid management is satisfactory.

! NURSING SAFETY PRIORITY

Critical Rescue

For patients being managed for a hyperglycemic-hyperosmolar state, immediately report changes in the level of consciousness; changes in pupil size, shape, or reaction; or seizures.

Continuing Therapy. IV insulin is administered after adequate fluids have been replaced. The typical intervention is an initial bolus dose of 0.15 unit per kg IV followed by an infusion of 0.1 unit per kg per hour until blood glucose levels fall to 250 mg/dL (13.9 mmol/L). A reduction of blood

glucose of 50 to 70 mg/dL per hour is a reasonable expected outcome. Monitor the patient closely for indications of hypokalemia. Total body potassium depletion is often unrecognized because the level of potassium in the blood may be normal or high. The serum potassium level may drop quickly when insulin therapy is started. Potassium replacement is initiated once urine output is adequate. Serum electrolytes should be obtained every 1 to 2 hours until stable, and the patient's cardiac rhythm should be monitored continuously for signs of hypokalemia or hyperkalemia. Patient education and interventions to minimize dehydration are similar to those for ketoacidosis.

COMMUNITY-BASED CARE

Teaching for Self-Management

Education about blood glucose control begins at the time of diagnosis. It takes place in a hospital or outpatient setting, clinic, or primary care provider's office and involves physicians, nurses, dietitians, pharmacists, social workers, and psychologists. Diabetes is a condition that is managed by the patient; therefore education should be a continuous process. Education is provided to patients to achieve blood glucose control to the maximum of their abilities.

Assessing Learning Needs and Readiness to Learn

Gather information about the patient's current knowledge, skills, attitudes, and behaviors. The patient must have a basic level of understanding about diabetes management in order to reach target blood glucose levels. Assess his or her awareness of diabetes and the needs of both patient and family before teaching. This assessment includes:

- Health and medical history
- Nutrition history and practices
- Physical activity and exercise behaviors
- Prescription and over-the-counter medications, and complementary and alternative therapies and practices
- Factors that influence learning such as education and literacy levels, perceived learning needs, motivation to learn, and health beliefs
- Diabetes self-management behaviors, including experience with self-adjusting the treatment plan
- Previous diabetes self-management training, actual knowledge, and skills
- Physical factors including age, mobility, visual acuity, hearing, manual dexterity, alertness, attention span, and ability to concentrate or special needs or limitations requiring adaptive support and use of alternative skills
- Psychosocial concerns, factors, or issues including family and social support
- Current mental health status
- History of substance abuse including alcohol, tobacco, and recreational drugs
- Occupation, vocation, education level, financial status, and social, cultural, and religious practices
- Access to and use of health care resources

Adult learners want information that applies directly to them. Find out what concerns the patient most about having diabetes, and ask what he or she wants to learn. Learning is enhanced when it is related to what the learner already knows. Start with what the patient already knows, and build on that

base. Because they will be managing their own care after discharge, patients tend to focus on issues most important to them. Treatment measures that need to start soon after diagnosis may be of more interest to the patient than long-term control. Learning is reinforced and retained when it can be applied immediately and repeatedly.

The patient's physical condition dictates the timing of teaching. He or she does not have the energy to learn complex information when blood glucose levels are fluctuating. Explaining that well-controlled blood glucose levels improve the sense of well-being can help the patient accept the therapy plan. Pace your teaching to match the patient's energy level. Use an informal teaching process until he or she feels able to attend a formal class.

Each patient learns in his or her own way. A successful diabetes education program combines several teaching methods. Some patients learn better when they read pamphlets. Others learn better when they watch videos. Learning improves when the equipment is handled, techniques are practiced, success is rewarded, and errors are corrected immediately.

Assessing Physical, Cognitive, and Emotional Limitations

Assess the patient's education and reading level to determine what level of information to present. He or she must be able to understand the printed material. It is important to match the literacy level of printed material provided to the literacy level of the patient. Even highly educated patients do not want to read complicated information when they are sick. Develop creative teaching strategies for the patient who cannot read.

Assess the patient's ability to read printed information, insulin labels, and markings on syringes and equipment. Many with type 2 diabetes have **presbyopia** (age-related farsightedness) and other visual problems made worse by blurred vision caused by fluctuating blood glucose levels.

Assess the patient's ability to reason with numbers and other mathematical concepts. Adjusting insulin dosage based on blood glucose monitoring is a difficult concept and may not be appropriate for patients who cannot understand it. Managing drugs, exercise, and diet requires complex interpretation and behavior.

Assess manual dexterity for any physical limitations that may alter the teaching plan. A hand injury, tremors, or severe arthritis may require a change in insulin preparation.

Information is best learned when the patient is ready. Those with newly diagnosed diabetes are facing a life crisis. Some are motivated to learn information and are willing to change lifelong behaviors. Others may grieve the loss of their previous lifestyle and use denial to cope. In this instance, the patient may not be able to learn needed information right away.

Survival Skills Information

The initial phase of diabetes education involves teaching information necessary for the survival of anyone diagnosed with diabetes. Survival information includes:

- Simple information on pathophysiology of diabetes
- Learning how to prepare and administer insulin or how to take oral drugs for diabetes
- Basic diet information
- Monitoring of blood glucose and ketones

- Recognition, treatment, and prevention of hypoglycemia and hyperglycemia
- Sick-day management
- Where to buy diabetes supplies and how to store them
- When and how to notify the primary care provider

A dietitian provides the initial diet instruction. The patient needs to understand what to eat, how much to eat, and when to eat. Stress the importance of eating on time and the dangers of skipping meals. He or she must know how to maintain food intake during illness. Reinforce dietary instruction, answer questions, and refer questions to the dietitian or primary care provider as indicated.

After being taught, the patient should be able to identify the drugs needed to control blood glucose levels. If insulin is used, he or she must be able to prepare and give the dose accurately using sterile technique. The patient must also be able to state when insulin is to be injected, where insulin is injected, and how insulin is stored. Stress the dangers of skipping doses. Carefully review drug interactions, especially with older patients taking oral antidiabetic drugs.

Patients should be able to state their plan for regular physical activity. They must be able to describe the relationship between exercise and blood glucose control and identify situations in which activity should not be performed. Provide guidelines for additional carbohydrate intake to prevent hypoglycemia from excessive exercise.

The patient also must be able to state the plan for monitoring blood glucose. The person doing the monitoring must be able to do the procedure accurately and understand the results. Explain when blood glucose should be monitored, acceptable ranges, and actions to take when results are out of these ranges. If the patient cannot perform self-monitoring of blood glucose (SMBG) because of illness, ensure that a resource (e.g., home care agency, health clinic, or primary care provider's office) will be available to do the monitoring.

The most important part of survival-level education is to ensure that the patient understands the significance, symptoms, causes, and treatment of hypoglycemia. He or she must be able to state the causes of hypoglycemia and the activities needed to prevent it. The patient must be able to describe appropriate carbohydrates to have available and the need to notify the physician of hypoglycemic episodes. Teach a family member how and when to inject glucagon.

The patient also must understand the significance of hyperglycemia and its relationship to illness. Instruct him or her on actions to take during illness and when to communicate with the primary care provider.

Most of this information is best retained when the patient is ready to learn. Education is a challenge because patients tend to be hospitalized for shorter periods. All diabetes education may be provided in an outpatient setting, where contact with the patient is limited. Important information must be squeezed into the time available. Many patients do not progress in self-management beyond the survival level because of psychological barriers.

In-Depth Education

In-depth education and counseling involve teaching more detailed information related to survival skills, as well as helping the patient learn preventive measures for avoiding long-term complications. Educational sessions with patient and family are needed to "patientize" the diabetes regimen for their needs

and abilities. Education is often provided by a team of a physician, nurse educator, dietitian, social worker, pharmacist, psychologist, case manager, and other health care professionals as needed. It may occur in various outpatient settings.

Besides knowledge gained at the survival level, the patient should be able to discuss the action of insulin in the body and the effects of insulin deficiency. He or she should also be able to explain the effects of diet, drugs, and activity on blood glucose. The patient should be able to relate maintaining normal blood glucose levels to preventing complications. This includes relating changes in glucose level to the possible need for a change in insulin dosage.

The patient must be able to describe the meal plan and explain the adjustments needed to meet diabetic diet requirements. He or she should state how food intake should be altered when eating out or increasing exercise. *The patient must be able to list specific foods to be eaten to prevent and treat hypoglycemia, as well as adjustments to make when ill.* Include in this teaching the family member usually responsible for buying groceries and preparing meals.

The patient with diabetes must be able to prepare and give insulin accurately and must be able to discuss the onset, peak, and duration of the insulin used. Review formulas for self-adjustment in insulin (when permitted by the physician), and explain blood glucose monitoring requirements needed to evaluate the effects of additional insulin. If the patient takes an oral antidiabetic drug, ask him or her to identify the drug and describe its prescribed schedule. The patient must identify over-the-counter drugs with the potential to cause adverse interactions and the need to inform all care providers of the drug regimen.

Review how to perform desired physical activities safely. The patient must state blood glucose levels that are safe for exercise, the frequency of SMBG during exercise, drug adjustments before exercise, food required before exercise, and what food to have available during exercise. He or she should be aware of the risk for injury during exercise and explain the importance of protective footwear.

The purposes of in-depth education are to help the patient solve problems of blood glucose fluctuation through the use of SMBG. He or she should be able to identify practices, such as travel (Chart 67-12), that cause blood glucose to fluctuate and to treat these problems with supplemental insulin, changes in activity, or changes in diet. Ask him or her to demonstrate urine ketone testing and to describe when urine ketones should be measured.

The patient must be able to describe a plan for periodic evaluation of blood glucose control by the primary care provider, as well as periodic dental and eye examinations. He or she must be able to perform foot care, wear properly fitting shoes, and describe hazards related to foot care. The patient must be able to describe ways to reduce specific risk factors, such as cigarette smoking and hypertension.

The patient must state that diabetes is a lifelong disease that requires lifestyle changes, describe the changes being made, and indicate those that need to be made. He or she should be able to identify stress-producing situations and discuss ways to reduce stress.

Psychosocial Preparation

The diagnosis of diabetes may represent a loss of control. All but a few patients lose flexibility. Life becomes ordered, and routines must be followed. Certain events surrounding

CHART 67-12 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Travel Tips for Patients with Diabetes

Before traveling, visit your primary care provider and diabetes educator.

- See your physician to make certain you do not have any other health problems.
- Obtain a letter from your physician (typed on office letterhead) that indicates you have diabetes and lists the drugs you are taking.
- Obtain any needed immunizations or inoculations.
- Obtain prescriptions from your physician for your drugs, including glucagon if you take insulin, and prescriptions for motion sickness, nausea and vomiting, and traveler's diarrhea.
- Develop a plan for changing strengths of insulin if you are traveling to a country that does not carry the type of insulin you use. Learn how to use a U-100 syringe to draw up U-40 insulin.
- Develop a plan for meal and drug adjustment across time zones. Eastbound travel will shorten the day, requiring a reduction in the amount of drug needed. Westbound travel may add an extra meal to the day and require additional drug.
- Obtain a list of foods from your diabetes educator that you can substitute for food served in restaurants or airplanes.

If you are traveling by air, train, or boat, call ahead and request special meals for those with diabetes.

- Plan for delays in eating.
- Eat something every 4 hours.
- Drink a glass of water every 2 hours to prevent dehydration.
- Do not assume that special meals will be available; substitute items you cannot eat with foods you have in your travel kit.

Notify airline and hotel personnel that you have diabetes.

- Always wear medical alert identification and keep your medical alert card in your wallet.

While traveling:

- Check your blood glucose level frequently.
- Do not engage in activities when blood glucose levels are lower than 65 mg/dL.
- Stretch and walk around every 2 hours to help your circulation.
- Check your feet frequently for blisters and sores. You may be doing more walking than usual.
- Take extra shoes with you, and plan to change shoes often when walking more than normal.
- Protect your skin against exposure to the sun. Drug-induced photosensitivity can occur with some oral hypoglycemic agents.

Always have your travel kit with you; do not check your kit along with the rest of your luggage. Include these items in your travel kit:

- Insulin bottles in boxes with prescription labels
- Twice as much drug and twice as many supplies as you think you will need (pack drugs separately from checked luggage)
- Insulin stored in an insulated carrying case that will maintain temperatures according to the manufacturer's directions
- The letter from your physician (typed on office letterhead) that indicates you have diabetes and lists the drugs you are taking
- A supply of fast-acting sugar (e.g., glucose tablets or gel, hard candy, sugar cubes), as well as longer-acting foods (e.g., cheese and crackers, peanut butter and crackers)
- A self-monitoring diary

diabetes are predictable. Taking an insulin injection and not eating for several hours causes hypoglycemia. Poorly controlled diabetes leads to complications and premature death. Tight control of blood glucose levels prevents complications.

The stress of diabetes is in addition to the demands of normal daily life. The patient must be able to integrate the

demands of diabetes into daily and recreational schedules while keeping blood glucose stable.

Assist in healthy psychological adaptation to diabetes by providing successful educational experiences. Mastery of blood glucose monitoring helps the patient feel that he or she has control over the disease. Knowing the effects of extra activities, extra food, or extra insulin is helpful in learning to adjust the regimen.

Feeling a sense of control over the condition does much to promote a positive attitude about diabetes. Success in injecting insulin provides concrete evidence that he or she can master the disease. Teach by breaking a task into small, achievable units to ensure mastery. For example, a patient may begin learning how to inject insulin by first obtaining an accurate dose.

Devote as much teaching time as possible to insulin injection and blood glucose monitoring. Patients with newly diagnosed diabetes are often fearful of giving themselves injections. After this technique has been mastered, they become less anxious and are able to attend to other tasks.

Recognize that not everyone will have a healthy adaptation to diabetes. Major depression affects many patients with diabetes and severely impacts quality of life and all aspects of functioning, including self-management behaviors. Clinical anxiety disorder is another problem common in patients with diabetes. Refer those who have significant problems coping with the day-to-day demands of diabetes to mental health counseling for appropriate treatment.

Home Care Management

Patients with diabetes self-manage their disease. Each day they decide what to eat, whether to exercise, and whether to take prescribed drugs. Maintaining blood glucose control depends on the accuracy of self-management skills. The main role of the health care professional is to provide support and education and to empower the patient to make informed decisions. Self-management education allows patients to identify their problems and provides techniques to help them make decisions, take appropriate actions, and alter these actions as needed.

Provide information about resources. The patient must know whom to contact in case of emergency. Older adults who live alone need to have daily telephone contact with a friend or neighbor. The patient may also need help shopping and preparing meals. He or she may have limited access to transportation and may not have sufficient supplies of food, particularly in bad weather. Because of the likelihood of visual problems in older patients, they may need assistance in preparing insulin syringes for injection or in monitoring blood glucose. Make referrals to home care or public health agencies as needed. [Chart 67-13](#) identifies areas for assessment during a home or clinic visit.

EVALUATION: OUTCOMES

Evaluate the care of the patient with diabetes based on the identified priority patient problems. Outcome success for diabetes education is the ability of the patient to maintain blood glucose levels within their established target range. General outcome criteria are listed below and in [Table 67-16](#). More specific outcomes are listed with each priority patient problem. The expected outcomes include that the patient should:

- Achieve blood glucose control
- Avoid acute and chronic complications of diabetes

CHART 67-13 FOCUSED ASSESSMENT

The Insulin-Dependent Patient with Diabetes During a Home or Clinic Visit

- Assess overall mental status, wakefulness, ability to converse.
- Take vital signs and weight:
 - Fever could indicate infection.
 - Are blood pressure and weight within target range? If not, why?
- Question patient regarding any change in visual acuity; check current visual acuity.
- Inspect oral mucous membranes, gums, and teeth.
- Question patient about injection areas used; inspect areas being used; assess whether patient is using areas and sites appropriately.
- Inspect skin for intactness, wounds that have not healed, new sores, ulcers, bruises, or burns; assess any previously known wounds for infection, progression of healing.
- Question patient regarding foot care.
- Assess lower extremities and feet for peripheral pulses, lack of or decreased sensation, abnormal sensations, breaks in skin integrity, condition of toes and nails.
- Question patient regarding color and consistency of stools and frequency of bowel movements; assess abdomen for bowel sounds.
- Review patient's home health diary:
 - Is blood glucose within targeted range? If not, why?
 - Is glucose monitoring being recorded often enough?
 - Is the patient's food intake adequate and appropriate? If not, why?
 - Is exercise occurring regularly? If not, why?
- Assess patient's ability to perform self-monitoring of blood glucose.
- Assess patient's procedures for obtaining and storing insulin and syringes, cleaning equipment, disposing of syringes and needles.
- Assess patient's insulin preparation and injection technique.

TABLE 67-16 OUTCOME CRITERIA FOR DIABETES TEACHING

Before being discharged to home, the patient with diabetes or the significant other should be able to:

- Tell why insulin or an oral hypoglycemic agent is being prescribed.
- Name which insulin or oral hypoglycemic agent is being prescribed, and name the dosage and frequency of administration.
- Discuss the relationship between mealtime and the action of insulin or the oral hypoglycemic agent.
- Discuss plans to follow diabetic diet instructions.
- Prepare and administer insulin accurately.
- Test blood for glucose, or state plans for having blood glucose levels monitored.
- Test urine for ketones, and state when this test should be done.
- Verbalize how to store insulin.
- List symptoms that indicate a hypoglycemic reaction.
- Tell what carbohydrate sources are used to treat hypoglycemic reactions.
- Tell what symptoms indicate hyperglycemia.
- Tell what dietary changes are needed during illness.
- Verbalize when to call the physician or the nurse (frequent episodes of hypoglycemia, symptoms of hyperglycemia).
- Verbalize the procedures for proper foot care.

- Have a satisfactory and complete postoperative recovery without complications
- Avoid injury
- Experience relief of pain
- Maintain optimal vision
- Maintain a urine output in the expected range

- Have an optimal level of mental status functioning
- Have decreased episodes of hypoglycemia
- Have decreased episodes of hyperglycemia

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use aseptic technique during any invasive procedure when caring for a patient with diabetes.
- Administer antidiabetic drugs and insulin in a safe manner.
- Use good handwashing techniques before providing any care to a patient who has diabetes.
- Wash your hands before and after testing the patient's blood glucose levels.

Health Promotion and Maintenance

- Encourage all patients to maintain weight within an appropriate range.
- Encourage all patients, including patients with diabetes, to participate regularly in exercise or physical activity appropriate to their health status.
- Teach the patient and family about the manifestations of infection and when to seek medical advice.
- Instruct patients with diabetes to wear a medical alert bracelet.
- Instruct patients to not share blood glucose monitoring equipment.
- Reinforce to all patients with diabetes that tight control over blood glucose levels reduces the risk for the vascular complications of diabetes.
- Remind patients with diabetes to have yearly eye examinations by an ophthalmologist.
- Teach patients with peripheral neuropathy to use a bath thermometer to test water for bathing, to avoid walking barefoot, and to inspect their feet daily.

Psychosocial Integrity

- Explore with the patient what the diagnosis of diabetes means to him or her.
- Allow the patient the opportunity to express concerns about the diagnosis of diabetes or the treatment regimen.
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
- Pace your education sessions to match the learning needs and style of the patient.
- Use return demonstration strategies when teaching the patient about drug regimen, insulin injection, blood glucose monitoring, and foot assessment.

- Refer patients newly diagnosed with diabetes to local resources and support groups.
- Assess patients' visual acuity and peripheral tactile sensation to determine needed adjustments in teaching self-medication and self-monitoring of blood glucose levels.

Physiological Integrity

- Teach the patient about any drugs to be continued after discharge from the hospital.
- Instruct the patient and family on the manifestations of complications and when to seek assistance.
- Instruct all patients with diabetes to avoid becoming dehydrated and to drink at least 3 L of water each day unless another medical condition requires fluid restriction.
- Instruct patients who are taking sulfonylurea drugs about an increased risk for hypoglycemic reactions.
- Teach patients who are taking metformin the clinical manifestations of lactic acidosis (fatigue, dizziness, difficulty breathing, stomach discomfort, irregular heartbeat).
- Warn patients to not take over-the-counter drugs with their oral antidiabetic drugs without consulting their primary care provider.
- When mixing different kinds of insulin together, draw the shorter-acting insulin into the syringe before drawing up the longer-acting insulin.
- Never dilute or mix insulin glargine with any other insulin or solution.
- Teach patients to rotate insulin injection sites within one area rather than to another area to prevent changes in absorption.
- Avoid injecting insulin within a 2-inch radius of the umbilicus.
- Avoid IM insulin injection.
- Teach patients to administer an accurate dose of insulin using a prefilled or disposable insulin pen.
- Teach patients who experience Somogyi phenomenon (early morning hyperglycemia) to ensure an adequate dietary intake at bedtime.
- Instruct patients to always carry a glucose source.
- Teach patients who exercise to test urine for ketone bodies if blood glucose levels are greater than 250 mg/dL before engaging in strenuous exercise.
- Instruct patients in foot care as outlined in [Chart 67-9](#).

CONCEPT OVERVIEW

Urinary Elimination

The need for urinary elimination is really the need for homeostasis—the ability of the body to maintain its internal environment at a “steady state” and within very narrow ranges of normal, regardless of external changes. The body works best when blood and other extracellular fluids have a serum sodium concentration of 135 to 145 mEq/L (mmol/L) and a serum potassium level of 3.5 to 5.0 mEq/L (mmol/L). Serious health problems and death occur when these electrolytes are much higher or lower than these normal ranges. Keeping the amount of total body water, especially blood volume, within the normal range is also important to proper function and health. When blood volume is too high, hypertension develops and damages vital organs. When blood volume is too low, hypotension can be so severe that vital organs are not perfused with oxygen and become hypoxic. In addition, protein waste products containing nitrogen, such as urea, act as a poison and must be prevented from getting too high. Humans ingest many foods and liquids that contain water, electrolytes, and substances that will be converted to waste products. Without control mechanisms to balance the intake of these substances with their elimination, we would rapidly accumulate too much of everything and die.

As part of the renal/urinary system, the kidneys are responsible for maintaining this balance of what is taken into the

body, what is allowed to remain in the body, and what is eliminated from the body. Although some products are eliminated in the stool, there is no discrimination or adjustment in bowel elimination. Urinary elimination, however, allows a person to eat and drink almost anything (except poisons and infectious organisms) in almost any amount without upsetting the homeostatic balance for body water, electrolytes, waste products, and blood pressure. For example, on one day a person may drink 2 L of fluids and eat food that contains 2 g of sodium and 5 g of potassium. The next day this same person may drink 3 L of fluids and eat food that contains 12 g of sodium and 10 g of potassium. Yet because the kidneys selectively adjust to change the amount of each substance that gets eliminated, the blood pressure, serum sodium, and serum potassium levels remain the same and within the normal ranges on both days. A “steady-state” or homeostatic balance of these substances is maintained because the kidneys adjust the output to match the intake (Fig. 1).

FIG. 1

When kidney function is impaired to any degree as a result of renal/urinary problems, the human need for urinary elimination is not met and the steady-state homeostasis of water, electrolyte, and waste products is disrupted (Fig. 2).

Without intervention, this lack of steady state leads to excesses of body water, electrolytes, and nitrogenous waste products that interfere with normal organ function and can cause death.

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges

Audio Glossary

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Use Standard Precautions when handling urine specimens or examining the patient's genitalia.
2. Determine whether the patient has risks for an allergic reaction to contrast dyes or a drug–contrast dye adverse interaction before testing procedures.
3. Verify that informed consent has been obtained and that the patient has a clear understanding of the potential risks before he or she undergoes invasive procedures to assess the kidneys and urinary function.
4. Examine individual patient factors contributing to safety risks.

Health Promotion and Maintenance

5. Teach all people about the importance of maintaining an adequate oral fluid intake.

6. Teach about or assist with cleansing of the perineum or urinary meatus after using the toilet and during daily bathing or showering.

Psychosocial Integrity

7. Use language comfortable for the patient during assessment of the kidneys and urinary system.
8. Encourage the patient to express feelings or concerns about a change in kidney or bladder function.
9. Respect the patient's dignity when performing kidney and urinary assessment.
10. Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.

Physiological Integrity

11. Briefly review the relevant anatomy and physiology of the kidney and urinary system.

LEARNING OUTCOMES—cont'd

12. Describe age-related changes in the kidney and urinary system.
13. Describe the correct techniques to use in physically assessing the kidney and urinary system.
14. Use laboratory data to distinguish between dehydration and kidney impairment.
15. Describe how to obtain a sterile urine specimen from a urinary catheter.
16. Coordinate nursing care for the patient during the first 24 hours after IV urography.
17. Coordinate nursing care for the patient during the first 24 hours after a kidney biopsy.

The kidneys help maintain health in many ways. Most important for urinary elimination, they maintain body fluid volume and composition and filter waste products for elimination. The kidneys also help regulate blood pressure and acid-base balance, produce erythropoietin for red blood cell (RBC) synthesis, and convert vitamin D to an active form.

The renal system includes the kidneys and the entire urinary tract. The ureters, bladder, and urethra are the drainage route for the excretion of urine. Structural or functional problems in the kidney or urinary tract may alter fluid, electrolyte, and acid-base balance.

Assessment of the patient at risk for or with actual problems of the kidney or urinary system begins with a history and physical assessment. Understanding the anatomy, physiology, and diagnostic tests of the renal system helps you in problem-solving about kidney function in the clinical setting. It also assists you in teaching the patient about the purpose of procedures and in physically and emotionally preparing the patient for assessment.

ANATOMY AND PHYSIOLOGY REVIEW

Kidneys

Structure

Gross Anatomy. Normally, two kidneys are located behind the peritoneum, not really in the abdominal cavity, one on either side of the spine (Fig. 68-1). The adult kidney is 4 to 5

inches (10 to 13 cm) long, 2 to 3 inches (5 to 7 cm) wide, and about 1 inch (2.5 to 3 cm) thick. It weighs about 8 ounces (250 g). The left kidney is slightly longer and narrower than the right kidney. Larger-than-usual kidneys may indicate obstruction or polycystic disease. Smaller-than-usual kidneys may indicate chronic kidney disease (CKD).

Variation in kidney shape and number is not uncommon and does not necessarily mean there is also a problem in kidney function. Some people have more than two kidneys or may have only one, large, horseshoe-shaped kidney. As long as tests of kidney function are normal, these variations are of no significance.

Several layers of tissue surround the kidney, providing protection and support. On the outer surface of the kidney is a layer of fibrous tissue called the **capsule** (Fig. 68-2). This capsule covers most of the kidney except the **hilum**, which is the area where the renal artery and nerve plexus enter and the renal vein and ureter exit. The renal capsule is surrounded by layers of fat and connective tissue.

Lying beneath the renal capsule are the two layers of functional kidney tissue—the cortex and the medulla. The **renal cortex** is the outer tissue layer and is covered by the renal capsule. The **medulla** is the medullary tissue lying below the cortex in the shape of many fans. Each “fan” is called a **pyramid**, and there are 12 to 18 pyramids per kidney. The **renal columns** are cortical tissue that dips down into the interior of the kidney and separates the pyramids.

The tip, or end, of each pyramid is called a **papilla**. The papillae drain urine into the collecting system. A cuplike structure called a **calyx** collects the urine at the end of each papilla. The calices join together to form the **renal pelvis**, which narrows to become the ureter.

The kidneys have a rich blood supply and receive 20% to 25% of the total cardiac output. Blood flow to the kidneys varies from about 600 to 1300 mL/min. The blood supply to each kidney comes from the renal artery, which branches from the abdominal aorta. The renal artery divides into progressively smaller arteries, supplying all blood to areas of the kidney tissue (**parenchyma**) and the nephrons. The smallest arteries (afferent arterioles) feed the nephrons directly to form urine.

Venous blood from the kidneys starts with the capillaries surrounding each nephron. These capillaries drain into progressively larger veins, with blood eventually returned to the inferior vena cava through the renal vein.

Microscopic Anatomy. The **nephron** is the “working” or functional unit of the kidney, and it is here that urine is actually formed from blood. There are about 1 million nephrons per kidney, and each nephron separately makes urine from blood.

FIG. 68-1 Anatomic location of the kidneys and structures of the urinary system.

FIG. 68-2 Bisection of the kidney showing the major structures of the kidney.

There are two types of nephrons: cortical nephrons and juxtamedullary nephrons. The cortical nephrons are short, with all parts located in the renal cortex. The juxtamedullary nephrons (about 20% of all nephrons) are longer, and their tubes and blood vessels dip deeply into the medulla. The purpose of the juxtamedullary nephrons is to concentrate urine during times of low fluid intake. The ability to concentrate urine allows for continued excretion of body wastes with less fluid loss.

Blood supply to the nephron is delivered through the **afferent arteriole**—the smallest, most distal portion of the renal arterial system. From the afferent arteriole, blood flows into the **glomerulus**, which is a series of specialized capillary loops. It is through these capillaries that water and small particles are filtered from the blood to make urine. The remaining blood leaves the glomerulus through the **efferent arteriole**, which is the first vessel in the venous system of the kidney. From the efferent arteriole, blood exits into one of two additional capillary systems:

- The *peritubular capillaries* around the tubular part of the cortical nephrons
- The *vasa recta* around the tubular part of juxtamedullary nephrons

Each nephron is a tubelike structure with distinct parts (Fig. 68-3). The tube begins with Bowman's capsule, a saclike structure that surrounds the glomerulus. The tubular tissue of Bowman's capsule narrows into the *proximal convoluted tubule (PCT)*. The PCT twists and turns, finally straightening into the descending limb of the *loop of Henle*. The descending loop of Henle dips in the direction of the medulla but forms a hairpin loop and comes back up into the cortex as the ascending loop of Henle.

There are two segments of the ascending limb of the loop of Henle: the thin segment and the thick segment. The *distal convoluted tubule (DCT)* forms from the thick segment of the ascending limb of the loop of Henle. The DCT ends in one

FIG. 68-3 Anatomy of the nephron, the functional unit of the kidney. Note that the particular nephron labeled here is a juxtamedullary nephron.

of many collecting ducts located in the kidney tissue. The urine in the collecting ducts passes through the papillae and empties into the renal pelvis.

Special cells in the afferent arteriole, efferent arteriole, and DCT are known as the **juxtaglomerular complex** (Fig. 68-4).

These specialized cells produce and store renin. **Renin** is a hormone that helps regulate blood flow, glomerular filtration rate (GFR), and blood pressure. Renin is secreted when sensing cells in the DCT (called the *macula densa*) sense changes in blood volume and pressure. The macula densa lies next to the renin-producing cells. Renin is produced when the macula densa cells sense that blood volume, blood

FIG. 68-4 The juxtaglomerular complex showing juxtaglomerular cells and the macula densa.

pressure, or blood sodium level is low. Renin then converts renin substrate (angiotensinogen) into angiotensin I. This leads to a series of reactions that cause secretion of the hormone *aldosterone* (Fig. 68-5). Aldosterone increases kidney reabsorption of sodium and water, restoring blood pressure, blood volume, and blood sodium levels. It also promotes excretion of potassium. (See Chapter 13 for more discussion of the renin-angiotensin-aldosterone pathway.)

The glomerular capillary wall has three layers (Fig. 68-6): the endothelium, the basement membrane, and the epithelium. The endothelial and epithelial cells lining these capillaries are separated by pores that filter water and small particles from the blood into Bowman's capsule. This fluid is called the "filtrate" or "early urine."

Function

The kidneys have both regulatory and hormonal functions. The regulatory functions control fluid, electrolyte, and acid-base balance. The hormonal functions control red blood cell (RBC) formation, blood pressure, and vitamin D activation.

Regulatory Functions. The kidney processes that maintain fluid, electrolyte, and acid-base balance are glomerular filtration, tubular reabsorption, and tubular secretion. These processes use filtration, diffusion, active transport, and osmosis. (See Chapter 13 for a review of these actions.) Table 68-1 lists the functions of nephron tubules and blood vessels.

Glomerular filtration is the first process in urine formation. As blood passes from the afferent arteriole into the glomerulus, water, electrolytes, and other small particles (e.g., creatinine, urea nitrogen, glucose) are filtered across the glomerular

FIG. 68-5 The role of aldosterone, renin substrate (angiotensinogen), angiotensin I, and angiotensin II in the renal regulation of water and sodium.

membrane into the Bowman's capsule to form *glomerular filtrate*. As the filtrate enters the proximal convoluted tubule (PCT), it is called *tubular filtrate*.

Large particles, such as blood cells, albumin, and other proteins, are too large to filter through the glomerular

capillary walls. *Therefore these substances are not normally present in the filtrate or in the final urine.*

About 180 L of glomerular filtrate is formed from the blood each day. The rate of filtration is expressed in milliliters per minute. Normal glomerular filtration rate (GFR) averages 125 mL/min. If the entire amount of filtrate were excreted as urine, death would occur quickly from dehydration. Actually, only about 1 to 3 L is excreted each day as urine. The rest is reabsorbed back into the circulatory system.

The GFR is controlled by blood pressure and blood flow. The ability of the kidneys to self-regulate renal blood pressure and renal blood flow keeps GFR constant. GFR is controlled by selectively constricting and dilating the afferent and efferent arterioles. When the afferent arteriole is constricted or the efferent arteriole is dilated, pressure in the glomerular capillaries falls and filtration decreases. When the afferent arteriole is dilated or the efferent arteriole is constricted, pressure in the glomerular capillaries rises and filtration increases. Through this process, the kidney can maintain a constant GFR, even when systemic blood pressure changes. When systolic pressure drops below about 70 mm Hg, these processes cannot compensate and GFR stops.

Tubular reabsorption is the second process involved in urine formation. This reabsorption of most of the filtrate keeps normal urine output at 1 to 3 L/day and prevents

FIG. 68-6 Glomerular capillary wall.

TABLE 68-1 VASCULAR AND TUBULAR COMPONENTS OF THE NEPHRON

STRUCTURE	ANATOMIC FEATURES	PHYSIOLOGIC ASPECTS	STRUCTURE	ANATOMIC FEATURES	PHYSIOLOGIC ASPECTS
Vascular Components					
Afferent arteriole	Delivers arterial blood from the branches of the renal artery into the glomerulus	Autoregulation of renal blood flow via vasoconstriction or vasodilation Renin-producing granular cells	Proximal convoluted tubule (PCT)	Evolves from and is continuous with Bowman's capsule Specialized cellular lining facilitates tubular reabsorption	Site for reabsorption of sodium, chloride, water, glucose, amino acids, potassium, calcium, bicarbonate, phosphate, and urea
Glomerulus	Capillary loops with thin, semipermeable membrane	Site of glomerular filtration Glomerular filtration occurs when hydrostatic pressure (blood pressure) is greater than opposing forces (tubular filtrate and oncotic pressure)	Loop of Henle	Continues from PCT Juxtamedullary nephrons dip deep into the medulla Permeable to water, urea, and sodium chloride	Regulation of water balance
Efferent arteriole	Delivers arterial blood from the glomerulus into the peritubular capillaries or the vasa recta	Autoregulation of renal blood flow via vasoconstriction or vasodilation Renin-producing granular cells	Descending limb (DL)	Continues from the loop of Henle Permeable to water, urea, and sodium chloride	Regulation of water balance
Peritubular capillaries (PTCs) and vasa recta (VR)	PTCs: surround tubular components of cortical nephrons VR: surround tubular components of juxtamedullary nephrons	Tubular reabsorption and tubular secretion allow movement of water and solutes to or from the tubules, interstitium, and blood	Ascending limb (AL)	Emerges from DL as it turns and is redirected up toward the renal cortex	Potassium and magnesium reabsorption in the thick segment Thin segment is impermeable to water
Tubular Components			Distal convoluted tubule (DCT)	Evolves from AL and twists so the macula densa cells lie adjacent to the juxtaglomerular cells of afferent arteriole	Site of additional water and electrolyte reabsorption, including bicarbonate Potassium and hydrogen secretion
Bowman's capsule (BC)	Thin membranous sac surrounding $\frac{2}{3}$ of the glomerulus	Collects glomerular filtrate (GF) and funnels it into the tubule	Collecting ducts	Collect formed urine from several tubules and deliver it into the renal pelvis	Receptor sites for antidiuretic hormone regulation of water balance

FIG. 68-7 Sodium and water reabsorption by the tubules of a cortical nephron. ADH, Antidiuretic hormone; Na^+ , sodium.

dehydration. As the filtrate passes through the tubular parts of the nephron, most of the water and electrolytes is reabsorbed. Reabsorption returns particles (**solute**s) and water to the blood. Reabsorption occurs *from the filtrate* across the tubular lumen of the nephron and into the blood of the peritubular capillaries. The PCT reabsorbs about 65% of the total glomerular filtrate.

The tubules return about 99% of all filtered water back into the body (Fig. 68-7). Most water reabsorption occurs as the filtrate passes through the PCT. Water reabsorption continues as the filtrate flows down the descending loop of Henle. The thin and thick segments of the ascending loop of Henle are *not* permeable to water, and water reabsorption does not occur here.

The distal convoluted tubule (DCT) can be permeable to water, and some water reabsorption can occur as the filtrate continues to flow through the tubule. The membrane of the DCT may be made more permeable to water through the action of antidiuretic hormone (ADH) and aldosterone. ADH increases tubular permeability to water, allowing water to leave the tube and be reabsorbed into the capillaries. ADH is also known as *vasopressin* and affects arteriole constriction. Arteriole constriction alters blood pressure, which, in turn,

affects the amount of fluid and solutes that exit glomeruli capillaries. Aldosterone promotes the reabsorption of sodium in the DCT. Water reabsorption occurs as a result of the movement of sodium (where sodium goes, water follows).

The ability of the kidneys to vary the volume or concentration of urine helps regulate water balance regardless of fluid intake. In this way, the healthy kidney can prevent dehydration when fluid intake is low and can prevent circulatory overload when fluid intake is excessive.

In addition to water, some particles in the tubular filtrate also are *returned to the blood*. This process is called *tubular reabsorption* and is selective. About 50% of all urea in the early urine is reabsorbed. On the other hand, no creatinine is reabsorbed.

Most sodium, chloride, and water reabsorption occurs in the PCT. The collecting ducts are the other site of sodium, chloride, and water reabsorption. Here reabsorption is caused by aldosterone. Potassium is also mostly reabsorbed in the PCT, with an additional 20% to 40% reabsorbed in the thick segment of the loop of Henle.

Bicarbonate, calcium, and phosphate are mostly reabsorbed in the PCT. Bicarbonate reabsorption helps balance acids and maintain a normal blood pH. Blood levels of calcitonin and parathyroid hormone (PTH) (see [Chapters 13 and 66](#)) control calcium balance.

The kidney reabsorbs some of the glucose filtered from the blood. However, there is a limit to how much glucose the kidney can reabsorb. This limit is called the **renal threshold** for glucose reabsorption or the **transport maximum** for glucose reabsorption. The usual renal threshold for glucose is about 220 mg/dL. This means that at a blood glucose level of 220 mg/dL or less, all glucose is reabsorbed and returned to the blood, with no glucose present in final urine. When blood glucose levels are greater than 220 mg/dL, some glucose stays in the filtrate and is present in the urine. Normally, almost all glucose and any amino acids or proteins are reabsorbed and are not present in the urine.

! NURSING SAFETY PRIORITY

Action Alert

Report the presence of glucose or proteins in the urine of a patient undergoing a screening examination to the health care provider because this is an abnormal finding and requires further assessment.

Tubular secretion is the third process involved in urine formation. Like glomerular filtration, it allows substances to move from the blood into the early urine. During tubular secretion, substances move from the peritubular capillaries in reverse, across capillary membranes, and into the cells that line the tubules. From the cells, these substances are moved into the urine and are excreted from the body. Potassium (K^+) and hydrogen (H^+) ions are some of the substances moved in this way to maintain homeostasis of electrolytes and pH.

Hormonal Functions. The kidneys produce renin, prostaglandins, bradykinin, erythropoietin, and activated vitamin D (Table 68-2). Other kidney products, such as the kinins, change kidney blood flow and capillary permeability. The kidneys also help break down and excrete insulin.

Renin, as discussed on p. 1468 in the Microscopic Anatomy section, assists in blood pressure control. It is formed and

TABLE 68-2 RENAL HORMONE PRODUCTION AND HORMONES INFLUENCING RENAL FUNCTION

	SITE	ACTION
Renal Hormone Production		
Renin	Renin-producing granular cells	Raises blood pressure as result of angiotensin (local vasoconstriction) and aldosterone (volume expansion) secretion
Prostaglandins	Kidney tissues	Regulate intrarenal blood flow by vasodilation or vasoconstriction
Bradykinins	Juxtaglomerular cells of the arterioles	Increase blood flow (vasodilation) and vascular permeability
Erythropoietin	Kidney parenchyma	Stimulates bone marrow to make red blood cells
Activated vitamin D	Kidney parenchyma	Promotes absorption of calcium in the GI tract
Hormones Influencing Kidney Function		
Antidiuretic hormone (ADH, vasopressin)	Released from posterior pituitary	Makes DCT and CD permeable to water to maximize reabsorption and produce a concentrated urine
Aldosterone	Released from adrenal cortex	Promotes sodium reabsorption and potassium secretion in DCT and CD; water and chloride follow sodium movement
Natriuretic hormones	Cardiac atria, cardiac ventricle, brain	Cause tubular secretion of sodium

CD, Collecting duct; DCT, distal convoluted tubule.

released when there is a decrease in blood flow, blood volume, or blood pressure through the renal arterioles or when too little sodium is present in kidney blood. These conditions are detected through the receptors of the juxtaglomerular complex.

Renin release causes the production of *angiotensin II* through a series of steps (see Fig. 68-5). Angiotensin II increases systemic blood pressure through powerful blood vessel constricting effects and triggers the release of aldosterone from the adrenal glands. Aldosterone increases the reabsorption of sodium in the distal tubule of the nephron. Therefore more water is reabsorbed and blood pressure is increased because of increases in blood volume. When blood flow to the kidney is reduced, this system also regulates pressures in the nephron to prevent fluid loss and maintain circulating blood volume (see also Chapter 13).

Prostaglandins are produced in the kidney and many other tissues. Those produced specifically in the kidney are prostaglandin E_2 (PGE_2) and prostacyclin (PGI_2). These substances help regulate glomerular filtration, kidney vascular resistance, and renin production. PGE_2 acts on the distal tubule and collecting duct to increase sodium and water excretion.

Bradykinin is released by the kidney in response to the presence of angiotensin II, prostaglandins, and ADH. It is a small hormone that dilates the afferent arteriole and increases capillary membrane permeability to some solutes. These actions maintain kidney blood flow and reabsorption even when other conditions cause systemic blood vessel constriction.

Erythropoietin is produced and released in response to decreased oxygen tension in the kidney's blood supply. It triggers red blood cell (RBC) production in the bone marrow. When kidney function is poor, erythropoietin production decreases and the person becomes anemic.

Vitamin D activation occurs through a series of steps. Some of these steps take place in the skin when it is exposed to sunlight, and then more processing occurs in the liver. From there, vitamin D is converted to its active form (1,25-dihydroxy-cholecalciferol) in the kidney. It is needed to absorb calcium in the intestinal tract and to regulate calcium balance.

Ureters

Each kidney has a single ureter—a hollow tube that connects the renal pelvis with the urinary bladder. The ureter is about $\frac{1}{2}$ inch (1.25 cm) in diameter and about 12 to 18 inches (30 to 45 cm) in length. The diameter of the ureter narrows in three areas:

- In the upper third of the ureter, at the point at which the renal pelvis becomes the ureter, is a narrowing known as the **ureteropelvic junction (UPJ)**.
- The ureter also narrows as it bends toward the abdominal wall (aortiliac bend).
- Each ureter narrows at the point it enters the bladder; this point is called the **ureterovesical junction (UVJ)**.

The ureter tunnels through bladder tissue for a short distance and then opens into the bladder at the trigone (Fig. 68-8).

The ureter has three layers: an inner lining of mucous membrane (*urothelium*), a middle layer of smooth muscle fibers, and an outer layer of fibrous tissue. The outer layer contains the blood supply. The middle layer of muscle fibers is controlled by several nerve pathways from the lower spinal cord.

Contractions of the smooth muscle in the ureter move urine from the renal pelvis of the kidney to the bladder. Stretch receptors in the renal pelvis regulate this movement. For example, a large volume of urine in the renal pelvis triggers the stretch receptors, which respond by increasing ureteral contractions and ureter peristalsis.

Urinary Bladder

Structure

The urinary bladder is a muscular sac (see Fig. 68-8). The upper surface lies next to the peritoneal cavity. In men, the bladder is in front of the rectum. In women, it is in front of the vagina. The bladder lies directly behind the pubic bone.

The bladder is composed of the *body* (the rounded sac portion) and the *bladder neck* (posterior urethra), which connects to the bladder body. The bladder has three linings—an inner lining of epithelial cells (*urothelium*), middle layers of smooth muscle (*detrusor muscle*), and an outer lining. The *trigone* is an area on the posterior wall between the points of ureteral entry (ureterovesical junctions [UVJs]) and the urethra.

FIG. 68-8 Gross anatomy of the urinary bladder.

The **internal urethral sphincter** is the smooth detrusor muscle of the bladder neck and elastic tissue. The **external urethral sphincter** is skeletal muscle that surrounds the urethra. In men, the external sphincter surrounds the urethra at the base of the prostate gland. In women, the external sphincter is at the base of the bladder. The pudendal nerve from the spinal cord controls the external sphincter.

Function

The bladder is a temporary urine storage site. The bladder also provides continence and enables voiding. The secretions of the bladder lining resist bacteria.

Continence is the ability to voluntarily control bladder emptying. Bladder continence occurs during bladder filling through the combination of detrusor muscle relaxation, internal sphincter muscle tone, and external sphincter contraction. As the bladder fills with urine, stretch sensations are transmitted to spinal sacral nerves S2 and S3.

Maintaining continence occurs by the interaction of the nerves that control the muscles of the bladder, bladder neck, urethra, and pelvic floor, as well as by factors that close the urethra. During bladder filling, the sympathetic nervous system fibers prevent detrusor muscle contraction. These control centers are located in the cerebral cortex, the brainstem, and the sacral part of the spinal cord. For urethral closure to be adequate for continence, the mucosal surfaces must be in contact and must be adhesive. Contact depends on the presence and proper function of the involved nerves and muscles. Adhesion depends on the adequate secretion of mucus-like substances.

Micturition (voiding) is a reflex of autonomic control that triggers contraction of the detrusor muscle at the same time as relaxation of the external sphincter and the muscles of the pelvic floor. With detrusor muscle contraction, the UVJ of

the ureter closes and the normally round bladder assumes the shape of a funnel. Voiding is a voluntary act as the result of a learned response and is controlled by the cerebral cortex and the brainstem. Contraction of the external sphincter inhibits the micturition reflex and prevents voiding.

Urethra

The urethra is a narrow tube lined with mucous membranes and epithelial cells. Its purpose is to eliminate urine from the bladder. The **urethral meatus**, or opening, is the endpoint of the urethra. In men, the urethra is about 6 to 8 inches (15 to 20 cm) long, with the meatus located at the tip of the penis. The male urethra has three sections:

- The prostatic urethra, which extends from the bladder to the prostate gland
- The membranous urethra, which extends to the wall of the pelvic floor
- The cavernous urethra, which is external and extends through the length of the penis

In women, the urethra is about 1 to 1.5 inches (2.5 to 3.75 cm) long and exits the bladder through the pelvic floor. The meatus lies slightly below the clitoris and directly in front of the vagina and rectum.

Kidney and Urinary System Changes Associated with Aging

Kidney Changes

Structural and functional changes occur in the kidney as a result of the aging process. These changes often affect health. The kidney loses cortical tissue and gets smaller by 80 years of age. This cortical loss is caused by reduced blood flow to the kidney. The medulla is not affected by aging, and the juxtamedullary nephron functions are preserved. However, the glomerular and tubular linings thicken. Both the number of glomeruli and their surface areas decrease with aging. Tubule length also decreases. These changes reduce the ability of the older adult to filter blood and excrete waste products.

Kidney size and function decrease with aging (Chart 68-1). Blood flow to the kidney declines by about 10% per decade as blood vessels thicken. This means that blood flow to the kidney is not as adaptive in older adults compared with younger adults, leaving nephrons more vulnerable to damage during episodes of either hypotension or hypertension.

Glomerular filtration rate (GFR) decreases with age, especially after 45 years of age. By age 65, the GFR is about 65 mL/min (half the rate of a young adult). This decline is more rapid in patients with diabetes, hypertension, or heart failure. As a result, the older patient is at greater risk for fluid overload. The combination of reduced kidney mass, reduced blood flow, and decreased GFR contributes to reduced drug clearance and a greater risk for drug reactions and kidney damage from drugs and contrast dyes in older adults.

Tubular changes with aging decrease the ability to concentrate urine, resulting in **urgency** (a sense of a nearly uncontrollable need to urinate) and **nocturnal polyuria** (increased urination at night). The regulation of sodium, acids, and bicarbonate remains effective but is less efficient. Along with an age-related impairment in the thirst mechanism, these changes increase the risk for dehydration and **hyponatremia** (increased blood sodium levels) in the older adult. Hormonal changes include a decrease in renin secretion, aldosterone levels, and activation of vitamin D.

CHART 68-1 NURSING FOCUS ON THE OLDER ADULT

Changes in the Renal/Urinary System Related to Aging

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
Decreased glomerular filtration rate (GFR)	Monitor hydration status. Ensure adequate fluid intake. Administer potentially nephrotoxic agents or drugs carefully.	With aging, the ability of the kidneys to regulate water balance is decreased. The kidneys are less able to conserve water when necessary. Dehydration results in decreased renal blood flow and increases the nephrotoxic potential of many agents. Acute or chronic kidney failure may result.
Nocturia	Ensure adequate nighttime lighting and a hazard-free environment. Ensure the availability of a toilet, bedpan, or urinal. Discourage excessive fluid intake for 2-4 hr before the patient retires for the evening. Evaluate drugs and timing.	Nocturia may occur from decreased renal concentrating ability associated with aging. The desire to maintain continence prompts people to seek the bathroom. Falls and injuries are common among older patients seeking bathroom facilities. Excessive fluid intake at night may increase nocturia. Some drugs increase urine output.
Decreased bladder capacity	Encourage the patient to use the toilet, bedpan, or urinal at least every 2 hr. Respond as soon as possible to the patient's indication of the need to void.	By emptying the bladder on a regular basis, urinary incontinence from overflow may be avoided. A quick response may alleviate episodes of urinary stress incontinence.
Weakened urinary sphincter muscles and shortened urethra in women	Provide thorough perineal care after each voiding.	The shortened urethra increases the potential for bladder infections. Good perineal hygiene may prevent skin irritations and urinary tract infection (UTI).
Tendency to retain urine	Observe the patient for urinary retention (e.g., bladder distention) or urinary tract infection (e.g., dysuria, foul odor, confusion). Provide privacy, assistance, and voiding stimulants such as warm water over the perineum as needed. Evaluate drugs for possible contribution to retention.	Urinary stasis may result in a UTI. UTIs may become bloodstream infections, resulting in urosepsis or septic shock. Nursing interventions can help initiate voiding. Anticholinergic drugs promote urinary retention.

Urinary Changes

Changes in the detrusor muscle elasticity lead to decreased bladder capacity and reduced ability to retain urine. The urge to void may cause immediate bladder emptying because the urinary sphincters lose tone and often become weaker with age. In women, weakened muscles shorten the urethra and promote incontinence. In men, an enlarged prostate gland makes starting the urine stream difficult and may cause urinary retention.

**CULTURAL AWARENESS**

African Americans have more rapid age-related decreases in GFR than do white people (Brenner, 2008). Kidney excretion of sodium is less effective in hypertensive African Americans who have high sodium intake, and the kidneys have about 20% less blood flow as a result of anatomic changes in small renal vessels and intrarenal responses to renin. Thus African-American patients are at greater risk for kidney failure than are white patients. Yearly health examinations should include urinalysis and checking for the presence of microalbuminuria.

ASSESSMENT METHODS**Patient History**

One way to assess kidney and urologic function is to use Gordon's Functional Health Patterns (Gordon, 2011). The patterns most related to the renal system are Nutritional/Metabolic and Elimination (Chart 68-2).

Demographic information, such as age, gender, race, and ethnicity, is important to consider as nonmodifiable risk factors in the patient with any kidney or urinary problem. A sudden onset of hypertension in patients older than 50 years suggests possible kidney disease. Clinical changes with adult polycystic kidney disease typically occur in patients in their 40s or 50s. In men older than 50 years, altered urinary patterns accompany prostate disease.

Anatomic gender differences make some disorders worse or more common. For example, men rarely have urinary tract infections unless there are abnormalities, such as ureteral reflux or prostatic enlargement. Women have a shorter urethra and more commonly develop **cystitis** (bladder infection) because bacteria pass more readily into the bladder.

Ask the patient about any previous kidney or urologic problems, including tumors, infections, stones, or urologic surgery. A history of any chronic health problems, especially diabetes mellitus or hypertension, increases the risk for development of kidney disease because these disorders damage kidney blood vessels.

Ask the patient about chemical exposures at the workplace or with hobbies. Exposure to hydrocarbons (e.g., gasoline, oil), heavy metals (especially mercury and lead), and some gases (e.g., chlorine, toluene) can impair kidney function. Use this opportunity to teach patients who come into contact with chemicals at work or during leisure time activities to avoid direct skin or mucous membrane contact with these chemicals. Use of heroin, cocaine, methamphetamine, ecstasy,

CHART 68-2 RENAL/URINARY ASSESSMENT

*Using Gordon's Functional Health Patterns***Nutritional/Metabolic Pattern**

- What is your typical daily food intake? Describe a day's meals, snacks, and vitamins.
- How much salt do you typically add to your food? Do you use salt substitutes?
- How is your appetite?
- Have you experienced any nausea or vomiting?
- What is your typical daily fluid intake?
- What types of fluids do you drink (water, juices, soft drinks, coffee, tea)?
- How much fluid do you drink each day?
- Have you had any recent change in your weight? Weight gain? Weight loss? How much?
- Have you noticed a change in the tightness of your rings or shoes? Tighter? Looser?
- Have you noticed any skin changes lately? More dry? Less dry? Itchy?

Elimination Pattern

- What is your usual bowel elimination pattern? Frequency? Character? Discomfort? Laxatives?
- What is your usual urinary elimination pattern? Frequency? Amount? Color? Odor? Control?
- Have you noticed a change in the amount of urine?
- Do you have any problem with excessive perspiration?
- Do you have any other type of drainage?

Based on Gordon, M. (2011). *Manual of nursing diagnosis* (12th ed.). New York: Jones & Bartlett.

and volatile solvents (inhalants) has also been associated with kidney damage.

Specifically ask the patient whether he or she has ever been told about the presence of protein or albumin in the urine. The question "Have you ever been told that your blood pressure is high?" may prompt a response different from the one to the question "Do you have high blood pressure?" Ask women about health problems during pregnancy (e.g., proteinuria, high blood pressure, gestational diabetes, urinary tract infections). Obtain information about:

- Chemical or environmental toxin exposure in occupational or other settings
- Recent travel to geographic regions that pose infectious disease risks
- Recent physical injuries
- Trauma
- Sexual contacts
- A history of altered patterns of urinary elimination

Socioeconomic status may influence health care practices. Prevention, early detection, and treatment of kidney or urinary problems may be limited by lack of insurance or access to health care, lack of transportation, and reduced income. Low income may also result in difficulty following medical advice, having prescriptions filled, and keeping follow-up appointments.

Educational level may affect health-seeking practices and the patient's understanding of a disease or its symptoms. Recurring urinary tract infections often result from inadequate or incomplete treatment, including lack of follow-up to ensure the infection is cleared. The lack of money to pay

TABLE 68-3 COMMONLY USED RENAL AND URINARY TERMS

anuria	Total urine output of less than 100 mL in 24 hours
azotemia	Increased blood urea nitrogen and serum creatinine levels suggestive of kidney impairment but without outward symptoms of kidney failure
dysuria	Discomfort or pain associated with micturition
frequency	Feeling the need to void often, usually voiding small amounts of urine each time; may void every hour or even more frequently
hesitancy	Difficulty in initiating the flow of urine, even when the bladder has sufficient urine to initiate a void and the sensation of the need to void is present
micturition	The act of voiding
nocturia	Awakening prematurely from sleep because of the need to empty the bladder
oliguria	Decreased urine output; total urine output between 100 and 400 mL in 24 hours
polyuria	Increased urine output; total urine output usually greater than 2000 mL in 24 hours
uremia	Full-blown manifestations of kidney failure; sometimes referred to as the <i>uremic syndrome</i> , especially if the cause of the renal failure is unknown
urgency	A sudden onset of the feeling of the need to void immediately; may result in incontinence if the patient is unable to get to toileting facilities quickly

for antibiotics or nutritious foods may inhibit or delay recovery.

The patient's health beliefs affect the approach to health and illness. Cultural background or religious affiliation may influence the belief system.

The language used by patients may be different from that used by the health care professional. Anatomic or medical terms may have no meaning for the patient (Table 68-3). When obtaining a history, listen to and explore the terms used by the patient. By using the patient's own terms, you may help him or her provide a more complete description of the problem. This technique may increase the amount of information obtained and decrease the patient's discomfort when discussing bodily functions.

Nutrition History

Ask the patient with known or suspected kidney or urologic disorders about his or her usual diet and any recent changes in the diet. Note any excessive intake or omission of certain food categories. Ask about food and fluid intake. Assess how much and what types of fluids the patient drinks daily, especially fluids with a high calorie or caffeine content. Use this opportunity to teach the patient the importance of drinking about 3 L of fluid daily (if another medical problem does not require fluid restriction) to prevent dehydration and cystitis. If the patient has followed a diet for weight reduction, the details of the diet plan are important and collaboration with a dietitian may be needed. A high-protein intake can result in temporary kidney problems. For example, a patient at risk for **calculi** (stone) formation who ingests large amounts of protein or has a poor fluid intake may form new stones.

Ask about any change in appetite or in the ability to discriminate tastes. These symptoms can occur with the buildup of nitrogenous waste products from kidney failure. Changes in thirst or fluid intake may also cause changes in urine

output. Endocrine disorders may also cause changes in thirst, fluid intake, and urine output (see [Chapter 64](#) for a discussion of endocrine influences on fluid balance).

Medication History

Identify all of the patient's prescription drugs because many can impair kidney function. Ask about the duration of drug use and whether there have been any recent changes in prescribed drugs. Drugs for diabetes mellitus, hypertension, cardiac disorders, hormonal disorders, cancer, arthritis, and psychiatric disorders are potential causes of kidney dysfunction. Antibiotics, such as gentamicin (Garamycin, Cidomycin ) , may also cause acute kidney injury. Drug-drug interactions and drug-contrast dye interactions also are potential causes of kidney dysfunction.

Explore the past and current use of over-the-counter (OTC) drugs or agents, including dietary supplements, vitamins and minerals, herbal agents, laxatives, analgesics, acetaminophen, and NSAIDs. Many of these agents affect kidney function. For example, dietary supplementation with synthetic creatine, used to increase muscle mass, has been associated with compromised kidney function. High-dose or long-term use of NSAIDs or acetaminophen can seriously reduce kidney function. Some agents are associated with hypertension, hematuria, or proteinuria, which may occur before kidney dysfunction.

Family History and Genetic Risk

The family history of the patient with a suspected kidney or urologic problem is important because some disorders have a familial inheritance pattern. Ask whether his or her siblings, parents, or grandparents have had kidney problems. Past terms used for kidney disease include *Bright's disease*, *nephritis*, and *nephrosis*. Patients may use these terms to describe kidney disease as it was known by their parents or grandparents years ago. Adult polycystic kidney disease can occur in either gender. Exposure to gadolinium-enhanced magnetic resonance imaging (MRI) can result in nephrogenic systemic fibrosis.

Current Health Problems

The effects of kidney failure result in changes in all body systems. Therefore document all of the patient's current health problems. Ask him or her to describe all health concerns, because some kidney disorders cause systemic problems or problems in other body systems. Recent upper respiratory problems, achy muscles or joints, chronic disease, or GI problems may be related to problems of kidney function.

Assess the kidney and urologic system specifically by asking about any changes in the appearance (color, odor, clarity) of the urine, pattern of urination, ability to initiate or control voiding, and other unusual symptoms. For example, urine that is reddish, dark brown or black, greenish, or different from the usual yellowish color usually prompts the patient to seek health care assistance. Urine typically has a mild but distinct odor of ammonia. An increase in the intensity of color, a change in odor quality, or a decrease in urine clarity may suggest infection.

Ask about changes in urination patterns, such as **incontinence** (involuntary bladder emptying), **nocturia** (urination at night), frequency, or an increase or decrease in the amount

of urine. The normal urine output for adults is about 1500 to 2000 mL/day, or within 500 mL of the volume of fluid ingested daily. Ask about how closely the urine output is to the volume of fluid ingested. The patient usually does not know the exact amount of urine produced. A bladder diary may provide useful data. Also ask whether:

- Initiating urine flow is difficult
- A burning sensation or other discomfort occurs with urination
- The force of the urine stream is decreased (in men)
- Persistent dribbling of urine is present

The onset of pain in the flank, in the lower abdomen or pelvic region, or in the perineal area triggers concern and usually prompts the patient to seek assistance. Ask about the onset, intensity, and duration of the pain, its location, and its association with any activity or event.

Pain associated with kidney or ureteral irritation is often severe and spasmodic. Pain that radiates into the perineal area, groin, scrotum, or labia is described as *renal colic*. This pain occurs with distention or spasm of the ureter, such as in an obstruction or the passing of a stone. Renal colic pain may be intermittent or continuous and may occur with pallor, diaphoresis, and hypotension. These general symptoms occur because of the location of the nerve tracts near or in the kidneys and ureters.

Because the kidneys are close to the GI organs and the nerve pathways are similar, GI manifestations may occur with kidney problems. These renointestinal reflexes often complicate the description of the kidney problem.

Uremia is the buildup of nitrogenous waste products in the blood as a result of kidney failure. Manifestations include anorexia, nausea and vomiting, muscle cramps, **pruritus** (itching), fatigue, and lethargy.

Physical Assessment

The physical assessment of the patient with a known or suspected kidney or urologic disorder includes general appearance, a review of body systems, and specific structure and functions of the kidney and urinary system.

Assess the patient's general appearance, and check the skin for the presence of any rashes, bruising, or yellowish discoloration. The skin and tissues may show edema, especially in the **pedal** (foot), **pretibial** (shin), and sacral tissues and around the eyes, which is associated with kidney disease. Use a stethoscope to listen to the lungs to determine whether fluid is present. Weigh the patient and measure blood pressure as a baseline for later comparisons.

Assess the level of consciousness and level of alertness. Record any deficits in memory, concentration, or thought processes. Family members may report subtle changes. Cognitive changes may be the result of the buildup of waste products when kidney disease is present.

Assessment of the Kidneys, Ureters, and Bladder

Assess the kidneys, ureters, and bladder during an abdominal assessment. Auscultate before percussion and palpation because these activities can enhance bowel sounds and obscure abdominal vascular sounds.

Inspect the abdomen and the flank regions with the patient in both the supine and the sitting positions. Observe the patient for asymmetry (e.g., swelling) or discoloration (e.g., bruising or redness) in the flank region, especially in the area

FIG. 68-9 Advanced technique for palpation of the kidney.

of the costovertebral angle (CVA). The CVA is located between the lower portion of the twelfth rib and the vertebral column.

Listen for a bruit by placing a stethoscope over each renal artery on the midclavicular line. A **bruit** is an audible swishing sound produced when the volume of blood or the diameter of the blood vessel changes. It often occurs with blood flow through a narrowed vessel, as in renal artery stenosis.

Kidney palpation is usually performed by a physician or advanced practice nurse. It can help locate masses and areas of tenderness in or around the kidney. Lightly palpate the abdomen in all quadrants. Ask about areas of tenderness or pain, and examine nontender areas first. The outline of the bladder may be seen as high as the umbilicus in patients with severe bladder distention. *If tumor or aneurysm is suspected, palpation may harm the patient.*

Because the kidneys are located deep and posterior, palpation is easier in thin patients who have little abdominal musculature. For palpation of the right kidney, the patient is in a supine position while the examiner places one hand under the right flank and the other hand over the abdomen below the lower right part of the rib cage. The lower hand is used to raise the flank, and the upper hand depresses the abdomen as the patient takes a deep breath (Fig. 68-9). The left kidney is deeper and often cannot be palpated. A transplanted kidney is readily palpated in either the lower right or left abdominal quadrant. The normal kidney is smooth, firm, and nontender.

A distended bladder sounds dull when percussed. After gently palpating to determine the outline of the distended bladder, begin percussion on the lower abdomen and continue in the direction of the umbilicus until dull sounds are no longer produced. If you suspect bladder distention, use a portable bladder scanner to determine the amount of retained urine.

If the patient reports flank pain or tenderness, percuss the nontender flank first. Have the patient assume a sitting, side-lying, or supine position, and then form one of your hands into a clenched fist. Place your other hand flat over the CVA of the patient. Then quickly deliver a firm thump to your hand over the CVA area. Costovertebral tenderness often

occurs with kidney infection or inflammation. Patients with inflammation or infection in the kidney or nearby structures may describe their pain as severe or as a constant, dull ache.

Assessment of the Urethra

Using a good light source and wearing gloves, inspect the urethra by examining the meatus and the tissues around it. Record any unusual discharge such as blood, mucus, or pus. Inspect the skin and mucous membranes of surrounding tissues. Record the presence of lesions, rashes, or other abnormalities of the penis or scrotum or of the labia or vaginal opening. Urethral irritation is suspected when the patient reports discomfort with urination. Use this opportunity to remind women to clean the perineum by wiping from front to back, never from back to front. Teach them that the front-to-back technique keeps organisms in stool from coming close to the urethra, which could increase the risk for infection.

Women from other cultures may have undergone female circumcision. This procedure alters the anatomic appearance of the vulvar-perineal area and increases the risk for urinary tract infections. It also makes urethral inspection or catheterization difficult. Document any noted anatomic changes and ask the patient to describe her hygiene practices for this area.

Psychosocial Assessment

Concerns about the urologic system may evoke fear, anger, embarrassment, anxiety, guilt, or sadness in the patient. Childhood learning often includes privacy with regard to toilet habits. Urologic disorders may bring up forgotten memories of difficult toilet training and bedwetting or of childhood experiences of exploring one's body. The patient may ignore symptoms or delay seeking health care because of emotional responses or cultural taboos about the urogenital area.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

A 67-year-old client who had an abdominal x-ray as part of pre-admission testing for a gastrointestinal problem has just been told that he has a horseshoe-shaped kidney. He is very upset, telling the nurse that he has never had any health problems until the past month and now feels that he is "falling apart." What is the nurse's best response?

- Remind him that it was lucky that he was being x-rayed anyway and that the problem was found at an early stage.
- Reassure him that it is unlikely that the kidney shape is important since he has not had other kidney problems.
- Ask him whether anyone else in his family has ever been diagnosed with a horseshoe-shaped kidney.
- Reassure him that his health care provider will request a consultation with a kidney specialist.

Diagnostic Assessment

Laboratory Assessment

Blood Tests. Serum creatinine is produced when protein or muscle breaks down. Creatinine is filtered by the kidneys and excreted in the urine. Because muscle mass and protein breakdown are usually constant, the serum creatinine level is a good indicator of kidney function. Normal serum creatinine levels vary with age, gender, and body muscle mass.

CHART 68-3 LABORATORY PROFILE

Renal Function Blood Studies

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Serum creatinine	Males: 0.6-1.2 mg/dL (53-106 mmol/L) Females: 0.5-1.1 mg/dL (44-97 mmol/L) Older adults: may be decreased	An <i>increased level</i> indicates kidney impairment. A <i>decreased level</i> may be caused by a decreased muscle mass.
Blood urea nitrogen (BUN)	10-20 mg/dL (3.6-7.1 mmol/L) Older adults: 60-90 yr: 8-23 mg/dL (2.9-8.2 mmol/L) Older than 90 yr: 10-31 mg/dL (3.6-11.1 mmol/L)	An <i>increased level</i> may indicate hepatic or renal disease, dehydration or decreased kidney perfusion, a high-protein diet, infection, stress, steroid use, GI bleeding, or other situations in which blood is in body tissues. A <i>decreased level</i> may indicate malnutrition, fluid volume excess, or severe hepatic damage.
BUN/creatinine ratio	Mass ratio: 12:1 to 20:1 Mole ratio: 48.5:1 to 80.8:1	An <i>increased ratio</i> may indicate fluid volume deficit, obstructive uropathy, catabolic state, or a high-protein diet. A <i>decreased ratio</i> may indicate fluid volume excess or acute renal tubular acidosis. No change in the ratio with increases in both the BUN and creatinine levels indicates renal impairment.

Data from Pagana, K.D., & Pagana, T.J. (2010). *Mosby's manual of diagnostic and laboratory tests* (4th ed.). St. Louis: Mosby.

Levels are slightly higher in men than in women because men tend to have a larger muscle mass than do women, but there are exceptions (Chart 68-3). Creatinine levels in bodybuilders tend to be higher than normal without reflecting a kidney function problem. Muscle mass and the amount of creatinine produced decrease with age. Because of decreased rates of creatinine clearance, however, the serum creatinine level remains relatively constant in older adults unless kidney disease is present.

No common pathologic condition other than kidney disease increases the serum creatinine level. The serum creatinine level does not increase until at least 50% of the kidney function is lost, and therefore any elevation of serum creatinine values is important and should be assessed further.

! NURSING SAFETY PRIORITY

Action Alert

An increase of serum creatinine 1.5 times above baseline or a decrease of urine output to <0.5 mL/kg/hr for 6 or more hours places a patient at risk for acute kidney injury. Monitor both baseline and trend values to determine risk for and actual kidney damage, especially among patients exposed to agents that can cause kidney dysfunction. Inform the health care provider of increased serum creatinine and decreased urine output values promptly.

Blood urea nitrogen (BUN) measures the kidney excretion of urea nitrogen, a by-product of protein breakdown in the liver. Urea nitrogen is produced mostly from liver metabolism of food sources of protein. The kidneys filter urea nitrogen from the blood and excrete the waste in urine. BUN levels indicate the extent of kidney clearance of this nitrogen waste product.

Other factors influence the BUN level, and an elevation does not always mean kidney disease is present (see Chart 68-3). For example, rapid cell destruction from infection, cancer treatment, or steroid therapy may elevate BUN level. In addition, blood is a protein. Blood in the tissues rather than in the blood vessels is reabsorbed as if it were a general protein. Thus reabsorbed blood protein is processed by the liver and increases BUN levels. This means that injured tissues can result in increased BUN levels even when kidney function is normal. Also, BUN is increased by protein turnover in exercising muscle and is elevated as a result of concentration during dehydration.

The liver must function properly to produce urea nitrogen. When liver and kidney dysfunction are present, urea nitrogen levels are actually *decreased* because the liver failure limits urea production. The BUN level is not always elevated with kidney disease and is not the best indicator of kidney function. However, an elevated BUN level is highly *suggestive* of kidney dysfunction.

Blood urea nitrogen to serum creatinine ratio can help determine whether non-kidney-related factors, such as low cardiac output or red blood cell destruction, are causing the elevated BUN level. When blood volume is deficient (e.g., dehydration) or cardiac output is low, the BUN level rises more rapidly than the serum creatinine level. As a result, the ratio of BUN to creatinine is *increased*.

When both the BUN and serum creatinine levels increase at the same rate, the BUN/creatinine ratio remains normal. However, the elevated serum creatinine and BUN levels suggest kidney dysfunction that is not related to dehydration or poor perfusion.

Blood osmolarity is a measure of the overall concentration of particles in the blood and is a good indicator of hydration status. The kidneys excrete or reabsorb water to keep blood osmolarity in the range of 285 to 295 mOsm/L. Osmolarity is slightly higher in older adults (285 to 301 mOsm/L). When blood osmolarity is decreased, the release of antidiuretic hormone (ADH) is inhibited. Without ADH, the distal tubule and collecting ducts are *not* permeable to water. As a result, water is *excreted*, not reabsorbed, and blood osmolarity increases. When blood osmolarity increases, ADH is released. ADH increases the permeability of the distal tubule to water. Then water is reabsorbed and blood osmolarity decreases.

Urine Tests

Urinalysis. Urinalysis is a part of any complete physical examination and is especially useful for patients with suspected kidney or urologic disorders (Chart 68-4). Ideally, the urine specimen is collected at the morning's first voiding. Specimens obtained at other times may be too dilute. The specimen may be collected by several techniques (Table 68-4).

Urine color comes from urochrome pigment. Color variations may result from increased levels of urochrome or other pigments, changes in the concentration or dilution of the urine, and the presence of drug metabolites in the urine. Urine smells faintly like ammonia and is normally clear without **turbidity** (cloudiness) or haziness.

CHART 68-4 LABORATORY PROFILE

Urinalysis

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Color	Pale yellow	<i>Dark amber</i> indicates concentrated urine. <i>Very pale</i> yellow indicates dilute urine. <i>Dark red</i> or brown indicates blood in the urine. Brown also may indicate increased urinary bilirubin level. Red also may indicate the presence of myoglobin. <i>Other color</i> changes may result from diet or drugs.
Odor	Specific aroma, similar to ammonia	<i>Foul smell</i> indicates possible infection, dehydration, or ingestion of certain foods or drugs.
Turbidity	Clear	<i>Cloudy urine</i> indicates infection, sediment, or high levels of urinary protein.
Specific gravity	Usually 1.005-1.030; possible range 1.000-1.040 (after 12-hr fluid restriction, >1.025) <i>Older adult:</i> Decreased because of decreased concentrating ability	<i>Increased</i> in decreased kidney perfusion, inappropriate antidiuretic hormone secretion, or congestive heart failure. <i>Decreased</i> in chronic kidney disease, diabetes insipidus, malignant hypertension, diuretic administration, and lithium toxicity.
pH	Average: 6; possible range: 4.6-8	<i>Changes</i> are caused by diet, the administration of drugs, infection, freshness of the specimen, acid-base imbalance, and altered renal function.
Glucose	<0.5 g/day (<2.78 mmol/L)	<i>Presence</i> reflects hyperglycemia or a decrease in the renal threshold for glucose.
Ketones	None	<i>Presence</i> reflects incomplete metabolism of fatty acids, as in diabetic ketoacidosis, prolonged fasting, anorexia nervosa.
Protein	0.8 mg/dL	<i>Increased</i> amounts may indicate stress, infection, recent strenuous exercise, or glomerular disorders.
Bilirubin (urobilinogen)	None	<i>Presence</i> suggests liver or biliary disease or obstruction.
Red blood cells (RBCs)	0-2 per high-power field	<i>Increased</i> amounts are normal with indwelling or intermittent catheterization or menses but may reflect tumor, stones, trauma, glomerular disorders, cystitis, or bleeding disorders.
White blood cells (WBCs)	<i>Males:</i> 0-3 per high-power field <i>Females:</i> 0-5 per high-power field	<i>Increased</i> amounts may indicate an infectious or inflammatory process anywhere in the renal/urinary tract, renal transplant rejection, fever, or exercise.
Casts	A few or none, composed of RBC, WBC, protein, or tubular cell casts	<i>Increased</i> amounts indicate the presence of bacteria or protein, which is seen in severe kidney disease and could also indicate urinary calculi.
Crystals	None	<i>Presence</i> of normal or abnormal crystals may indicate that the specimen has been allowed to stand.
Bacteria	<1000 colonies/mL	<i>Increased</i> amounts indicate the need for urine culture to determine the presence of urinary tract infection.
Parasites	None	<i>Presence</i> of <i>Trichomonas vaginalis</i> indicates infection, usually of the urethra, prostate, or vagina.
Leukoesterase	None	<i>Presence</i> suggests urinary tract infection.
Nitrites	None	<i>Presence</i> suggests urinary <i>Escherichia coli</i> .

Specific gravity is the density of urine compared with water, which has a specific gravity of 1.000. Density is related to the number of particles in a specific volume of urine. The normal specific gravity of urine ranges from 1.005 to about 1.030. In kidney disease, changes in specific gravity do not reflect systemic fluid volume. For example, dilute urine with a low specific gravity may occur in a dehydrated patient who is deficient in antidiuretic hormone (ADH).

An *increase* in specific gravity occurs with dehydration, decreased kidney blood flow, or the presence of ADH. (ADH production is normally increased with stress, surgery, anesthetic agents, and certain drugs such as morphine and commonly used oral antidiabetic drugs.) In these situations, the normal kidney response is to reabsorb water and decrease urine output. As a result, the urine produced is more concentrated.

A *decrease* in specific gravity occurs with increased fluid intake, diuretic drugs, and diabetes insipidus. In these

conditions, the normal kidney response is to excrete more water; thus urine output is increased. In kidney disease, the specific gravity decreases because the damaged kidneys reabsorb less water. The specific gravity does not vary with changes in plasma osmolarity (i.e., it becomes fixed).

pH is a measure of urine acidity or alkalinity. A pH value less than 7 is acidic, and a value greater than 7 is alkaline. Many factors influence urine acidity or alkalinity. A diet high in certain fruits and vegetables results in a more alkaline urine. A high-protein diet produces a more acidic urine. The presence of *Escherichia coli* in the urine also results in an acidic urine.

Urine specimens become more alkaline when left standing unrefrigerated for more than 1 hour, when bacteria are present, or when a specimen is left uncovered. Alkaline urine increases cell breakdown; thus the presence of red blood cells may be missed on analysis. Ensure that urine specimens are covered and delivered to the laboratory promptly or

TABLE 68-4 COLLECTION OF URINE SPECIMENS

NURSING INTERVENTIONS	RATIONALES
Voided Urine Collect the first specimen voided in the morning. Send the specimen to the laboratory as soon as possible. Refrigerate the specimen if a delay is unavoidable.	Urine is more concentrated in the early morning. After urine is collected, cellular breakdown results in more alkaline urine. Refrigeration delays the alkalization of urine. Bacteria are more likely to multiply in an alkaline environment.
Clean-Catch Specimen Explain the purpose of the procedure to the patient. Instruct the patient to self-clean before voiding: Instruct the female patient to separate the labia and use the sponges and solution provided to wipe with three strokes over the urethra. The first two wiping strokes are over each side of the urethra; the third wiping stroke is centered over the urethra (from front to back). Instruct the male patient to retract the foreskin of the penis and to similarly clean the urethra, using three wiping strokes with the sponge and solution provided (from the head of the penis downward). Instruct the patient to initiate voiding after cleaning. The patient then stops and resumes voiding into the container. Only 1 ounce (30 mL) is needed; the remainder of the urine may be discarded into the commode. Ensure that the patient understands the procedure. Assist the patient as needed.	Correct technique is needed to obtain a valid specimen. Surface cleaning is necessary to remove secretions or bacteria from the urethral meatus. A midstream collection further removes secretions and bacteria because urine flushes the distal portion of the internal urethra. An improperly collected specimen may result in inappropriate or incomplete treatment. The patient's understanding and the nurse's assistance ensure proper collection.
Catheterized Specimen For non-indwelling (straight) catheters: Avoid routine use. Follow the facility's procedures for catheterization technique. For indwelling catheters: Apply a clamp to the drainage tubing, distal to the injection port. Clean the injection port cap of the catheter drainage tubing with an appropriate antiseptic. Povidone-iodine solution or alcohol is acceptable. Attach a sterile 5-mL syringe into the port and aspirate the quantity of urine required. Inject the urine sample into a sterile specimen container. Remove the clamp to resume drainage. Properly dispose of the syringe.	The one-time passage of a urinary catheter may be necessary to obtain an uncontaminated specimen for analysis or to measure the volume of residual urine. These procedures minimize bacterial entry. Urine is collected from an indwelling catheter or tubing when patients have catheters for continence or long-term urinary drainage. Clamping allows urine to collect in the tubing at the location where the specimen is obtained. Surface contamination is prevented by following the cleaning procedures. A minimum of 5 mL is needed for culture and sensitivity (C&S) testing. A sterile container is used for C&S specimens.
24-Hour Urine Collection Instruct the patient thoroughly. Provide written materials to assist in instruction. Place signs appropriately. Inform all personnel or family caregivers of test in progress. Check laboratory or procedure manual on proper technique for maintaining the collection (e.g., on ice, in a refrigerator, or with a preservative). On initiation of the collection, ask the patient to void, discard the urine, and note the time. If a Foley catheter is in use, empty the tubing and drainage bag at the start time and discard the urine. Collect all urine of the next 24 hr. Twenty-four hours after initiation, ask the patient to empty the bladder and add that urine to the container. Do not remove urine from the collection container for other specimens.	A 24-hr collection of urine is necessary to quantify or calculate the rate of clearance of a particular substance. Instructional materials for patients, signs, etc. remind patients and staff to ensure that the total collection is completed. Proper technique prevents breakdown of elements to be measured. Proper techniques ensure that <i>all</i> urine formed within the 24-hr period is collected. Urine in the container is not considered a "fresh" specimen and may be mixed with preservative.

refrigerated. During acidosis or alkalosis, the kidneys, along with blood buffers and the lungs, normally respond to keep serum pH normal. [Chapter 14](#) discusses acid-base balance and imbalance.

Glucose is filtered by the glomerulus and is reabsorbed in the proximal tubule of the nephron. When the blood glucose level rises above 220 mg/dL, the renal threshold for reabsorption is exceeded and some glucose is present in the urine. Changes in the renal threshold for glucose occur in many patients, such as those with infection or those with long-standing diabetes mellitus. It is possible that their serum glucose level may be high (e.g., greater than 400 mg/dL) and glucose may still not be present in the urine. More often, these patients show glucose in the urine even when blood glucose levels are normal or only slightly elevated.

Ketone bodies are formed from the incomplete metabolism of fatty acids. Three types of ketone bodies are acetone, acetoacetic acid, and beta-hydroxybutyric acid. *Normally there are no ketones in urine.* Ketone bodies are produced when fat is used instead of glucose for cellular energy. Ketones present in the blood are partially excreted in the urine.

Protein, such as albumin, is not normally present in the urine. Levels greater than 300 mg/24 hr, or 200 mcg/min, are abnormal. Protein molecules are too large to pass through intact glomerular membranes. When glomerular membranes are not intact, protein molecules pass through and are excreted in the urine. Increased membrane permeability is caused by infection, inflammation, or immunologic problems. Some systemic problems cause production of abnormal proteins, such as globulin. These proteins are not detected by routine urinalysis and require electrophoresis or other tests for detection.

A random finding of **proteinuria** (protein in the urine) followed by a series of negative (normal) findings does not imply kidney disease. If infection is the cause of the proteinuria, urinalyses after elimination of the infection should be negative for protein. Persistent proteinuria needs further investigation.

Microalbuminuria is the presence of albumin in the urine that is not measurable by a urine dipstick or usual urinalysis procedures. Specialized assays are used to quickly analyze a freshly voided urine specimen for microscopic levels of albumin. The normal microalbumin levels in a freshly voided specimen should range between 2.0 and 20 mg/mmol for men and between 2.8 and 28 mg/mmol for women. Higher levels indicate microalbuminuria and could mean very early kidney disease, especially in patients with diabetes mellitus. In 24-hour urine specimens, levels of 30 to 300 mg/24 hr, or 20 to 200 mcg/min, indicate microalbuminuria.

Leukoesterase is an enzyme found in some white blood cells, especially neutrophils. When the number of these cells increases in the urine or they are broken (*lysed*), the urine then contains leukoesterase. The presence of leukoesterase and nitrites in the urine is a sensitive screen for assessing urinary tract infections. A normal reading is no leukoesterase in the urine. A positive test (+ sign) indicates increasing leukocytes in the urine.

Nitrites are not usually present in urine. Many types of bacteria, when present in the urine, convert nitrates (normally found in urine) into nitrites. A positive finding indicates urinary tract infection.

Sediment is precipitated particles in the urine. These particles include cells, casts, crystals, and bacteria. Normally, urine contains few, if any, cells. Types of cells abnormally present in the urine include tubular cells (from the tubule of the nephron), epithelial cells (from the lining of the urinary tract), red blood cells (RBCs), and white blood cells (WBCs).

Casts are structures formed around other particles. There may be casts of cells, bacteria, or protein. When cells, bacteria, or proteins are present in the urine, minerals and sticky materials clump around them and form a cast. Casts are described by the type of particle they have surrounded (e.g., RBC cast, WBC cast, tubular epithelial cast) or the stage of cast breakdown. Casts are described as “granular” (coarse or fine) and “waxy.”

Urine crystals come from mineral salts as a result of diet, drugs, or disease. Common salt crystals are formed from calcium, oxalate, urea, phosphate, magnesium, or other substances. Some drugs, such as the sulfates, can also form crystals.

Bacteria multiply quickly, so the urine specimen must be analyzed promptly to avoid falsely elevated counts of bacterial colonization. Normally urine is sterile, but it is easily contaminated by perineal bacteria during collection.

Recent advances in technology and molecular biology are leading to new diagnostic tests using urine, including identification of biomarkers of disease and profiling for specific proteins. Markers are being used in investigation to identify early-onset kidney dysfunction, target therapy, and predict responsiveness to intervention. Markers for angiogenesis and kidney cell adhesion, regulation, and apoptosis will likely contribute to clinical diagnostics in the future.

Urine for Culture and Sensitivity. Urine is analyzed for the number and types of organisms present. Manifestations of infection and unexplained bacteria in a urine specimen are indications for urine culture and sensitivity testing. Bacteria from urine are placed in a medium with different antibiotics. In this way, we can know which antibiotics are effective in killing or stopping the growth of the organisms (organisms are “sensitive”) and which are not effective (organisms are “resistant”). A clean-catch or catheter-derived specimen is best for culture and sensitivity testing.

Composite Urine Collections. Some urine collections are made for a specified number of hours (e.g., 24 hours) for more precise analysis of one or more substances. These collections are often used to measure urine levels of creatinine or urea nitrogen, sodium, chloride, calcium, catecholamines, or other components ([Chart 68-5](#)). For a composite urine specimen, *all* urine within the designated time frame must be collected (see [Table 68-4](#)). If other urine must be obtained while the collection is in progress, measure and record the amount collected but not added to the timed collection.

The urine collection may need to be refrigerated or stored on ice to prevent changes in the urine during the collection time. Follow the procedure from the laboratory for urine storage. The urine collection must be free from fecal contamination. Menstrual blood and toilet tissue also contaminate the specimen and can invalidate the results.

The collection of urine for a 24-hour period is often more difficult than it seems. With hospitalized patients, the cooperation of staff personnel, the patient, family members, and visitors is essential. Placing signs in the bathroom, instructing

CHART 68-5 LABORATORY PROFILE

24-Hour Urine Collections

COMPONENT	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Creatinine	0.8-2 g/24 hr Males: 1-2 g/24 hr or 14-26 mg/kg/24 hr (124-230 μ mol/kg/24 hr or 7.1-17.7 mmol/24 hr) Females: 0.6-1.8 g/24 hr or 11-20 mg/kg/24 hr (97-177 μ mol/kg/24 hr or 5.3-15.9 mmol/24 hr) Older adults: 10 mg/kg/24 hr (88.4 μ mol/kg/24 hr) at 90 yr	<i>Decreased amounts</i> indicate a deterioration in kidney function caused by kidney disease. <i>Increased amounts</i> occur with infections, exercise, diabetes mellitus, and meat meals.
Urea nitrogen	12-20 g/24 hr (0.43-0.71 mmol/24 hr)	<i>Decreased amounts</i> occur when kidney damage or liver disease is present. <i>Increased amounts</i> commonly result from a high-protein diet, dehydration, trauma, or sepsis.
Sodium	40-220 mEq/24 hr (40-220 mmol/24 hr)	<i>Decreased amounts</i> are seen in hemorrhage, shock, hyperaldosteronism, and prerenal acute kidney injury. <i>Increased amounts</i> are common with diuretic therapy, excessive salt intake, hypokalemia, and acute tubular necrosis.
Chloride	110-250 mEq/24 hr (110-250 mmol/24 hr) Older adults: 95-195 mEq/24 hr (95-195 mmol/24 hr)	<i>Decreased amounts</i> are seen in certain kidney diseases, malabsorption syndrome, pyloric obstruction, prolonged nasogastric tube drainage, diarrhea, diaphoresis, heart failure, and emphysema. <i>Increased amounts</i> are seen with hypokalemia, adrenal insufficiency, and massive diuresis.
Calcium	100-400 mg/24 hr (2.50-7.50 mmol/kg/24 hr)	<i>Decreased amounts</i> are often associated with hypocalcemia, hypoparathyroidism, nephrosis, and nephritis. <i>Increased amounts</i> are commonly seen with calcium kidney stones, hyperparathyroidism, sarcoidosis, certain cancers, immobilization, and hypercalcemia.
Total catecholamines*	<100 mcg/24 hr (<591 mmol/24 hr)	<i>Increased amounts</i> occur with pheochromocytoma, neuroblastomas, stress, or strenuous exercise.
Protein	1-14 mg/dL (10-140 mg/L) or 50-80 mg/24 hr at rest	<i>Increased amounts</i> indicate glomerular disease, nephrotic syndrome, diabetic nephropathy, urinary tract malignancies, and irritations.

*Epinephrine and norepinephrine only; dopamine is not measured.

the patient and family, and emphasizing the need to save the urine are helpful.

Creatinine Clearance. Creatinine clearance is a calculated measure of glomerular filtration rate. It is the best indication of overall kidney function. The amount of creatinine cleared from the blood (e.g., filtered into the urine) is measured in the total volume of urine excreted in a defined period. The optimal calculation for glomerular filtration rate (GFR) is based on a 24-hour urine collection, but urine can be collected for shorter periods (e.g., 8 or 12 hours). The analysis compares the urine creatinine level with the blood creatinine level, and therefore a blood specimen for creatinine must also be collected.

The laboratory or care provider calculates the creatinine clearance. The patient's age, gender, height, weight, diet, and activity level influence the expected amount of creatinine to be excreted. Thus these factors are considered when interpreting creatinine clearance test results. Although creatinine clearance can be calculated based on age, weight, serum creatinine, and other non-urine measures, a 24-hour collection and direct measurement is preferred for patients with high risk for or actual kidney dysfunction.

The rate of creatinine clearance is expressed as milliliters per minute per square meter of body surface area. The range for normal creatinine clearance is 90 to 139 mL/min/m² for men and 80 to 125 mL/min/m² for women.

Creatinine clearance values are used to determine the patient's current kidney function. Decreases in the creatinine clearance rate may require reducing drug doses and often signifies the need to further explore the cause of kidney deterioration.

Urine Electrolytes. Urine samples can be analyzed for electrolyte levels (e.g., sodium, chloride). Normally the amount of sodium excreted in the urine is nearly equal to that consumed. Urine sodium levels of less than 10 mEq/L indicate that the tubules are able to conserve (reabsorb) sodium.

Urine Osmolarity. Osmolarity measures the concentration of particles in solution. The particles in urine contributing to osmolarity include electrolytes, glucose, urea, and creatinine. Urine osmolarity can vary from 50 to 1400 mOsm/L, depending on the patient's hydration status and kidney function. With average fluid intake, the range for urine osmolarity is 300 to 900 mOsm/L. Electrolytes, acids, and other wastes of normal metabolism are continually produced. These particles are the solute load that must be excreted in the urine on a regular basis. This is referred to as *obligatory solute excretion*. If the patient loses excessive fluids, the kidney response is to save water while excreting wastes by excreting small amounts of highly concentrated urine. Diet, drugs, and activity can change urine osmolarity. Thus urine with an increased osmolarity is concentrated urine with less water and more

TABLE 68-5 COMMON RADIOLOGIC AND SPECIAL DIAGNOSTIC TESTS FOR PATIENTS WITH DISORDERS OF THE KIDNEY AND URINARY SYSTEM

TEST	PURPOSE	COMMENTS
Radiography of kidneys, ureters, and bladder (KUB) (plain film of abdomen)	To screen for the presence of two kidneys To measure kidney size To detect gross obstruction	
Excretory urography	To measure kidney size To detect obstruction To assess parenchymal mass	Radiopaque contrast medium may cause an allergic (hypersensitivity) reaction in iodine-sensitive patients. Contrast agent is also hypertonic and increases the risk for acute kidney injury in adults with serum creatinine levels greater than 1.5 mg/dL. Nephrotoxic complications can be prevented by parenteral fluid administration.
Nephrotomography	To assess various planes of kidney tissue for cysts, tumors, or calculi	Same as for excretory urography.
Computed tomography (CT)	To measure kidney size To evaluate contour to assess for masses or obstruction	Contrast medium may provoke acute kidney injury. See comments with excretory urography for high-risk patients and preventive measures related to contrast. May be performed without contrast medium and still obtain adequate visualization.
Cystography and cystoscopy	To identify abnormalities of the bladder wall and urethral and ureteral occlusions To treat small obstructions or lesions via fulguration, lithotripsy, or removal with a stone basket	Instrumentation of the urinary tract increases the risk for infection. Monitor for infection for 48-72 hr after the procedure.
Voiding cystourethrography (VCUG)	To outline bladder's contour and detect urinary reflux from vesicourethral junctions	The risk for infection is similar to that in cystography because urinary catheterization is necessary. Monitor for postprocedure infection.
Ultrasonography (US)	To identify the size of the kidneys or obstruction in the kidneys or the lower urinary tract May detect tumors or cysts	Ultrasonography entails minimal risk to the patient. Ultrasonography is a good alternative to excretory urography.
MAG3 study 99m	To assess kidney function, structural abnormalities, kidney injury or impairment, obstruction, and kidney stones	Radioactive material (technetium Tc mertiatide) is used for this test.
Intravenous pyelography (IVP) (fluoroscopy)	To assess kidney function, identify anomalies To image kidney/urinary stones (size, location, radiodensity) To screen for kidney injury after trauma	Contraindicated during pregnancy (ionizing radiation is a risk to the fetus). Contrast dye can cause renal dysfunction. Colonic cleaning improves quality of image.
Magnetic resonance imaging (MRI)	Staging of cancers, similar to CT	Patient must be able to lie still (motion can interfere with imaging).
Renal scan	Evaluation of kidney blood flow Estimation of glomerular filtration rate Provides functional information without exposing the patient to iodinated contrast dye	ACE inhibitors should be held for 48 hours before the test. ACE inhibitors may be given during the test, placing the patient at risk for episodes of hypotension. Ensure adequate hydration for best results.

ACE, Angiotensin-converting enzyme.

preparation procedures vary but usually include the use of laxatives the day before the procedure. Enemas also may be prescribed, but their use is controversial because some air and fluid can be retained.

CONSIDERATIONS FOR OLDER ADULTS

Bowel preparation procedures increase the risk for dehydration, especially in older adult patients. To help prevent dehydration, contact the testing department and ask that urograms be scheduled early in the day for older patients.

The contrast dye is potentially kidney-damaging (nephrotoxic). The risk for *contrast-induced kidney failure* is greatest in patients who are older or dehydrated, who have some renal insufficiency (e.g., serum creatinine levels greater than 1.5 mg/dL), or who are also taking other nephrotoxic drugs.

In addition, patients taking metformin are at risk for lactic acidosis when they receive iodinated contrast media. Metformin should be discontinued 24 hours before the time of a procedure and for at least 48 hours after the procedure. Kidney function should be re-evaluated before the patient resumes metformin therapy.

All patients at risk for contrast-induced nephrotoxicity need additional IV fluids before the procedure to maintain hydration and decrease the risk for kidney damage. Acetylcysteine (an antioxidant) may be used to prevent contrast-induced nephrotoxic effects in radiologic procedures, although its benefits have not been proven. Diuretics may be given immediately after the dye is injected to enhance dye excretion in patients who are well hydrated.

Instruct the patient in the preparation procedures for the urogram, and explain the procedure so that he or she knows

CHART 68-6 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Assessing the Patient About to Undergo a Diagnostic Test or Interventional Procedure Using Contrast Medium

Before the procedure:

- Ask the patient if he or she has ever had a reaction to contrast media. (Such a patient has the highest risk for having another reaction.)
- Ask the patient about a history of asthma. (Patients with asthma have been shown to be at greater risk for contrast reactions than the general public. When reactions do occur, they are more likely to be severe.)
- Ask the patient about known hay fever or food or drug allergies, especially to seafood, eggs, milk, or chocolate. (Contrast reactions have been reported to be as high as 15% in these patients.)
- Ask the patient to describe any specific allergic reactions (e.g., hives, facial edema, difficulty breathing, bronchospasm).
- Assess for a history of kidney impairment and for conditions that have been implicated in increasing the chance of developing kidney failure after contrast media (e.g., diabetic nephropathy, class IV heart failure, dehydration, concomitant use of potentially nephrotoxic drugs such as the aminoglycosides or NSAIDs, and cirrhosis).
- Ask the patient if he or she is taking metformin (Glucophage). (Metformin must be discontinued at least 24 hours before any study using contrast media because the life-threatening complication of lactic acidosis, although rare, could occur.)
- Assess hydration status by checking blood pressure, heart and respiratory rates, mucous membranes, skin turgor, and urine concentration.
- Ask the patient when he or she last ate or drank anything.

From Cohan, R.H., & Ellis, J.H. (1997). Iodinated contrast material in urology: Choice of agent and management of complications. *Urologic Clinics of North America*, 24(3), 471-491.

! NURSING SAFETY PRIORITY

Drug Alert

Ensure that the patient who is prescribed metformin does not receive the drug after a procedure requiring IV contrast material until adequate kidney function has been determined.

what to expect (Chart 68-7). Intervene on behalf of the patient to ensure that questions are answered *before* the procedure.

Procedure. The dye is injected IV with the patient in a supine position. As blood (with the dye) rapidly circulates into the kidney blood vessels and is filtered by the glomeruli, the dye is excreted in the urine. A series of x-rays are taken at various times after injection. Nephrotomograms may be taken at the same time as the urogram. Tomograms take images of different planes of tissue and show any abnormalities present at varying depths. The technologist then asks the patient to empty the bladder and return for a few more x-rays. An outline of the kidneys, ureters, and bladder results as urine containing the dye is excreted.

The urogram provides information about:

- The number, size, shape, and location of the kidneys
- The adequacy of filling and the rate of excretion of contrast medium

CHART 68-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Excretory Urogram

- The urogram outlines your urinary tract and helps determine any problems there.
- Notify your nurse or physician if you have had any reactions (allergic or otherwise) to any food or drugs, especially shellfish (e.g., shrimp, scallops, crab, lobster) or iodine, or to x-ray “dyes” such as contrast media; if you have a history of asthma; or if you are taking metformin (Glucophage) or Glucovance.
- The day before the test, follow the instructions about changes in your diet and fluid intake to be sure that as much information as possible is gained from the test.
- After you start the bowel preparation, you may need to be close to toileting facilities. The preparation drugs usually work quickly.
- You will be lying on an x-ray table with the x-ray machine above you for most of the procedure.
- A pressure band, similar to a large blood pressure cuff, may be placed around your stomach or abdomen to help obtain better x-rays.
- If you do not already have an IV access site, one will be started to give you the contrast agent.
- After the contrast is injected, you may feel a sense of warmth or heat as it travels throughout your body. You also may have a taste in your mouth that is sometimes described as metallic. These sensations last only a few seconds or minutes.
- When the pressure band is inflated, you may feel some tightness around your abdomen. The sensation is similar to the feeling on your arm when you have your blood pressure taken.
- A series of x-rays will be taken. You may be asked to empty your bladder and return to the table for more films. You also may be asked to have a standing film taken.
- After the test is completed, you are usually able to resume your normal activities and diet.
- You will not notice any change in the color or characteristics of your urine.
- Please do not hesitate to ask your nurse, physician, or x-ray technologist any question, no matter how slight the question may seem to you. It is important that you have as much understanding as possible.

- The number, size, location, appearance, and patency of the calices, pelves, and ureters
- The size, location, and nature of the urinary bladder

Follow-up Care. After the urogram, monitor the patient for altered kidney function and other effects from the dye. Ensure adequate hydration by urging the patient to take oral fluid or by giving IV fluids. Hydration reduces the risk for kidney damage. Monitor blood creatinine levels to assess ongoing kidney function.

Computed Tomography. Inform the patient that a computed tomography (CT) scan provides three-dimensional information about the kidneys, ureters, bladder, and surrounding tissues. The CT scan is performed in a special room, usually in the radiology department. It is usually performed after other diagnostic procedures and can provide information about tumors, cysts, abscesses, other masses, and obstruction. CT can also be used to image the kidney’s vascular system (i.e., CT angiography). Some hospitals require patients having CT scans to be NPO for some period before the scan, although there is no specific evidence guiding this practice.

Determine whether the scan requires administration of a dye. Oral or injected contrast dye is usually given before starting the imaging procedure. Dye use may be omitted in patients at risk for contrast-induced acute kidney injury (AKI), but the images produced are less distinct.

When a dye is used, the follow-up care is the same as for IV urography. When no contrast or dye is used, there is no special postprocedural care.

Cystography and Cystourethrography. Explain the procedure to the patient. A urinary catheter is temporarily needed to instill contrast dye. The dye is needed to enhance x-ray visibility of the lower urinary tract.

In both cystography and cystourethrography, dye is instilled into the bladder via a urethral catheter. After bladder filling, x-rays are taken from the front, back, and side positions. For the voiding cystourethrogram (VCUG), the patient is requested to void and x-rays are taken during the voiding. A VCUG is obtained to determine whether urine refluxes into the ureter. The cystogram is often used in cases of trauma when urethral or bladder injury is suspected.

Monitor for infection as a result of catheter placement. In this test, the dye is not nephrotoxic because it does not enter the bloodstream and does not reach the kidney. Encourage fluid intake to dilute the urine and reduce the burning sensation from catheter irritation after removal. Monitor for changes in urine output because pelvic or urethral trauma may be present.

Renography (Kidney Scan). Explain that a kidney scan is performed to provide general information about blood flow to and in the kidneys. A small amount of radioactive material, a radionuclide, is used. Reassure the patient that there is no danger from the small amount of radioactive material present in the agent. Radionuclides are not associated with nephrotoxicity.

For a kidney scan, the radionuclide is injected IV. After injection, the agent is absorbed into kidney tissue and gives off low-level radioactive emissions (scintillations). The amount of emission is measured by a scintillation counter. A special camera records the emissions and produces an image. At the same time, the rate and location of the emissions are recorded by computer and information about blood flow, or glomerular filtration, is provided.

In some cases, captopril (Capoten), an antihypertensive drug, is given at the start of the procedure to change blood flow in the kidney. This procedure is a “captopril renal scan.” The drug can cause severe hypotension during and after the procedure.

When the patient can urinate, urination into a commode does not place anyone at risk from the small amount of radioactive material excreted. If he or she is incontinent, change the bed linens promptly and wear gloves for Standard Precautions. If captopril was used during the procedure, assess the patient’s blood pressure frequently. Warn him or her to avoid rapid position changes and about the risk for falling as a result of orthostatic (positional) hypotension.

Ultrasonography. Inform the patient that ultrasonography does not cause discomfort and is without risk. This test usually requires a full bladder. Ask the patient to drink water, if needed, to help fill the bladder. This test applies sound waves to structures of different densities to produce images of the kidneys, ureters, and bladder and surrounding tissues. Ultrasonography allows assessment of kidney size, cortical

thickness, and status of the calices. The test can identify obstruction in the urinary tract, tumors, cysts, and other masses without the use of contrast dye.

The patient undergoing kidney ultrasound is usually placed in the prone position. Sonographic gel is applied to the skin over the back and flank areas to enhance sound-wave conduction. A transducer in contact with and moving across the skin delivers sound waves and measures the echoes. Images of the internal structures are produced. Skin care to remove the gel is all that is needed after ultrasonography.

Renal Arteriography (Angiography). Renal arteriography allows dye to enter the renal blood vessels and generates images to determine blood vessel size and abnormalities. This test has largely been replaced by other imaging techniques (e.g., nuclear renal scans, ultrasonography, computed tomography) and is seldom used as a stand-alone diagnostic procedure. The most common use of renal arteriography is at the time of a renal angioplasty or other intervention.

Cystoscopy and Cystourethroscopy

Patient Preparation. Cystoscopy and cystourethroscopy are operative procedures and require completion of a preoperative checklist and a signed informed consent statement. The physician provides a complete description of and reasons for the procedure, and the nurse reinforces this information. Cystoscopy may be performed for diagnosis or treatment. This test is used to examine for bladder trauma (cystoscopy) or urethral trauma (cystourethroscopy) and to identify causes of urinary tract obstruction. Cystoscopy may be used to remove bladder tumors or an enlarged prostate gland.

Cystoscopy may be performed under general or local anesthesia with sedation. The patient’s age and general health and the expected duration of the procedure are considered in the decision about anesthesia. A light evening meal may be eaten. Usually the patient is NPO after midnight on the night before the cystoscopy. A bowel preparation with laxatives or enemas is performed the evening before the procedure.

Procedure. The cystoscopy is performed in a designated cystoscopic examination room. If the procedure is performed in a surgical suite under general anesthesia, the usual surgical support personnel are present (see Chapter 17). This procedure is often performed in clinics, ambulatory surgery or short-procedure units, or urologist’s office.

Assist the patient onto a table, and after sedation, place him or her in the lithotomy position. After the anesthesia is given and the area cleansed and draped, the urologist inserts a cystoscope through the urethra into the urinary bladder. This examination commonly includes the use of both the cystoscope and the urethroscope.

Follow-up Care. After this procedure with general anesthesia, the patient is returned to a postanesthesia care unit (PACU) or area. If local anesthesia and sedation were used, he or she may be returned directly to the hospital room. Patients undergoing cystoscopic examinations as outpatients are transferred to an area for monitoring before discharge to home. Monitor for airway patency and breathing, changes in vital signs (including temperature), and changes in urine output. Also observe for the complications of bleeding and infection.

A catheter may or may not be present after cystoscopy. The patient without a catheter has urinary frequency as a result of irritation from the procedure. The urine may be pink tinged, but gross bleeding is not expected. Bleeding or the

presence of clots may obstruct the catheter and decrease urine output. Monitor urine output, and notify the physician of obvious blood clots or a decreased or absent urine output. Irrigate the Foley catheter with sterile saline, if prescribed. Notify the physician if the patient has a fever (with or without chills) or an elevated white blood cell (WBC) count, which suggests infection. Urge the patient to take oral fluids to increase urine output (which helps prevent clotting) and to reduce the burning sensation on urination.

Retrograde Procedures. Retrograde means going against the normal flow of urine. A retrograde examination of the ureters and pelves (*pyelogram*), the bladder (*cystogram*), and the urethra (*urethrogram*) involves instilling dye into the lower urinary tract. Because the dye is instilled directly to obtain an outline of the structures desired, the dye does not enter the bloodstream. Therefore the patient is not at risk for dye-induced acute kidney injury or a systemic allergic response.

The patient is prepared for retrograde procedures (retrograde pyelography, retrograde cystography, and retrograde urethrography) in the same way as for cystoscopy. Retrograde x-rays are obtained during the cystoscopy. After placement of the cystoscope by the urologist, catheters are placed into each ureter and contrast dye is instilled into each ureter and renal pelvis. The catheters are removed by the urologist, and x-rays are taken to outline these structures as the dye is excreted. The procedure identifies obstruction or structural abnormalities.

For patients undergoing retrograde cystoscopy or urethrography, contrast dye is instilled similarly into the bladder or urethra. Cystography and urethrography identify structural problems, such as fistulas, diverticula, and tumors.

After retrograde procedures, monitor the patient for infection caused by placing instruments in the urinary tract. Because these procedures are performed during cystoscopic examination, follow-up care is the same as that for cystoscopy.

Other Diagnostic Assessments

Urodynamic Studies. Urodynamic studies examine the processes of voiding and include:

- Tests of bladder capacity, pressure, and tone
- Studies of urethral pressure and urine flow
- Tests of perineal voluntary muscle function

These tests are often used along with voiding urographic or cystoscopic procedures to evaluate problems with urine flow.

Cystometrography (CMG) can determine how well the bladder wall (detrusor) muscle functions and how sensitive it is to stretching as the bladder fills. This test provides information about bladder capacity, bladder pressure, and voiding reflexes.

Explain the procedure, and inform the patient that a urinary catheter may be needed temporarily during the procedure. Ask the patient to void normally. Record the amount, rate of flow, and time of voiding. Insert a urinary catheter to measure the residual urine volume. The cystometer is attached to the catheter, and fluid is instilled via the catheter into the bladder. The point at which the patient first notes a feeling of the urge to void and the point at which he or she notes a strong urge to void are recorded. Bladder capacity and bladder pressure readings are recorded graphically. The patient is asked to void when the bladder instillation is complete (about

500 mL). The residual urine after voiding is recorded, and the catheter is removed. Electromyography of the perineal muscles may be performed during this examination.

For any procedure that involves inserting instruments into the urinary tract, monitor for infection. Record the patient's temperature, the character of the urine, and urine output volume.

Urethral pressure profile (also called a *urethral pressure profilometry [UPP]*) can provide information about the nature of urinary incontinence or urinary retention.

Explain the procedure, and inform the patient that a urinary catheter may be needed temporarily during the procedure. A special catheter with pressure-sensing capabilities is inserted into the bladder. Variations in the pressure of the smooth muscle of the urethra are recorded as the catheter is slowly withdrawn.

As with any study involving inserting instruments into the urinary tract, monitor the patient for manifestations of infection.

Urine stream testing is used to evaluate pelvic muscle strength and the effectiveness of pelvic muscles in stopping the flow of urine. It is useful in assessing urinary incontinence.

Explain the procedure, and reassure the patient that efforts will be made to ensure privacy. The patient is asked to begin urinating. Three to five seconds after urination begins, the examiner gives the patient a signal to stop urine flow. The length of time required to stop the flow of urine is recorded.

Cleaning the perineal area, as after any voiding, is all that is necessary after the urine stream test.

Electromyography (EMG) of the perineal muscles tests the strength of the muscles used in voiding. This information may help identify methods of improving continence. Inform the patient that some mild, temporary discomfort may accompany placement of the electrodes. In EMG of the perineal muscles, electrodes are placed in either the rectum or the urethra to measure muscle contraction and relaxation. After the completion of EMG, administer analgesics as prescribed to promote the patient's comfort.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which assessments are most important for the nurse to perform when monitoring a client after a retrograde cystogram?

- A. Temperature and urine character
- B. Kidney tenderness and flank pain
- C. 24-hour urine volume, BUN and creatinine levels
- D. Angioedema and other indicators of systemic allergic response

Kidney Biopsy

Patient Preparation. Explain that a kidney biopsy can help determine a cause of unexplained kidney problems and can help direct or change therapy. Most kidney biopsies are performed **percutaneously** (through the skin and other tissues) using ultrasound or CT guidance. The patient signs an informed consent. Patients are NPO for 4 to 6 hours before the procedure.

Because of the risk for bleeding after the biopsy, coagulation studies such as platelet count, activated partial thromboplastin time (aPTT), prothrombin time (PT), and bleeding time are performed before surgery. A blood transfusion may

be needed to correct anemia before biopsy. Hypertension and uremia increase the risk for bleeding, and antihypertensive drugs or dialysis may be prescribed before a biopsy.

Procedure. In a percutaneous biopsy, the nephrologist or radiologist obtains tissue samples without an incision. Patients receive sedation and are monitored throughout the procedure. The patient is placed in the prone position on the procedure table. The entry site is selected after taking preliminary images. The area is prepped and sterilely draped. A local anesthetic is injected, and the physician then inserts the biopsy device into the tissues toward the kidney. Needle depth and placement are confirmed by ultrasound or CT. While the patient holds his or her breath, the needle is advanced into the renal cortex. Samples are then taken with a spring-loaded coring biopsy needle and sent for pathologic study.

Follow-up Care. After a percutaneous biopsy, the major risk is bleeding from the biopsy site. For 24 hours after the biopsy, monitor the dressing site, vital signs, urine output, hemoglobin level, and hematocrit. Even if the dressing is dry and there is no hematoma, the patient could be bleeding from the site. An internal bleed is not readily visible but is suspected with flank pain, decreasing blood pressure, decreasing urine output, or other signs of hypovolemia or shock.

The patient follows a plan of strict bedrest, lying in a supine position with a back roll for additional support for 2 to 6 hours after the biopsy. The head of the bed may be elevated, and the patient may resume oral intake of food and fluids. After bedrest, the patient may have limited bathroom privileges if there is no evidence of bleeding.

Monitor for hematuria, the most common complication of kidney biopsy. Hematuria occurs microscopically in most patients, but 5% to 9% have gross hematuria. This problem usually resolves without treatment in 48 to 72 hours after the biopsy but can persist for 2 to 3 weeks. In rare cases, transfusions and surgery are required. There should be no obvious blood clots in the urine.

The patient may have some local pain after the biopsy. If aching originates at the biopsy site and begins to radiate to

the flank and around the front of the abdomen, bleeding may have started or a hematoma is forming around the kidney. This pattern of discomfort with bleeding occurs because blood in the tissues around the kidney increases pressure on local nerve tracts.

If bleeding occurs, IV fluid, packed red blood cells, or both may be needed to prevent shock. In general, a small amount of bleeding creates enough pressure to compress bleeding sites. This is called a “tamponade effect.” If tamponade does not occur and bleeding is extensive, surgery for hemostasis or even nephrectomy may be needed. A hematoma in, on, or around the kidney may become infected, requiring treatment with antibiotics and surgical drainage.

If no bleeding occurs, the patient can resume general activities after 24 hours. Instruct him or her to avoid lifting heavy objects, exercising, or performing other strenuous activities for 1 to 2 weeks after the biopsy procedure. Driving may also be restricted. Refer to [Chapter 18](#) for general postoperative care for the patient undergoing an open kidney biopsy.

DECISION-MAKING CHALLENGE

Safety; Patient-Centered Care

At the start of the shift, you are assessing a 36-year-old patient 12 hours after a percutaneous biopsy of the left kidney. You observe that the bruising around the site extends about 2 inches past the dressing (a total diameter of 4 inches) and is swollen. The patient rates his pain at a 5 on a 0-to-10 pain-rating scale, which is up from the 3 he reported several hours ago. When you empty the urinal, the urine is pink-tinged. The patient has been lying on his right side for the past several hours and asks if he can change positions.

1. What assessment information will you document in the chart?
2. What additional information should you ask the patient and assess directly?
3. How could you accurately monitor changes in the size of the bruising at the surgical site?
4. What would be the best position for this patient for the next 2 hours?
5. Should you notify the surgeon at this time? Why or why not?

NURSING CONCEPT REVIEW

What should you expect to NOTICE in a patient with adequate urinary elimination?

Vital signs

- Body temperature is within normal range.
- Blood pressure is within normal range.

Physical assessment

- Daily urine output is within 500 mL of daily fluid intake.
- Skin texture is normal (no edema or superficial crystals present).
- Skin color is appropriate for race with no excessive yellowing, bruising, or petechiae.
- Urine is clear and some variation of yellow in color.
- Patient voids 300 to 500 mL per voiding.
- Patient does not report pain or burning on urination.
- Patient has no difficulty starting or stopping the stream of urine.

- Patient is continent of urine and can maintain continence without sensation of urgency.
- Patient is alert and oriented.

Psychological assessment

- Patient is able to communicate concerns about the urinary tract system.
- Patient is aware and informed about kidney function and diagnostic tests.

Laboratory assessment

- Hematocrit and hemoglobin are within normal limits (no anemia).
- BUN and creatinine are within normal limits.
- Serum electrolytes are within normal ranges.
- Urinalysis shows no bacteria, blood, sediment, or protein.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use sterile technique when inserting a catheter or any other instrument into the urinary system.
- Use Contact Precautions with any patient who has drainage from the genitourinary tract.
- Evaluate risk for kidney injury from diagnostic testing by asking about allergy to radiopaque contrast dye, shellfish, or iodine or adverse reactions following the use of diagnostic agents such as gadolinium in MRI.
- Identify prescribed and over-the-counter drugs that increase risk for kidney dysfunction.

Health Promotion and Maintenance

- Teach patients to clean the perineal area after voiding, after having a bowel movement, and after sexual intercourse.
- Urge all patients to maintain an adequate fluid intake (sufficient to dilute urine to a light yellow color). A minimum of 2 L/day may be recommended unless another health problem requires fluid restriction.
- Teach patients who come into contact with chemicals in their workplaces or for leisure time activities to avoid direct skin or mucous membrane contact with these chemicals.

Psychosocial Integrity

- Allow the patient the opportunity to express concerns about tests of the kidney and urinary tract or about a potential change in kidney function.
- Assess the patient's level of comfort in discussing issues related to elimination and the urogenital area.
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.
- Provide as much privacy as possible for patients undergoing examination or testing of the kidney/urinary tract.
- Use language and terminology that the patient can understand during discussions of kidney/urinary assessment.

Physiological Integrity

- Ask the patient about kidney problems in any other members of the family, because some problems have a genetic component.
- Ask the patient about current and past drug use (prescribed, over-the-counter, and illicit), and evaluate drug use for potential nephrotoxicity.
- Assess urine output closely after any procedure in which contrast dye is used IV.
- Assess the patient for bleeding or manifestations of infection after any invasive test of kidney/urinary function.

Care of Patients with Urinary Problems

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Assess the appropriateness for continuing therapy with indwelling urinary catheters.
2. Use principles of asepsis during catheter insertion.

Health Promotion and Maintenance

3. Encourage everyone to have a daily fluid intake of 1.5 to 2.5 L unless another health problem requires fluid restriction or to have sufficient fluid intake to result in urine output of 2 to 2.5 L daily.
4. Teach women risk-reduction interventions for urinary tract infections.
5. Teach the proper application of pelvic floor exercises to reduce or prevent urinary incontinence.
6. Encourage anyone who comes into contact with chemicals as part of work or hobbies to use appropriate personal protective equipment to reduce the risk for bladder cancer.

Psychosocial Integrity

7. Use language the patient is comfortable with when discussing urinary and sexual issues.
8. Encourage patients and families to express their feelings and concerns about a change in urinary elimination.
9. Explain to the patient and family what to expect during tests and procedures for urinary problems.
10. Refer patients with long-term urinary problems to appropriate community resources and support groups.

Physiological Integrity

11. Coordinate care to prevent urinary tract infections among hospitalized patients.
12. Compare the pathophysiology and manifestations of stress incontinence, urge incontinence, overflow incontinence, mixed incontinence, and functional incontinence.
13. Coordinate nursing care for the patient who has invasive bladder cancer.

The urinary system consists of the ureters, bladder, and urethra. Their functions are to store the urine made by the kidney and eliminate it from the body. These actions do not contribute to the homeostatic purposes of *urinary elimination*. However, when problems in the urinary system interfere with the mechanics of moving urine out of the body, urinary elimination is inadequate and homeostasis of fluids, electrolytes, nitrogenous wastes, and blood pressure is disrupted.

Urinary problems affect the storage or elimination of urine. Both acute and chronic urinary problems are common and costly. More than 20 million people in the United States are treated annually for urinary tract infections, cystitis, kidney and ureter stones, or urinary incontinence (U.S. Renal Data Systems, 2010). Although life-threatening complications are rare with urinary problems, patients may have significant functional, physical, and psychosocial changes that reduce quality of life. Nursing interventions are directed

TABLE 69-1 FACTORS CONTRIBUTING TO URINARY TRACT INFECTIONS

FACTOR	MECHANISM
Obstruction	Incomplete bladder emptying creates a continuous pool of urine in which bacteria can grow, prevents flushing out of bacteria, and allows bacteria to ascend more easily to higher structures. Bacteria have a greater chance of multiplying the longer they remain in residual urine. Overdistention of the bladder damages the mucosa and allows bacteria to invade the bladder wall.
Stones (calculi)	Large stones can obstruct urine flow. The rough surface of a stone irritates mucosal surfaces and creates a spot where bacteria can establish and grow. Bacteria can live within stones and cause re-infection.
Vesicoureteral reflux	Bacteria-laden urine is forced backward from the bladder up into the ureters and kidneys, where pyelonephritis can develop. Reflux of sterile urine can cause kidney scarring, which may promote kidney dysfunction.
Diabetes mellitus	Excess glucose in urine provides a rich medium for bacterial growth. Peripheral neuropathy affects bladder innervation and leads to a flaccid bladder and incomplete bladder emptying.
Characteristics of urine	Alkalotic urine promotes bacterial growth. Concentrated urine promotes bacterial growth.
Gender	Women are susceptible to periurethral colonization with coliform bacteria. Use of diaphragms, frequency of intercourse, and a new partner within the past year are associated with urinary tract infection (UTI) in women. Bladder displacement during pregnancy predisposes women to cystitis and the development of pyelonephritis. A diaphragm or pessary that is too large can obstruct urine flow or traumatize the urethra.
Age	Urinary stasis may be caused by incomplete bladder emptying as a result of an enlarged prostate in men and cystocele and prolapse in women. Neuromuscular conditions that cause incomplete bladder emptying, such as Parkinson disease and strokes, affect older adults more frequently. The use of anticholinergic drugs in older adults contributes to delayed bladder emptying. Fecal incontinence contributes to poor perineal hygiene. Hypoestrogenism in older women adversely affects the cells of the vagina and urethra, making them more susceptible to infections.
Sexual activity	Irritation of the perineum and urethra during intercourse can promote migration of bacteria from the perineal area to the urinary tract in some women. Spermicides can alter vaginal pH, increasing potential numbers of pathogens. Inadequate vaginal lubrication may exacerbate potential urethral irritation. Bacteria may be introduced into the man's urethra during anal intercourse or during vaginal intercourse with a woman who has a bacterial vaginitis.
Recent use of antibiotics	Antibiotics change normal protective flora, providing opportunity for pathogenic bacterial overgrowth and colonization.

toward prevention, detection, and management of urologic disorders.

INFECTIOUS DISORDERS

Infections of the urinary tract and kidneys are common, especially among women. Manifestations of urinary tract infection (UTI) account for more than 7 million health care visits and 1 million hospital admissions annually in the United States (U.S. Renal Data Systems, 2010). UTIs are the most common health care–acquired infection. Total direct and indirect costs for adult urinary tract infections are estimated at \$1.6 billion each year (Centers for Disease Control and Prevention [CDC], 2009).

Urinary tract infections are described by their location in the tract. Acute infections in the urinary tract include *urethritis* (urethra), *cystitis* (bladder), and *prostatitis* (prostate gland). Acute *pyelonephritis* is a kidney infection. The site of infection is important to know because site, along with the specific type of bacteria present, determines treatment. Several risk factors are associated with occurrence of UTIs (Table 69-1).

CYSTITIS

Pathophysiology

Cystitis is an inflammation of the bladder. It can be caused by irritation or, more commonly, by infection from bacteria, viruses, fungi, or parasites. Infectious cystitis is the most common of the UTIs. Noninfectious cystitis is caused by irritation from chemicals or radiation. **Interstitial cystitis** is an inflammatory disease that has no known cause.

Infectious agents, most commonly bacteria, move up the urinary tract from the external urethra to the bladder. Less common, spread of infection through the blood and lymph fluid can occur. Once bacteria enter the urinary tract, several factors influence the outcome (Table 69-2).

The presence of bacteria in the urine is **bacteriuria** and can occur with any urologic infection. When bacteriuria is without symptoms of infection, it is called *colonization*. Colonization, asymptomatic bacteriuria, is more common in older adults. This problem does not appear to progress to acute infection or kidney impairment unless the patient has other pathologic problems, and then it requires treatment.

TABLE 69-2 IMPORTANT FACTORS INFLUENCING THE OUTCOME OF URINARY TRACT INFECTION

FACILITATING ASPECTS	PROTECTIVE ASPECTS
Anatomy Females: Short length of the urethra and its proximity to the vagina and rectum facilitate colonization of coliform bacteria. Males: With age, the prostate enlarges and may obstruct the normal flow of urine, producing stasis. Physiology Females: Pregnancy predisposes a woman to ureteral reflux and subsequent pyelonephritis; with age, the decline in estrogen facilitates colonization of <i>Escherichia coli</i>. In addition, vaginal atrophy can alter urethral competency. Males: With age, prostatic secretions lose their antibacterial characteristics and predispose to bacterial proliferation in the urine. Trauma Females: Vaginal penetration with sexual intercourse may traumatize the urethra and bladder base, leading to postcoital (or “honeymoon”) cystitis; a vaginal diaphragm that is too large can place pressure on the urethra, causing trauma; vaginal childbirth can cause permanent damage to the urethra. Males: Sexually transmitted diseases may cause urethral strictures that obstruct the flow of urine and predispose to urinary stasis. Both males and females: Urethral instrumentation (e.g., catheterization) may disturb the urothelial surface and predispose to adherence of bacteria that would ordinarily not be pathogenic. Infectious Agent Some organisms are better able to adhere to host cells and secrete substances that induce inflammation.	Males: Long length of the urethra and its distance from the rectum provide protection from colonization with coliform bacteria. Females: Well-estrogenized mucosa in the urethra and trigone may inhibit bacterial colonization and enhance urogenital blood flow. Males: Normal prostatic secretions inhibit bacterial growth. Both males and females: Mucin is produced by urothelial cells lining the bladder—this helps maintain mucosal integrity and prevent cellular damage; mucin may also prevent bacteria from adhering to urothelial cells. Females: Adequate lubrication, either natural or artificial, with intercourse may prevent any trauma. A small inoculum (number of microorganisms introduced into the body) is more easily flushed away by the flow of urine.

Etiology and Genetic Risk

UTIs, like other infections, are the result of interactions between a pathogen and the host. Usually, a high bacterial *virulence* (ability to invade and infect) is needed to overcome normal strong host resistance. However, a compromised host is more likely to become infected even with bacteria that have low virulence. Genetically, invading bacteria with special adhesions are more likely to cause ascending UTIs that start in the urethra or bladder and move up into the ureter and kidney. Patient-specific genetic factors such as blood type and ability to produce bladder surface biofilms that protect bacteria may influence the risk for UTI (Bowen & Hellstrom, 2007).

Infectious cystitis is most commonly caused by organisms from the intestinal tract. About 90% of UTIs are caused by *Escherichia coli*. Less common organisms include *Staphylococcus saprophyticus*, *Klebsiella pneumoniae*, and organisms from the *Proteus* and *Enterobacter* species (Bowen & Hellstrom, 2007).

In most cases, organisms first grow in the perineal area, then move into the urethra as a result of irritation, trauma, or catheterization of the urinary tract, and finally ascend to the bladder. Catheters are the most common factor placing patients at risk for UTIs in the hospital setting. Within 48 hours of catheter insertion, bacterial colonization begins. About 50% of patients with indwelling catheters become infected within 1 week of catheter insertion.

How a catheter-related infection occurs varies between genders. Bacteria from a woman's perineal area are more likely to ascend to the bladder by moving along the outside

of the catheter. In men, bacteria tend to gain access to the bladder from inside the lumen of the catheter. Any break in the closed urinary drainage system allows bacteria to move through the urinary tract. Best practices to reduce the risk for catheter contamination and catheter-related UTIs are listed in Chart 69-1.

Organisms other than bacteria also can cause cystitis. Fungal infections, such as those caused by *Candida*, can occur during long-term antibiotic therapy, because antibiotics reduce normal protective flora. Patients who are severely immunosuppressed, are receiving corticosteroids or other immunosuppressive agents, or have diabetes mellitus or acquired immune deficiency syndrome (AIDS) are at higher risk for fungal UTIs.

Viral and parasitic infections are rare and usually are transferred to the urinary tract from an infection at another body site. For example, *Trichomonas*, a parasite found in the vagina, can also be found in the urine. Treatment of the vaginal infection (see Chapter 74) also resolves the UTI.

Noninfectious cystitis may result from chemical exposure, such as to drugs (e.g., cyclophosphamide [Cytoxan, Procytox]), from radiation therapy, and from immunologic responses, as with systemic lupus erythematosus (SLE).

Interstitial cystitis is a rare, chronic inflammation of the bladder, urethra, and adjacent pelvic muscles that is not a result of infection. The condition affects women ten times more often than men, and the diagnosis is difficult to make. Manifestations are similar to those of infectious cystitis with voiding occurring as often as 60 times daily, more intense urgency preceding urination, and suprapubic or pelvic pain,

CHART 69-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Minimizing Catheter-Related Infection

- Assess patients daily for those who no longer need indwelling catheters.
- Consider appropriate alternatives to an indwelling catheter.
- Use aseptic routine when handling catheter devices; manipulation can promote an environment favorable to pathogens.
- Select a small-size catheter (14 to 18 Fr with a 5-mL balloon).
- Use strict sterile technique to insert the catheter (in the hospital setting); a break in technique can introduce pathogens into the urinary tract.
- Do not inject more than 10 mL into the balloon.
- Maintain a closed-system irrigation by ensuring that catheter tubing connections are sealed securely; disconnections can introduce pathogens into the urinary tract.
- Avoid routine catheter irrigation.
- Keep urine collection bags below the level of the bladder at all times; elevating the collection bag above the bladder causes reflux of pathogens from the bag into the urinary tract.
- Secure the catheter to the patient's thigh (women) or lower abdomen (men); catheter movement can cause urethral friction and irritation.
- Perform daily catheter care by washing the perineum and proximal portion of the catheter with soap and water and drying gently (removes pathogens and reduces pathogenic population).
- Consider the use of coated catheters for patients requiring indwelling catheters for more than 3 to 5 days. This coating reduces bacterial colonization along the catheter.

Application of antiseptic solutions or antibiotic ointments to the perineal area of catheterized patients has not been demonstrated to have any beneficial effect.

Data from Smith, J. (2003). Indwelling catheter management: From habit to evidence-based practice. *Ostomy and Wound Management*, 49(12), 34-45.

sometimes radiating to the groin, vulva or rectum, that is relieved by voiding. Results from urinalysis and urine culture are negative for infection (Evans & Sant, 2007; Siegel et al., 2008).

Although cystitis is not life threatening, infectious cystitis can lead to life-threatening complications, including pyelonephritis and sepsis. Severe kidney damage is a rare complication unless the patient also has other predisposing factors, such as anatomic abnormalities, pregnancy, obstruction, reflux, calculi, or diabetes.

The spread of the infection from the urinary tract to the bloodstream is termed **urosepsis** and is more common among older adults (Kessenich, 2010). Sepsis from any source is a systemic infection that can lead to overwhelming organ failure, shock, and death. The most common cause of sepsis in the hospitalized patient is a UTI (CDC, 2009). Sepsis has a high mortality and prolongs hospital stays (see Chapter 39).

Incidence/Prevalence

The incidence of UTI is second only to that of upper respiratory infections in primary care. Patients who have **frequency** (an urge to urinate frequently in small amounts), **dysuria** (pain or burning with urination), and **urgency** (the feeling that urination will occur immediately) account for more than 5 million health care visits annually. About 50% of these patients will have a confirmed UTI (U.S. Renal Data Systems, 2010).

CONSIDERATIONS FOR OLDER ADULTS

The prevalence of UTIs varies with age and gender. Women of any age are more commonly affected with UTIs than are men. In men, the incidence of UTI greatly increases after 73 years of age. In women, the prevalence of UTIs increases from 20% among all women to 50% in those older than 80 years (U.S. Renal Data Systems, 2010). Skin and mucous membrane changes from a lack of estrogen appear to account for much of the increased risk in older women. Prostate disease increases risk for UTIs in men.

Health Promotion and Maintenance

Although cystitis is common, in many cases it is preventable. In the health care setting, reducing the use of indwelling urinary catheters is a major prevention strategy (Gray, 2010). When catheters must be used, strict attention to sterile technique during insertion can reduce the risk for UTIs as can consistent and adequate perineal and catheter care (see Chart 69-1).

! NURSING SAFETY PRIORITY

Action Alert

Ensuring that urinary catheters are used appropriately and discontinued as early as possible is everyone's responsibility. Do not allow catheters to remain in place for staff convenience.

Changes in fluid intake patterns, urinary elimination patterns, and hygiene patterns can help prevent or reduce cystitis in the general population. Teach all people to have a minimum fluid intake of 1.5 to 2.5 L daily unless fluid restriction is required for other health problems. Another strategy is to have sufficient fluid intake to cause 2 to 2.5 L of urine daily. Encourage people to drink more water rather than sugar-containing drinks. Teach people to avoid urinary stasis by urinating every 3 to 4 hours rather than waiting until the bladder is greatly distended. Encourage everyone either to shower daily or to wash the perineal and urethral areas daily with mild soap and a water rinse. Teach women to avoid the use of vaginal washes. Other hygiene measures that specifically reduce the risk for cystitis and other UTIs are listed in Chart 69-2.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

Frequency, urgency, and dysuria are the common manifestations of a urinary tract infection (UTI), but other manifestations may be present (Chart 69-3). Urine may be cloudy, foul smelling, or blood tinged. Ask the patient about risk factors for UTI during the assessment (see Table 69-1). For noninfectious cystitis, the Pelvic Pain and Urgency/Frequency (PUF) Patient Symptom Scale can identify patients with interstitial cystitis.

Before performing the physical assessment, ask the patient to void so that the urine can be examined and the bladder emptied before palpation. Assess vital signs to help rule out sepsis. Inspect the lower abdomen, and palpate the urinary

CHART 69-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Preventing a Urinary Tract Infection

- Drink at least 2 to 3 L of sugarless fluid every day.
- Be sure to get enough sleep, rest, and nutrition daily.
- [For women] Clean your perineum (the area between your legs) from front to back.
- [For women] Avoid using or wearing irritating substances, such as bubble bath, nylon underwear, and scented toilet tissue. Wear loose-fitting cotton underwear.
- [For women] Empty your bladder before and after intercourse.
- For both women and men, gently wash the perineal area before intercourse.
- Avoid the use of scented or flavored lubricants.
- If you experience burning when you urinate, if you have to urinate frequently, or if you find it difficult to begin urinating, notify your physician or other health care provider right away, especially if you have a chronic medical condition (e.g., diabetes) or are pregnant.
- Empty your bladder as soon as you feel the urge to urinate.
- Empty your bladder regularly (every 4 hours), even if you do not feel the urge to urinate.
- You may try these home therapies:
 - Cranberry juice (pure), 50 mL daily
 - Apple cider vinegar, 2 tablespoons three times daily in juice
 - Vitamin C, 500 mg daily to acidify the urine
- To prevent recurrent infection:
 - Take your prescribed antibiotic or other drug as directed, even after the symptoms go away.
 - Schedule a follow-up appointment for 10 to 14 days after you finish taking the drug. At your follow-up visit, another urine sample may be taken for analysis or culture.

CHART 69-3 KEY FEATURES

Urinary Tract Infection

Common Clinical Manifestations

- Frequency
- Urgency
- Dysuria
- Hesitancy or difficulty in initiating urine stream
- Low back pain
- Nocturia
- Incontinence
- Hematuria
- Pyuria
- Bacteriuria
- Retention
- Suprapubic tenderness or fullness
- Feeling of incomplete bladder emptying

Rare Clinical Manifestations

- Fever
- Chills
- Nausea or vomiting
- Malaise
- Flank pain

Clinical Manifestations that May Occur in the Older Adult

- The only symptom may be something as vague as increasing mental confusion or frequent, unexplained falls.
- A sudden onset of incontinence or a worsening of incontinence may be the only symptom of an early UTI.
- Fever, tachycardia, tachypnea, and hypotension, even without any urinary symptoms, may be signs of urosepsis.
- Loss of appetite, nocturia, and dysuria are common symptoms.

UTI, Urinary tract infection.

bladder. Distention after voiding indicates incomplete bladder emptying.

Using Standard Precautions, examine any lesions around the urethral meatus and vaginal opening. To help differentiate between a vaginal and a urinary tract infection, note whether

there is any vaginal discharge (vaginal discharge and irritation are more indicative of vaginal infection). Women often report burning with urination when normal acidic urine touches labial tissues that are inflamed or ulcerated by vaginal infections or sexually transmitted diseases (STDs). Maintain privacy with drapes during the examination.

The prostate is palpated by digital rectal examination (DRE) for size, change in shape or consistency, and tenderness. The physician or advanced practice nurse performs the DRE.

Laboratory Assessment

Laboratory assessment for a UTI is a urinalysis with testing for leukocyte esterase and nitrate. The combination of a positive leukocyte esterase and nitrate is 68% to 88% sensitive in the diagnosis of a UTI (Bowen & Hellstrom, 2007). Although a urinalysis can include a microscopic count of bacteria, white blood cells (WBCs), and red blood cells (RBCs), this additional testing is more expensive, is time consuming, and may not improve diagnostic accuracy. The presence of more than 20 epithelial cells/high power field (hpf) suggests contamination. The presence of 100,000 colonies/mL or the presence of three or more WBCs (pyuria) with RBCs (hematuria) indicates infection.

A urinalysis is performed on a clean-catch midstream specimen. If the patient cannot produce a clean-catch specimen, you may need to obtain the specimen with a small-diameter (6 Fr) catheter. For a routine urinalysis, 10 mL of urine is needed; smaller quantities are sufficient for culture.

A urine culture confirms the type of organism and the number of colonies. Urine culture is expensive, and results take at least 48 hours. It is indicated when the UTI is complicated or does not respond to usual therapy or the diagnosis is uncertain. A UTI is confirmed when more than 10^5 colony-forming units are in the urine from any patient. In patients who also have symptoms of UTI, as few as 10^3 colony-forming units may allow the diagnosis to be made. The presence of many different types of organisms in low colony counts usually indicates that the specimen is contaminated. Sensitivity testing follows culture results when complicating factors are present (e.g., stones or recurrent infection), when the patient is older, or to ensure the appropriate antibiotics are prescribed.

Occasionally the serum WBC count may be elevated, with the differential WBC count showing a “left shift” (see Chapter 19). This shift indicates that the number of immature WBCs is increasing in response to the infection. As a result, the number of bands, or immature WBCs, is elevated. Left shift most often occurs with urosepsis and rarely occurs with uncomplicated cystitis, which is a local rather than a systemic infection.

Other Diagnostic Assessment

The diagnosis of cystitis is based on the history, physical examination, and laboratory data. If urinary retention and obstruction of urine outflow are suspected, urography, abdominal sonography, or computed tomography (CT) may be needed to locate the site of obstruction or the presence of calculi. Voiding cystourethrography (see Chapter 68) is needed when ureteral reflux is suspected.

Cystoscopy (see Chapter 68) may be performed when the patient has recurrent UTIs (more than three or four a year).

A urine culture is performed first to ensure that no infection is present. If infection is present, the urine is sterilized with antibiotic therapy before the procedure to reduce the risk for sepsis. Cystoscopy identifies abnormalities that increase the risk for cystitis. Such abnormalities include bladder calculi, bladder diverticula, urethral strictures, foreign bodies (e.g., sutures from previous surgery), and **trabeculation** (an abnormal thickening of the bladder wall caused by urinary retention and obstruction). Retrograde pyelography, along with the cystoscopic examination, shows outlines and images of the drainage tract. Areas of obstruction or malformation and the presence of reflux are then identified early.

Cystoscopy is needed to accurately diagnose interstitial cystitis. A urinalysis usually shows WBCs and RBCs but no bacteria. Common findings in interstitial cystitis are a small-capacity bladder, the presence of Hunner's ulcers (a type of bladder lesion), and small hemorrhages after bladder distention.

INTERVENTIONS

Nonsurgical Management

The expected outcome is to maintain an optimal urinary elimination pattern. Nursing interventions for the management of cystitis focus on comfort and teaching about drug therapy, nutrition therapy, and prevention measures.

Drug Therapy. Drugs used to treat bacteriuria and promote patient comfort include urinary antiseptics or antibiotics, analgesics, and antispasmodics. Cure of a UTI depends on the antibiotic levels achieved in the urine (Chart 69-4). Oral antifungal agents are usually prescribed for fungal infections. When oral antifungal therapy is not sufficient, amphotericin B is most often given in daily bladder instillations. Antispasmodic drugs decrease bladder spasm and promote complete bladder emptying.

Antibiotic therapy is used for bacterial UTIs (see Chart 69-4). Guidelines indicate that a 3-day, high-dose course of trimethoprim/sulfamethoxazole or a fluoroquinolone is effective in treating uncomplicated, community-acquired UTIs in women (Bowen & Hellstrom, 2007). Fluoroquinolones cannot be used to treat UTIs during pregnancy because

of the potential for birth defects. The shorter courses increase adherence and reduce cost. Longer antibiotic treatment (7 to 21 days) and/or different agents are required for hospitalized patients; those with complicating factors, such as pregnancy, indwelling catheters, or stones; and those with diabetes or immunosuppression.

Long-term, low-dose antibiotic therapy is used for chronic, recurring infections caused by structural abnormalities or stones. Trimethoprim 100 mg daily may be used for long-term management of the older patient with frequent UTIs. For women who have recurrent UTIs after intercourse, one low-dose tablet of trimethoprim (TMP) (Proloprim, Trimpex) or TMP/sulfamethoxazole (half or single-strength Bactrim, Cotrim, Septra) or nitrofurantoin (Macrochantin, Nephronex ♣, Novofuran ♣) after intercourse is often prescribed. Estrogen used as an intravaginal cream may prevent recurrent UTIs in the postmenopausal woman, although this therapy is controversial.

WOMEN'S HEALTH CONSIDERATIONS

Pregnant women with a bacterial UTI require prompt and aggressive treatment because simple cystitis can lead to acute pyelonephritis during pregnancy. Pyelonephritis in pregnancy can cause preterm labor and adversely affect the fetus.

Nutrition Therapy. The diet should include all food groups and include more calories for the increased metabolism caused by infection. Urge patients to drink enough fluid to maintain a diluted urine throughout the day and night unless fluid restriction is required for other health problems. The drinking of 50 mL of concentrated cranberry juice daily appears to decrease the ability of bacteria to adhere to the epithelial cells lining the urinary tract, decreasing the incidence of symptomatic UTIs in some patients. Cranberry juice must be consumed for 3 to 4 weeks to be effective, and the efficacy of cranberry tablets has not been established (Bowen & Hellstrom, 2007). It is important to note that cranberry juice is an irritant to the bladder with interstitial cystitis and should be avoided by patients with this condition. Avoiding caffeine, carbonated beverages, and tomato products may decrease bladder irritation during cystitis.

Comfort Measures. A warm sitz bath taken two or three times a day for 20 minutes may provide comfort and some relief of local symptoms. If burning with urination is severe or urinary retention occurs, teach the patient to sit in the sitz bath and urinate into the warm water.

Surgical Management

Surgery for cystitis treats the conditions that increase the risk for recurrent UTIs (e.g., removal of obstructions and repair of vesicoureteral reflux). Procedures may include cystoscopy (see Chapter 68) to identify and remove calculi or obstructions.

Community-Based Care

Assess the patient's level of understanding of the problem. His or her knowledge about factors that promote the development of cystitis determines the teaching interventions planned.

Teach the patient how to take prescribed drugs. Stress the need for correct spacing of doses throughout the day and the

! NURSING SAFETY PRIORITY

Drug Alert

Two of the fluoroquinolone antibiotics, Tequin and Noroxin, are designated as sound-alike, look-alike agents with other drugs and could easily be administered in error. Take care to not confuse Tequin with Tegretol, an oral anticonvulsant, or with Ticlid, a platelet inhibitor. Take care to not confuse Noroxin with Neurontin, an oral anticonvulsant.

? NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client prescribed cephalexin (Keflex) for cystitis reports that she has had a severe allergic reaction to penicillin in the past. What is the nurse's best action?

- A. Reassure the client that Keflex is not penicillin.
- B. Place an allergy alert band on the client's wrist.
- C. Notify the prescriber before administering the first Keflex dose.
- D. Highlight this important information in the client's medical record.

CHART 69-4 COMMON EXAMPLES OF DRUG THERAPY

Urinary Tract Infections

DRUG/DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Antimicrobials			
Sulfonamides			
Trimethoprim*/sulfamethoxazole (Bactrim, Bacter-Aid, Septra, Sulfatrim, Sultrex, Roubac ) 160 mg trimethoprim/800 mg sulfamethoxazole orally every 12 hr	Drug reduces bacteria in the urinary tract by direct killing (trimethoprim) and by inhibiting bacterial reproduction (sulfamethoxazole).	Ask patients about drug allergies, especially to sulfa drugs, before beginning drug therapy. Teach patients to drink a full glass of water with each dose and to have an overall fluid intake of at least 3 L daily. Teach patients to keep out of the sun or to wear protective clothing outdoors and use a sunscreen. Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner.	Allergies to sulfa drugs are common and require changing the drug therapy. Sulfamethoxazole can form crystals that precipitate in the kidney tubules. Fluid intake prevents this complication. This drug increases skin sensitivity to the sun and can lead to severe sunburns, even in darker-skinned patients. Not completing the drug regimen can lead to an infection recurrence and to bacterial drug resistance.
Fluoroquinolones			
Ciprofloxacin (Cipro, ProQuin) 250 mg orally twice daily Gatifloxacin  (Tequin, Zymar) 200-400 mg orally or IV once daily Levofloxacin (Levaquin) 400 mg orally daily Lomefloxacin (Maxaquin) 250 mg orally daily Norfloxacin (Noroxin) 400 mg orally twice daily Ofloxacin (Floxin) 200 mg orally twice daily Sparfloxacin (Zagam) 200-400 mg orally daily	Drugs from this class reduce bacteria in the urinary tract by direct killing (bactericidal actions) and by inhibiting bacterial reproduction (bacteriostatic actions).	Teach patients taking the extended-release drugs to swallow them whole, not to crush or chew the tablets. Warn patients to not take the drug within 2 hours of taking an antacid. Teach patients how to take their pulse, to monitor it twice daily while on this drug, and to notify the prescriber if new-onset irregular heartbeats occur. Teach patients to keep out of the sun or to wear protective clothing outdoors and use a sunscreen. Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner.	Crushing or chewing the tablet releases all the drug at once, ruining the extended effect. Many antacids (especially those containing magnesium or aluminum) interfere with drug absorption. This class of drugs can induce serious cardiac dysrhythmias. Most quinolones increase skin sensitivity to the sun and can lead to severe sunburns even in darker-skinned patients. Not completing the drug regimen can lead to an infection recurrence and to bacterial drug resistance.
Penicillins			
Amoxicillin (Amoxil) 500 mg orally every 12 hr Amoxicillin/clavulanate (Augmentin, Clavulin ) 500 mg/125 mg orally every 12 hr	Drugs from this class reduce bacteria in the urinary tract by direct killing (bactericidal actions) as a result of interrupting bacterial cell wall synthesis.	Ask patients about drug allergies to penicillin before beginning drug therapy. Teach patients to take the drug with food. Instruct patients to call the prescriber if severe or watery diarrhea develops. Suggest that women who take oral contraceptives use an additional method of birth control while taking this drug. Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner.	Allergies to penicillin are common and require changing the drug therapy. Taking it with food reduces the risk for GI upset. A complication of penicillin therapy is pseudomembranous colitis, which may require discontinuing the drug. Penicillin appears to reduce the effectiveness of estrogen-containing oral contraceptives. Not completing the drug regimen can lead to an infection recurrence and to bacterial drug resistance.
Cephalosporins			
Cefadroxil (Duricef) 1-2 g orally every 12 hr Cefixime (Suprax) 400 mg orally every 12 to 24 hr	Drugs from this class reduce bacteria in the urinary tract by direct killing (bactericidal actions) as a result of interrupting bacterial cell wall synthesis.	Ask about drug allergies to penicillin or cephalosporins before beginning drug therapy. Instruct patients to call the prescriber if severe or watery diarrhea develops. Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner.	Drugs in this class are structurally similar to penicillin. Anyone with allergies to penicillin is likely to be allergic to the cephalosporins. A complication of penicillin therapy is pseudomembranous colitis, which may require discontinuing the drug. Not completing the drug regimen can lead to an infection recurrence and to bacterial drug resistance.

Continued

CHART 69-4 COMMON EXAMPLES OF DRUG THERAPY

Urinary Tract Infections—cont'd

DRUG/DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Fosfomycin (Monurol) 3 g orally as a one-time dose	This drug reduces bacteria in the urinary tract by direct killing (bactericidal actions) as a result of interrupting bacterial cell wall synthesis.	Instruct patients to mix the contents of a package in about $\frac{1}{2}$ cup of cold water, stir well, and drink all the liquid. Avoid taking this drug when also taking metoclopramide or any other drug that increases GI motility.	This oral drug is available as granules that must be dissolved before taking. Drugs that increase GI motility reduce the absorption of fosfomycin.
Urinary Antiseptics			
Nitrofurantoin (Furadantin, Macrobid, Macrodantin, Nephronex  , Urotoin) 100 mg orally every 12 hr	Drugs from this class usually reduce bacteria in the urinary tract by inhibiting bacterial reproduction (bacteriostatic actions).	Teach patients to shake the bottle well before measuring the drug. Suggest that patients obtain a calibrated spoon for liquid drugs and to not use household spoons. Teach patients to drink a full glass of water with each dose and to have an overall fluid intake of at least 3 L daily. Caution patients to complete the drug regimen even if the symptoms improve or disappear sooner.	Drug is a suspension and requires shaking to ensure homogeneity. Household spoons are not accurate for measuring drugs. Drug precipitates in the kidney tubules and damages the kidney. Fluid intake prevents this complication. Not completing the drug regimen can lead to an infection recurrence and to bacterial drug resistance.
Bladder Analgesics			
Phenazopyridine (Azo-Dine, Prodim, Pyridate, Pyridium, Uristat, Phenazo ) 200 mg orally 3 times daily, after meals	Drug reduces bladder pain and burning on urination by exerting a topical analgesic or local anesthetic effect on the mucosa of the urinary tract.	Remind patients that this drug will not treat an infection, only the symptoms. Teach patients to take the drug with or immediately after a meal. Warn patients that urine will turn red or orange.	Drug does not have any antibacterial actions. Food reduces the risk for GI disturbances. This expected response to the drug may stain clothing or toilets.
Antispasmodics			
Hyoscyamine (Anaspaz, Cystospaz, many others) 0.125 mg-0.25 mg orally 3 to 4 times daily	Drug relieves bladder spasms by inhibiting nerve stimulation to the bladder muscle.	Teach patients to notify the prescriber if blurred vision or other eye problems, confusion, dizziness or fainting spells, fast heartbeat, fever, or difficulty passing urine occurs. Teach patients to wear dark glasses in sunlight or other bright-light areas.	These are manifestations of drug toxicity. Drug dilates the pupil and increases eye sensitivity to light.

*Trimethoprim can be given alone to patients with a sulfa allergy.

need to complete all of the prescribed drugs. If the drug will change the color of the urine, as it does with phenazopyridine (Pyridium, Urogesic, Phenazo ) , inform the patient to expect this change. Offer techniques for remembering the drug schedule, such as the use of a daily calendar or the association of drugs with usual activities (e.g., mealtimes).

Patients may associate symptoms of discomfort with sexual activities and have feelings of guilt and embarrassment. Open and sensitive discussions with a woman who has recurrences of UTI after sexual intercourse can help her find techniques to handle the problem (see [Chart 69-2](#)). Explore with her the factors that contribute to her infections, such as sexual penetration when the bladder is full, diaphragm use, and her general resistance to infection. Some positions during intercourse may reduce urethral irritation and subsequent cystitis. Remind the patient that although perineal washing before intercourse is helpful, vigorous cleaning of the perineum with harsh soaps and vaginal douching may irritate the perineal tissues and increase the risk for UTI. At the patient's request, discuss the problem with her and her partner to help them find ways of maintaining their intimate relationship.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

The 26-year-old female patient with recurrent cystitis tells you that she now “holds” her urine all day and drinks very little to prevent the need to use the public toilet while at work. She is convinced that the toilet is the source of her repeated bladder infections.

1. Is this patient's understanding of the cause of recurrent cystitis correct? Why or why not?
2. What other assessment data should you obtain and why?
3. What will you tell her about the effectiveness of her actions to reduce the need to urinate at a public toilet?
4. What techniques could you suggest for her to use a public toilet for urination?

URETHRITIS

Pathophysiology

Urethritis is an inflammation of the urethra that causes symptoms similar to urinary tract infection (UTI). In men, manifestations include burning or difficulty urinating and a discharge from the urethral meatus. The most common cause

of urethritis in men is sexually transmitted diseases (STDs). These include gonorrhea or nonspecific urethritis caused by *Ureaplasma* (a gram-negative bacterium), *Chlamydia* (a sexually transmitted gram-negative bacterium), or *Trichomonas vaginalis* (a protozoan found in both the male and female genital tract).

In women, urethritis causes manifestations similar to those of bacterial cystitis. Urethritis is known by several other terms: *pyuria-dysuria syndrome*, *frequency-dysuria syndrome*, *trigonitis syndrome*, and *urethral syndrome*. Urethritis is most common in postmenopausal women and appears to be caused by tissue changes related to low estrogen levels.

PATIENT-CENTERED COLLABORATIVE CARE

Ask the patient about a history of STD, painful or difficult urination, discharge from the penis or vagina, and discomfort in the lower abdomen. Urinalysis may show **pyuria** (white blood cells [WBCs] in the urine) without a large number of bacteria. However, results of urethral culture may indicate an STD. In women, the diagnosis may be made by excluding cystitis when urinalysis and urethral culture are negative for bacteria but symptoms persist. In such cases, pelvic examination may reveal tissue changes from low estrogen levels in the vagina. Urethroscopy may show low estrogen changes with inflammation of urethral tissues.

STDs and infection are treated with antibiotic therapy. More information on STDs can be found in [Chapter 76](#).

Postmenopausal women often have improvement in their urethral symptoms with the use of estrogen vaginal cream. Estrogen cream applied locally to the vagina increases the amount of estrogen in the urethra as well, and irritating symptoms are reduced.

NONINFECTIOUS DISORDERS

URETHRAL STRICTURES

Urethral strictures are narrowed areas of the urethra. These problems may be caused by complications of an STD (usually gonorrhea) and by trauma during catheterization, urologic procedures, or childbirth. About one third of urethral strictures have no obvious cause. Strictures occur more often in men than in women. They may be a factor in other urologic problems, such as recurrent UTIs, urinary incontinence, and urinary retention.

The most common symptom of urethral stricture is obstruction of urine flow. Strictures rarely cause pain. Because urine stasis can result when flow is obstructed, the patient with a stricture is at risk for developing a UTI and may have overflow incontinence. **Overflow incontinence** is the involuntary loss of urine when the bladder is overdistended. Assess the patient for these two problems.

A urethral stricture is treated surgically. Dilation of the urethra (using a local anesthetic) is only a temporary measure, not a curative one. Stent placement can be used in some patients. The best chance of long-term cure is with **urethroplasty**, which is the surgical removal of the affected area with or without grafting to create a larger opening. The recurrence rate after surgery is still high, and most patients need repeated procedures. The urethral stricture location and length are the

most important factors affecting choice of interventions and recovery.

URINARY INCONTINENCE

Pathophysiology

Continence is the control over the time and place of urination and is unique to humans and some domestic animals. It is a learned behavior in which a person can suppress the urge to urinate until a socially appropriate location is available (e.g., a toilet). Efficient bladder emptying (i.e., coordination between bladder contraction and urethral relaxation) is needed for continence.

Incontinence is an involuntary loss of urine severe enough to cause social or hygienic problems. It is *not* a normal consequence of aging or childbirth and often is a stigmatizing and an underreported health problem. Many people suffer in silence, are socially isolated, and may be unaware that treatment is available. In addition, the cost of incontinence can be enormous.

Continence occurs when pressure in the urethra is greater than pressure in the bladder. For normal voiding to occur, the urethra must relax and the bladder must contract with enough pressure and duration to empty completely. Voiding should occur in a smooth and coordinated manner under a person's conscious control. Incontinence has several possible causes and can be either temporary or chronic ([Table 69-3](#)). Temporary causes usually do not involve a disorder of the urinary tract. The most common forms of adult urinary incontinence are stress incontinence, urge incontinence, overflow incontinence, functional incontinence, and a mixed form.

Stress incontinence is the most common type. Its main feature is the loss of small amounts of urine during coughing, sneezing, jogging, or lifting. In the continent person, the urethra can be relaxed and tightened under conscious control because skeletal muscles of the pelvic floor surround it. When a person feels the urge to urinate, the conscious contraction of the urethra can override a bladder contraction if the urethral contraction is strong enough.

Patients with *stress incontinence* cannot tighten the urethra enough to overcome the increased bladder pressure caused by contraction of the detrusor muscle. This is common after childbirth, when the pelvic muscles are stretched and weakened. The weakened pelvic floor allows the urethra to move during exertion. If the pelvic muscles are not strengthened, this condition continues. Low estrogen levels after menopause also contribute to stress incontinence. Vaginal, urethral, and pelvic floor muscles become thin and weak without estrogen.

Urge incontinence is the perception of an urgent need to urinate as a result of bladder contractions regardless of the volume of urine in the bladder. Normally when the bladder is full, contraction of the smooth muscle fibers of the bladder detrusor muscle signals the brain that it is time to urinate. Continent persons override that signal and relax the detrusor muscle for the time it takes to locate a toilet. Those who suffer from urge incontinence cannot suppress the signal and have a sudden strong urge to void and often leak large amounts of urine at this time. Urge incontinence is also known as an *overactive bladder* (OAB). Overactivity may have no known cause or may be the result of abnormal detrusor contractions

TABLE 69-3 TYPES OF URINARY INCONTINENCE

TYPE	DEFINITION/DESCRIPTION	CAUSE	CLINICAL MANIFESTATIONS
Stress incontinence	The involuntary loss of urine during activities that increase abdominal and detrusor pressure. Patients cannot tighten the urethra sufficiently to overcome the increased detrusor pressure; leakage of urine results.	Weakening of bladder neck supports; associated with childbirth. Intrinsic sphincter deficiency caused by such congenital conditions as epispadias (abnormal location of the urethra on the dorsum of the penis) or myelomeningocele. Acquired anatomic damage to the urethral sphincter (from repeated incontinence surgeries, prostatectomy, radiation therapy, and trauma).	Urine loss with physical exertion, cough, sneeze, or exercise. Usually only small amounts of urine are lost with each exertion. Normal voiding habits (≤ 8 times per day, ≤ 2 times per night). Post-void residual usually ≤ 50 mL. Pelvic examination shows hypermobility of the urethra or bladder neck with Valsalva maneuvers.
Urge incontinence	The involuntary loss of urine associated with a strong desire to urinate. Patients cannot suppress the signal from the bladder muscle to the brain that it is time to urinate.	Unknown.	An abrupt and strong urge to void. May have loss of large amounts of urine with each occurrence.
Detrusor hyperreflexia (reflex incontinence)	The abnormal detrusor contractions result from neurologic abnormalities.	Central nervous system (CNS) lesions from stroke, multiple sclerosis, and parasacral spinal cord lesions. Local irritating factors such as caffeine, medications, or bladder tumor.	Post-void residual ≤ 50 mL.
Overflow incontinence	The involuntary loss of urine associated with overdistention of the bladder when the bladder's capacity has reached its maximum. The urethra is obstructed, so it fails to relax sufficiently to allow urine to flow, resulting in incomplete bladder emptying or complete urinary retention, causing overflow incontinence.	Diabetic neuropathy; side effects of medication; after radical pelvic surgery or spinal cord damage; outlet obstruction. Causes external to the mechanism of the urethra: an enlarged prostate (male patients) and large genital prolapse (female patients). When the cause is intrinsic to the urethra, abnormal contraction of the skeletal muscle occurs, causing obstruction. This condition, called detrusor dyssynergia, is seen in patients with spinal cord injuries and multiple sclerosis.	Bladder distention, often up to the level of the umbilicus. Constant dribbling of urine.
Mixed incontinence	A combination of stress, urge, and overflow incontinence.	As with each separate disorder.	As with each separate disorder.
Functional incontinence	Leakage of urine caused by factors other than disease of the lower urinary tract.		Quantity and timing of urine leakage vary; patterns are difficult to discern.
Transient causes	Transient causes improve with treatment of the underlying condition.	Loss of cognitive functioning. Loss of awareness that urination is to occur in a socially acceptable place. Abnormal openings in the urinary tract, such as a fistula or diverticulum. Drugs, such as sedatives, hypnotics, diuretics, anticholinergics, decongestants, antihypertensives, and calcium channel blockers. Diabetes insipidus or psychogenic polydipsia. Inability to get to toileting facilities. Direct bladder pressure or urethral obstruction.	Altered mental state, as in delirium, confusion, depression, dementia, sepsis, mental illness, or severe psychological stress. Urinary drainage noted from areas other than the urinary meatus. Some drugs cause altered mental state; others cause increased urine production.
Permanent causes	Permanent causes are organic but may be improved with treatment.	Cognitive impairment. Traumatic or surgical effects. Those factors contributing to stress incontinence, urge incontinence, and overflow incontinence. Structural or functional defects of the bladder or the sphincters. Injuries or diseases of the spinal cord, brainstem, or cerebral cortex (neurogenic bladder). Congenital defects, including exstrophy of the bladder (bladder turned "inside out") and spina bifida.	Increased urine output. Restrains, restricted mobility. Constipation or fecal impaction. Clinical manifestations depend on the cause.

related to other problems. Such problems include stroke and other neurologic problems, other urinary tract problems, and irritation from concentrated urine or artificial sweeteners, caffeine, alcohol, and citric intake. Drugs, such as diuretics, and nicotine can also irritate the bladder.

Mixed incontinence is the presence of more than one type of incontinence. Often urine loss is related to both stress and urge incontinence. The manifestations mimic more than one subtype. This category is more common in older women.

Overflow incontinence occurs when the detrusor muscle fails to contract and the bladder becomes overdistended. This type of incontinence (also known as *reflex incontinence*) occurs when the bladder has reached its maximum capacity and some urine must leak out to prevent bladder rupture. Causes for the underactive (acontractile) bladder may or may not be determined.

The urethra can be obstructed and fail to relax enough to allow urine flow. Incomplete bladder emptying or urinary retention from urethral obstruction results in overflow incontinence.

Functional incontinence is incontinence occurring as a result of factors other than the abnormal function of the bladder and urethra. A common factor is the loss of cognitive function in patients affected by dementia. To maintain continence, a person must be aware that urination needs to occur in a socially acceptable place. Patients with dementia may not have that awareness.

Etiology and Genetic Risk

Incontinence may have temporary or permanent causes. Evaluation of the incontinent patient means considering all possible causes, beginning with those that are temporary and correctable. Surgical and traumatic causes of urinary incontinence are related to procedures or surgery in the lower pelvic structures, areas that contain complex nerve pathways. Radical urologic, prostatic, and gynecologic procedures for treatment of pelvic cancers may result in urinary incontinence. Injury to segments S2 to S4 of the spinal cord may cause incontinence from impairment of normal nerve pathways.

Inappropriate bladder contraction may result from disorders of the brain and nervous system or from bladder irritation due to chronic infection, stones, chemotherapy, or radiation therapy. Failure of bladder contraction occurs with neuropathy of diabetes mellitus and syphilis.

CONSIDERATIONS FOR OLDER ADULTS

Many factors contribute to urinary incontinence in older adults (Chart 69-5). An older person may have decreased mobility from many causes. In inpatient settings, mobility is limited when the older patient is restrained or placed on bedrest. Vision and hearing impairments may also prevent the patient from locating a call light to notify the nurse or assistive personnel of the need to void. Assess for these factors, and minimize them to prevent urinary incontinence. Getting out of bed to urinate is a common cause of falls among older adults.

Incidence/Prevalence

Incontinence is a major health problem that affects more than 13 million people of all ages in the United States (Agency for Health Care Policy and Research [AHCPR], 2001a); about 85% are women. It is most common in older adults, including

CHART 69-5 NURSING FOCUS ON THE OLDER ADULT

Factors Contributing to Urinary Incontinence*

Drugs

- Central nervous system depressants, such as opioid analgesics, decrease the patient's level of consciousness and the urge to void, and they contribute to constipation.
- Diuretics cause frequent voiding, often of large amounts of urine.
- Multiple drugs can contribute to changes in mental status or mobility, and they can irritate the bladder.
- Anticholinergic drugs or drugs with anticholinergic side effects are especially challenging, because they affect both cognition and the ability to void. Monitor patient responses to these drugs early in treatment.

Disease

- Cerebrovascular accidents and other neurologic disorders decrease mobility, sensation, or cognition.
- Arthritis decreases mobility and causes pain.
- Parkinson disease causes muscle rigidity and an inability to initiate movement.

Depression

- Depression decreases the energy necessary to maintain continence.
- Decreased self-esteem and feelings of self-worth decrease the importance to the patient of maintaining continence.

Inadequate Resources

- Patients who need assistive devices (e.g., eyeglasses, cane, walker) may be afraid to ambulate without them or without personal assistance.
- Products that help patients manage incontinence are often costly.
- No one may be available to assist the patient to the bathroom or help with incontinence products.

*These factors are in addition to the physiologic changes of aging given in Chapter 3.

15% to 30% of community-dwelling older people and at least one half of all nursing home residents (AHCPR, 2001a).

In adult patients younger than 65 years, urinary incontinence occurs twice as often in women as in men. Incontinence in women may occur after one or more pregnancies. Men in this age-group rarely experience incontinence unless they have prostate disease or a spinal cord injury.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Effective screening includes asking patients to respond “always,” “sometimes,” or “never” to these questions:

- Do you ever leak urine or water when you don't want to?
- Do you ever leak urine or water when you cough, laugh, or exercise?
- Do you ever leak urine or water on the way to the bathroom?
- Do you ever use pads, tissue, or cloth in your underwear to catch urine?

If any answer is “always” or “sometimes,” proceed with a focused assessment (AHCPR, 2001b) (Chart 69-6).

CHART 69-6 FOCUSED ASSESSMENT

The Patient with Urinary Incontinence

Note the presence of risk factors for urinary incontinence:	Detail the symptoms of urinary incontinence:
• Age • If female, menopausal status • Neurologic disease: • Parkinson disease • Dementia • Multiple sclerosis • Stroke • Spinal injury • Diabetes mellitus • Childbirth • Urologic procedures • Prescribed and over-the-counter drugs • Bowel patterns • Stress/anxiety level	• Leakage • Frequency • Urgency • Nocturia • Sensation of full bladder before leakage
	Obtain a 24-hour intake and output record or a voiding diary:
	• Time and amount of oral intake and continent voidings • Time and estimated amount of incontinent leakages • Activity around the time of leakage
	Assess the patient's:
	• Mobility • Self-care ability • Cognitive ability • Communication patterns
	Assess the environment for barriers to toileting:
	• Privacy • Restrictive clothing • Access to toilet

Data from Mather, K. (2002). Nursing assistants' perceptions of their ability to provide continence care. *Geriatric Nursing*, 23(2), 76-81; and Agency for Health Care Policy and Research (AHCPR). (1996; revised 2001). *Urinary incontinence in adults: Acute and chronic management. Clinical practice guideline*. AHCPR Publication No. 96-0682. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services; www.ahcpr.gov/clinic/uhistory.html (Clinical Practice Guidelines Online: *Urinary Incontinence Guideline: Real World Examples of Use*).

Incontinence may be underreported because health care professionals do not ask patients about urine loss. *Do not assume that patients will volunteer the information without specifically being asked.*

Physical Assessment/Clinical Manifestations

Assess the abdomen to estimate bladder fullness, to rule out palpable hard stool, and to evaluate bowel sounds. Determine the amount of *residual urine* (urine remaining in the bladder immediately after voiding) by portable ultrasound. With a health care provider's order, catheterizing the patient immediately after voiding can also be used to determine residual volume. Urinary incontinence is confirmed by evaluating the force and character of the urine stream during voiding. Asking the patient to cough while wearing a perineal pad is useful in evaluating stress incontinence; a wet pad on forceful coughing may indicate stress incontinence. A cystometrogram (see Chapter 68) is used most often for diagnosis.

For women, inspect the external genitalia to determine whether there is apparent urethral or uterine prolapse, **cystocele** (herniation of the bladder into the vagina), or rectocele. These conditions occur with pelvic floor muscle weakness. An advanced practice nurse puts on an examination glove and inserts two fingers into the vagina to assess the strength of these muscles. Strength is described as *weak*, *adequate*, or *strong* based on the amount of pressure felt by the nurse as the patient tightens her vaginal muscles. Describe and document the color, consistency, and odor of any secretions from the genitourinary orifices. The urine stream

interruption test (see Chapter 68) is another method of determining pelvic muscle strength. For men, inspect the urethral meatus for any discharge.

A digital rectal examination (DRE) is performed by the physician or advanced practice nurse on both male and female patients. It provides information about the nerve integrity to the bladder. The examiner determines whether there is tactile sensation in the anal area by observing whether the rectal sphincter is relaxed or contracted on digital insertion. Because nerve supply to the bladder is similar to nerve supply to the rectum, the presence of tactile sensation and a rectal sphincter that contracts suggest that the nerve supply to the bladder is intact. The health care provider assesses for prostate enlargement in men as a possible cause of incontinence.

Laboratory Assessment

A urinalysis is useful to rule out infection. This test is the first step in the assessment of incontinent patients of any age. The presence of red blood cells (RBCs), white blood cells (WBCs), leukocyte esterase, or nitrites is an indication for culturing the urine. Any infection is treated before further assessment of incontinence.

Imaging Assessment

Imaging is rarely needed unless surgery is being considered. Urography is most useful for locating the kidneys and ureters. A voiding cystourethrogram (VCUG) may be performed to assess the size, shape, support, and function of the bladder. Problems identified by this test include obstruction (especially prostate obstruction in men) and post-void residual (PVR). Assessment of PVR also can be made with a portable ultrasonographic bladder scanner.

Other Diagnostic Assessment

Patients who have unusual symptoms, medical complications, or a history of failed incontinence surgery may need urodynamic studies to determine the cause of their incontinence. These studies are not standardized procedures and may consist of any combination of these tests:

- Cystourethroscopy to examine the inside of the bladder and urethra directly
- Cystometrogram (CMG) to measure the pressure inside the bladder as it fills
- Urethral pressure profilometry (UPP) to measure the pressure in the urethra in relation to the bladder pressure during various activities
- Uroflowmetry to measure rate and degree of bladder emptying

Testing may take several hours and more than one visit.

Electromyography (EMG) of the pelvic muscles may be a part of the urodynamic studies. A perineometer is a tampon-shaped instrument inserted into the vagina to measure the strength of pelvic muscle contractions. The graph shows the amplitude of muscle contraction to the patient as a method of biofeedback.

ANALYSIS

Priority problems for patients with urinary incontinence include:

1. Stress Urinary Incontinence related to weak pelvic muscles and structural supports

2. Urge Urinary Incontinence related to decreased bladder capacity, bladder spasms, diet, and neurologic impairment
3. Reflex Urinary Incontinence related to neurologic impairment
4. Functional Urinary Incontinence related to impaired cognition or neuromuscular limitations
5. Complete urinary incontinence (mixed) related to many causes

PLANNING AND IMPLEMENTATION

Several interventions are useful for each type of incontinence in addition to drugs, surgical repair, and nutrition therapy.

Reducing Stress Urinary Incontinence

Planning: Expected Outcomes. With appropriate therapy, the patient with urinary incontinence is expected to develop urinary continence. Indicators include that the patient rarely or never demonstrates these actions:

- Urine leakage between voidings
- Urine leakage with increased abdominal pressure (e.g., sneezing, laughing, lifting)

Interventions. Initial interventions for patients with stress incontinence include keeping a diary, behavioral interventions, and drugs. Surgery also may be an option if other interventions are not effective. Explain the purpose of a detailed diary in which the patient records times of urine leakage, activities, and foods eaten. The diary is then used by the health care provider to plan and evaluate interventions. Collection devices, absorbent pads, and undergarments may be used during the sometimes lengthy process of assessment and treatment and by those patients who elect not to pursue further interventions.

Nonsurgical Management. Drug therapy and behavioral interventions (primarily diet and exercise) for stress incontinence require the patient's active participation for success. Nursing interventions focus on teaching patients about the drugs and behavioral strategies and on providing ongoing encouragement, clarification, and support to maximize intervention effects.

Pelvic floor (Kegel) exercise therapy for women with stress incontinence strengthens the muscles of the pelvic floor (circumvaginal muscles). These muscles become strengthened, as any other skeletal muscle does, by frequent, systematic, and repeated contractions.

The most important step in teaching pelvic muscle exercises is to help the patient learn which muscle to exercise. During the pelvic examination in women and the rectal examination in men or women, instruct the patient to tighten the pelvic muscles around your fingers. Then provide feedback about the strength of the contraction. Biofeedback devices, such as electromyography or perineometers (see discussion on p. 1500 in the Other Diagnostic Assessment section), measure the strength of contraction. Retention of a vaginal weight also shows that the patient has identified the proper muscle. Starting and stopping the urine stream or stopping the passage of flatus also indicates that the patient has correctly identified the pelvic muscles.

Instructions for pelvic muscle exercises are given in [Chart 69-7](#). Although improvement may take several months, most patients notice a positive change after 6 weeks. Teach patients to continue the exercises to maintain the improvement.

CHART 69-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Pelvic Muscle Exercises

- The pelvic muscles are composed of a sling of muscles that support your bladder, urethra, and vagina. Like any other muscles in your body, you can make your pelvic muscles stronger by alternately contracting (tightening) and relaxing them in regular exercise periods. By strengthening these muscles, you will be able to stop your urine flow more effectively.
- To identify your pelvic muscles, sit on the toilet with your feet flat on the floor about 12 inches apart. Begin to urinate, and then try to stop the urine flow. Do not strain down, lift your bottom off the seat, or squeeze your legs together. When you start and stop your urine stream, you are using your pelvic muscles.
- To perform pelvic muscle exercises, tighten your pelvic muscles for a slow count of 10 and then relax for a slow count of 10. Do this exercise 15 times while you are lying down, sitting up, and standing (a total of 45 exercises). Repeat—and this time rapidly contract and relax the pelvic muscles 10 times. This should take no more than 10 to 12 minutes for all three positions, or 3 to 4 minutes for each set of 15 exercises.
- Begin with 45 exercises a day in three sets of 15 exercises each. You will notice faster improvement if you can do this twice a day, or a total of 20 minutes each day. Remember to exercise in all three positions so your muscles learn to squeeze effectively despite your position. At first, it is helpful to have a designated time and place to do these exercises because you will have to concentrate to do them correctly. After you have been doing them for several weeks, you will notice improvement in your control of urine. However, many people report that improvement may take as long as 3 months.

Nutrition therapy in the form of weight reduction is helpful for obese patients because stress incontinence is made worse by increased abdominal pressure from obesity. Teach the patient to avoid alcohol, nicotine, artificial sweeteners, citrus, and caffeine (bladder irritants). Stress the importance of maintaining an adequate fluid intake, especially water. Refer the patient to the dietitian as needed.

Drug therapy can be useful for some people with stress incontinence. Because bladder pressure is greater than urethral resistance in patients with stress incontinence, drugs may be used to improve urethral resistance ([Chart 69-8](#)).

Estrogen is used to treat postmenopausal women with stress incontinence, although it is not known exactly how this drug helps improve continence. Estrogen may increase the blood flow and tone of the muscles around the vagina and urethra, thus improving the patient's ability to contract those muscles during times of increased intra-abdominal stress.

Vaginal cone therapy involves using a set of five small, cone-shaped weights. They are of equal size but of varying weights and are used together with pelvic muscle exercise. The woman inserts the lightest cone, labeled 1, into her vagina ([Fig. 69-1](#)), with the string to the outside, for a 1-minute test period. If she can hold the first cone in place without its slipping out while she walks around, she proceeds to the second cone, labeled 2, and repeats the procedure. The patient begins her treatment with the heaviest cone she can comfortably hold in her vagina for the 1-minute test period. Treatment periods are 15 minutes twice a day. When the patient can comfortably hold the cone in her vagina for the

15-minute period, she progresses to the next heaviest weight. Treatment is completed with the cone labeled 5.

Weighted vaginal cones can help strengthen the pelvic muscles and decrease stress incontinence but may not help pelvic prolapse. Vaginal cones do not require a prescription.

Other interventions for stress incontinence include behavior modification, psychotherapy, electrical stimulation devices to strengthen urethral contractions, and urethral plugs. Many intravaginal and intrarectal electrical stimulation devices have been used with varying degrees of success. More research is needed to determine the ideal level of stimulation and methods of reducing discomfort before electrical stimulation becomes a standard treatment for incontinence.

One brand of urethral plug is the Reliance insert. It is like a tiny tampon that the patient inserts into the urethra. After insertion, the patient inflates a tiny balloon, which rests at the bladder neck and prevents the flow of urine. To void, the patient pulls a string to deflate the balloon and removes the device. The applicator is reusable, although the tampon part is disposed of after each void.

Surgical Management. Stress incontinence may be corrected by vaginal, abdominal, or retropubic surgeries. Success rates vary between 50% and 90% for most procedures, but these rates are difficult to evaluate because of the varying

definitions of cure. Cure also may vary between short-term and long-term (over 5 years) results. Complications can be significant, with rates ranging from less than 2% for collagen or siloxane injection to 50% for bladder neck suspension.

Preoperative Care. Teach the patient about the procedure, and clarify the surgeon's explanation of events surrounding the surgery. Extensive urodynamic testing (see [Chapter 68](#)) is often performed before surgery, and you must explain the need for such thorough assessment to the patient and family.

Operative Procedures. The procedures used for women include repositioning the urethra and bladder, changing the structure of the involved tissues, or inserting artificial devices to improve function ([Table 69-4](#)).

Postoperative Care. After surgery, assess for and intervene to prevent or detect complications. For prevention of movement or traction on the bladder neck, secure the urethral catheter with tape or a tube holder. If a suprapubic catheter is used instead of a urethral catheter, monitor the dressing for urine leakage and other drainage. Catheters are usually in place until the patient can urinate easily and has residual urine volume after voiding of less than 50 mL. (See [Chapters 16 and 18](#) for a discussion of general care before and after surgery.)

CHART 69-8 COMMON EXAMPLES OF DRUG THERAPY

Urinary Incontinence

DRUG/DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Estrogen (Cenestin, Cenestin, Enjuvia, Premarin, C.E.S. ) 0.3-1.25 mg orally daily OR 2-4 g vaginal cream every other day	This drug reduces incontinence, possibly by improving vaginal and urethral blood flow and tone.	Teach patients to report any unusual vaginal bleeding to their health care provider. Teach patients to avoid smoking while on this drug and to report any calf pain or swelling.	Estrogen increases the risk for endometrial cancer. Estrogen increases the risk for thrombophlebitis, especially among women who smoke.
Anticholinergics/Antispasmodics			
Oxybutynin (Ditropan) 5 mg orally 3-4 times daily; (Ditropan XL) 5-10 mg orally daily Tolterodine (Detrol) 2 mg orally twice daily; (Detrol LA) 4 mg orally daily Propantheline (Pro-Banthine, Propanthel ) 7.5-30 mg orally 3-4 times daily Dicyclomine (Barmine, Bentyl) 10-40 mg orally 3-4 times daily Trospium (Sanctura) 20 mg orally every 12 hr	These drugs reduce incontinence by causing bladder muscle relaxation and suppressing the urge to void.	Ask whether the patient has glaucoma before starting the drug. Suggest that patients increase fluid intake and use hard candy to moisten the mouth. Teach patients to increase fluid intake and the amount of dietary fiber. Teach patients to monitor urine output and to report an output significantly lower than intake to the health care provider. Instruct patients taking the extended-release forms of these drugs not to chew or crush the tablet/capsule	Anticholinergics can increase intraocular pressure and make glaucoma worse. Dry mouth is a common side effect of drugs in this category. Constipation is a common side effect of drugs in this category. Drugs in this category can cause urinary retention. Crushing or chewing the tablet/capsule releases all the drug at once, ruining the extended effect and increasing the possibility of side effects
Tricyclic Antidepressants			
Imipramine (Tofranil, Novo-Pramine ) 25-100 mg orally 4 times daily Desipramine (Norpramin) 10-25 mg orally 3 times daily Nortriptyline (Pamelor, Aventyl) 10-25 mg orally 3 times daily	Drugs from this class have some anticholinergic actions and also block acetylcholine receptors. Both actions can relieve urinary incontinence.	Warn patients not to take these drugs with any other tricyclic antidepressants or MAO inhibitors. Teach patients to change positions slowly, especially in the morning. Teach patients the same interventions as for anticholinergic agents.	These drugs prolong the effects of catecholamines (epinephrine and norepinephrine) and lead to hypertensive crisis. These drugs cause dizziness and orthostatic hypotension and can increase the risk for falls. These drugs have anticholinergic activity and produce the same side effects.

MAO, Monoamine oxidase.

FIG. 69-1 **A**, FemTone vaginal weights, or cones. The number on the top of each cone represents increasing weight up to the heaviest cone, a 5. **B**, Diagram showing the correct positioning of a vaginal weight, or cone, in place.

Reducing Urge Urinary Incontinence

Planning: Expected Outcomes. The patient with urinary incontinence is expected to use techniques to prevent or manage urge incontinence. Indicators include that the patient often or consistently demonstrates these behaviors:

- Responds to urge in a timely manner
- Gets to toilet between urge and passage of urine
- Avoids substances that stimulate the bladder (e.g., caffeine, alcohol)

Interventions. Interventions for patients with urge incontinence or overactive bladder include behavioral interventions and drugs. Surgery is not the recommended treatment of this condition. Collection devices and absorbent pads and undergarments may be used.

Drug Therapy. Because the hypertonic bladder contracts involuntarily in patients with urge incontinence, drugs that relax the smooth muscle and increase the bladder's capacity are prescribed (see Chart 69-8).

The most effective drugs are anticholinergics, such as propantheline (Pro-Banthine, Propanthel $\clubsuit$), and anticholinergics with smooth muscle relaxant properties, such as oxybutynin (Ditropan and Ditropan XL), tolterodine (Detrol and Detrol LA), and dicyclomine hydrochloride (Barmine, Bentyl, Spasmodan $\clubsuit$), all of which inhibit the nerve fibers that stimulate bladder contractions. Anticholinergic drugs have serious side effects and are used along with behavioral interventions. Tricyclic antidepressants with anticholinergic and alpha-adrenergic agonist activity, such as imipramine (Tofranil, Novopramine $\clubsuit$), have been used successfully. The effectiveness of other drugs, such as flavoxate (Urispas) and

TABLE 69-4 SURGICAL PROCEDURES FOR STRESS INCONTINENCE

PROCEDURE	PURPOSE	NURSING CONSIDERATIONS
Anterior vaginal repair (colporrhaphy)	Elevates the urethral position and repairs any cystocele.	Because the operation is performed by vaginal incision, it is often done in conjunction with a vaginal hysterectomy. Recovery is usually rapid, and a urethral catheter is in place for 24-48 hr.
Retropubic suspension (Marshall-Marchetti-Krantz or Burch colposuspension)	Elevates the urethral position and provides longer-lasting results.	The operation requires a low abdominal incision and a urethral or suprapubic catheter for several days postoperatively. Recovery takes longer, and urinary retention and detrusor instability are the most frequent complications.
Needle bladder neck suspension (Pereyra or Stamey procedure)	Elevates the urethral position and provides longer-lasting results without a long operative time.	The combined vaginal approach with a needle and a small suprapubic skin incision does not allow direct vision of the operative site; however, the high complication rates may be due to the selection of patients who, because of their medical condition, are not good candidates for longer retropubic procedures.
Pubovaginal sling procedures	A sling made of synthetic or fascial material is placed under the urethrovesical junction to elevate the bladder neck.	The operation uses an abdominal, vaginal, or combined approach to treat intrinsic sphincter deficiencies. Temporary or permanent urinary retention is common postoperatively.
Midurethral sling procedures	A tensionless vaginal sling is made from polypropylene mesh (or other materials) and placed near the urethrovesical junction to increase the angle, which inhibits movement of urine into the urethra with lower intravesicular pressures.	This outpatient procedure uses a vaginal approach to improve symptoms of stress incontinence. Temporary or permanent urinary retention is common postoperatively.
Artificial sphincters	A mechanical device to open and close the urethra is placed around the anatomic urethra.	The operation is done more frequently in men. The most common complications include mechanical failure of the device, erosion of tissue, and infection.
Periurethral injection of collagen or Siloxane	Implantation of small amounts of an inert substance through several small injections provides support around the bladder neck.	The procedure can be done in an ambulatory care setting and can be repeated as often as necessary. Certain compounds may migrate after injection; an allergy test to bovine collagen must be performed before implantation.

the antihistamines, NSAIDs, beta-adrenergic agonists, and calcium channel blockers, has yet to be determined.

! NURSING SAFETY PRIORITY

Drug Alert

Teach patients taking the extended-release forms of anticholinergic drugs to swallow the tablet or capsule whole without chewing it or crushing it. Chewing or crushing the tablet/capsule ruins the extended-release feature, allowing the entire dose to be absorbed quickly, which increases drug side effects.

? NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

While assessing a client with overactive bladder, the nurse discovers the client also has the following health problems. Which health problem could be made worse by the drug *tolterodine* (Detrol)?

- A. Asthma
- B. Glaucoma
- C. Hypotension
- D. Diabetes mellitus

Nutrition Therapy. Teach the patient to avoid foods that have a direct bladder-stimulating or diuretic effect, such as caffeine and alcohol. Spacing fluids at regular intervals throughout the day (e.g., 120 mL every hour or 240 mL every 2 hours) and limiting fluids after the dinner hour (e.g., only 120 mL at bedtime) help avoid fluid overload on the bladder and allow urine to collect at a steady pace.

Behavioral Interventions. Behavioral interventions for urge incontinence include bladder training, habit training, exercise therapy, and electrical stimulation.

Interventions for urinary bladder training and urinary habit training are listed in [Chart 69-9](#). It can be difficult for patients to use these interventions because they involve a great deal of patient participation. Provide ongoing encouragement, clarification, and support to increase the effects of all interventions. Behavioral interventions are often combined with drug therapy for greatest effect.

Bladder training is an education program for the patient that begins with a thorough explanation of the problem of urge incontinence. Instead of the bladder being in control of the patient, the patient learns to control the bladder. For the program to succeed, he or she must be alert, aware, and able to resist the urge to urinate.

Start a schedule for voiding, beginning with the longest interval that is comfortable for the patient, even if the interval is only 30 minutes. Instruct the patient to void every 30 minutes and to ignore any urge to urinate between the set intervals. Once he or she is comfortable with the starting schedule, increase the interval by 15 to 30 minutes. Instruct the patient to follow the new schedule until he or she achieves success again. As the interval increases, the bladder gradually tolerates more volume. Teach him or her relaxation and distraction techniques to maximize success in the retraining. Provide positive reinforcement for maintaining the prescribed schedule.

Habit training (scheduled toileting) is a type of bladder training that is successful in reducing incontinence in cognitively impaired patients. To use habit training, caregivers assist the patient in voiding at specific times (e.g., every 2

CHART 69-9 BEST PRACTICE FOR PATIENT SAFETY AND QUALITY CARE

Bladder Training and Habit Training to Reduce Urinary Incontinence

Bladder Training

- Assess patient's awareness of bladder fullness and ability to cooperate with training regimen.
- Assess the patient's 24-hour voiding pattern for 2 to 3 consecutive days.
- Base the initial interval of toileting on the voiding pattern (e.g., 45 minutes).
- Teach the patient to void every 45 minutes on the first day and to ignore or suppress the urge to urinate between the 45-minute intervals.
- Take the patient to the toilet or remind him or her to urinate at the 45-minute intervals.
- Provide privacy for toileting and run water in the sink to promote the urge to urinate at this time.
- If the patient is not consistently able to resist the urge to urinate between the intervals, reduce the intervals by 15 minutes.
- Continue this regimen for at least 24 hours or for as many days as it takes for the patient to be comfortable with this schedule and not urinate between the intervals.
- When the patient remains continent between the intervals, increase the intervals by 15 minutes daily until a 3- to 4-hour interval is comfortable for the patient.
- Praise successes. If incontinence occurs, work with the patient to re-establish an acceptable toileting interval.

Habit Training

- Assess the patient's 24-hour voiding pattern for 2 to 3 days.
- Base the initial interval of toileting on the voiding pattern (e.g., 2 hours).
- Assist the patient to the toilet or provide a bedpan/urinal every 2 hours (or whatever has been determined to be an appropriate toileting interval for the individual patient).
- During the toileting, remind the patient to void and provide cues such as running water.
- If the patient is incontinent between scheduled toileting, reduce the time interval by 30 minutes until the patient is continent between voidings.
- Assist the patient to toilet and prompt to void at prescribed intervals.
- Do not leave the patient on the toilet or bedpan for longer than 5 minutes.
- Ensure that all nursing staff members comply with the established toileting schedule and do not apply briefs or encourage the patient to "just wet the bed."
- Reduce toileting interval by 30 minutes if there are more than two incontinence episodes in 24 hours.
- If the patient remains continent at the toileting interval, attempt to increase the interval by 30 minutes until a 3- to 4-hour continence interval is reached.
- Praise the patient for successes, and spend extra time socializing with the patient.
- When incontinence occurs, ensure that the patient and bed are cleaned appropriately but do not spend extra time socializing with the patient.
- Discuss daily record of continence with staff to provide reinforcement and encourage compliance with toileting schedule.
- Include unlicensed assistive personnel in all aspects of the habit training.

hours on the even hours). The goal is to get the patient to the toilet before incontinence occurs. The focus is on reducing incontinence. When that has been achieved, the focus may change to increase bladder capacity by gradually lengthening the voiding intervals, but this is only secondary.

! NURSING SAFETY PRIORITY

Action Alert

Habit training is undermined when unlicensed assistive personnel (UAP) apply absorbent briefs or tell patients to “just wet the bed.” This practice also increases the risk for falls because patients may try to get out of bed unassisted to use the toilet. Work with all staff members, including UAP, to implement consistently the toileting schedule for habit training.

Prompted voiding, a supplement to habit training, attempts to increase the patient’s awareness of the need to void and to prompt him or her to ask for toileting assistance. Habit training otherwise relies completely on a time schedule.

Exercise therapy with pelvic muscle exercises for urge incontinence has been helpful and is taught in the same way as for stress incontinence (see [Chart 69-7](#)). Improved urethral resistance helps the patient overcome abnormal detrusor contractions long enough to get to the toilet.

Electrical stimulation with either an intravaginal or intra-rectal electrical stimulation device is available to treat both urge and stress incontinence.

Reducing Reflex Urinary Incontinence

Planning: Expected Outcomes. With appropriate intervention, the patient with reflex incontinence is expected to achieve continence. Indicators include that the patient often or consistently demonstrates these behaviors:

- Recognizes the urge to void
- Maintains a predictable pattern of voiding
- Responds to urge in a timely manner
- Empties bladder completely
- Keeps urine volume in the bladder under 300 mL to prevent overdistention

Interventions. Interventions for the patient with reflex (overflow) incontinence caused by obstruction of the bladder outlet may include surgery to relieve the obstruction. The most common surgical procedures are prostate removal (see [Chapter 75](#)) and repair of uterine prolapse (see [Chapter 74](#)). For overflow incontinence related to detrusor muscle weakness, the most effective methods of treatment are the behavioral interventions of bladder compression and intermittent self-catheterization.

Drug Therapy. Drugs are prescribed for short-term management of urinary retention, often after surgery. They are not used in long-term management of overflow incontinence caused by a hypotonic bladder. The most commonly used drug is bethanechol chloride (Urecholine), an agent that increases bladder pressure.

Behavioral Interventions. The most common behavioral interventions are bladder compression and intermittent self-catheterization.

Bladder compression uses techniques that promote bladder emptying and include the Credé method, the Valsalva maneuver, double-voiding, and splinting.

For the Credé method, teach the patient how to press over the bladder area, increasing its pressure, or to trigger nerve

stimulation by tugging at pubic hair or massaging the genital area. These techniques manually assist the bladder in emptying. In the Valsalva maneuver, breathing techniques increase chest and abdominal pressure. This increased pressure is then directed toward the bladder during exhalation. With the technique of double-voiding, the patient empties the bladder and then, within a few minutes, attempts a second bladder emptying.

For women who have a large *cystocele* (prolapse of the bladder into the vagina), a technique called *splinting* both compresses the bladder and moves it into a better position. The woman inserts her fingers into her vagina, gently lifts the cystocele, and begins to urinate.

Intermittent self-catheterization is often used to help patients with long-term problems of incomplete bladder emptying. It is effective, can be learned fairly easily, and remains the preferred method of bladder emptying in patients who have incontinence as a result of a neurogenic bladder ([Newman & Willson, 2011](#)). These points are important in teaching the technique:

- Proper handwashing and cleaning of the catheter reduce the risk for infection.
- A small lumen and good lubrication of the catheter prevent urethral trauma.
- A regular schedule for bladder emptying prevents distention and mucosal trauma.

Patients must be able to understand instructions and have the manual dexterity to manipulate the catheter. Caregivers or family members in the home can also be taught to perform straight catheterization using a clean (rather than sterile) technique with good outcomes ([Kannankeril et al., 2011](#)).

Reducing Functional Urinary Incontinence

Planning: Expected Outcomes. The patient with functional urinary incontinence is expected to remain dry. Indicators include that the patient often or consistently demonstrates these behaviors:

- Uses urine containment or collection measures to ensure dryness
- Manages clothing independently

Interventions. Causes of functional (or chronic intractable) incontinence vary greatly. Some are reversible, and others are not. The focus of intervention is treatment of reversible causes. When incontinence is not reversible, urinary habit training (see discussion of habit training, p. 1504) is used to establish a predictable pattern of bladder emptying to prevent incontinence. A final strategy focuses on containment of the urine and protection of the patient’s skin. Nonsurgical interventions include applied devices, containment, and catheterization.

Applied devices include intravaginal pessaries for women and penile clamps for men. The intravaginal pessary supports the uterus and vagina and helps maintain the correct position of the bladder. (See [Chapter 74](#) for further discussion of pessaries.) The penile clamp is applied around the outside of the penis to compress the urethra and prevent urine leakage.

The dangers of pessaries and penile clamps include damage to the tissues and infection from constant pressure in sensitive areas. Both devices require either that the patient has manual dexterity or that a caregiver applies and removes the device. Instruct the patient or caregivers in the use of

these devices. Male patients may use an external collecting device, such as a condom catheter. Design of an effective external collecting device for women has not been as successful.

Containment is achieved with absorbent pads and briefs designed to collect urine and keep the patient's skin and clothing dry. Many types and sizes of pads are available:

- Shields or liners inserted inside a panty
- Undergarments consisting of full-size pads with waist straps
- Plastic-lined protective underpants with or without elastic legs
- Combination pad and pant systems
- Absorbent bed pads

A major concern with the use of protective pads is the risk that skin breakdown will occur. Materials and costs vary. Some are reusable; others are disposable. The disposal of these products raises ecologic concerns. Avoid use of the word "diaper" when discussing these adult protective pants, however, because of the usual association of diapers with a baby.

Catheterization for control of incontinence may be intermittent or involve an indwelling catheter. Intermittent catheterization is preferred to an indwelling catheter because of the reduced risk for infection. An indwelling urinary catheter is appropriate for patients with skin breakdown who need a dry environment for healing, for those who are terminally ill and need comfort, and for those who are critically ill and require careful measurement of urine output.

Reducing Total or Mixed Urinary Incontinence

Total or mixed urinary incontinence is a combination of two or more types of involuntary urine loss syndromes. For example, stress incontinence and urge incontinence often occur together in women during and after menopause. For the patient with total or mixed incontinence, combinations of assessment techniques (as discussed under each syndrome) are used. Interventions are also combined to promote continence. The problems and interventions for mixed incontinence are the same as for each specific type of incontinence separately. After identifying the specific types of incontinence an individual patient has, apply the appropriate priority patient problems, interventions, and expected outcomes discussed earlier with each incontinence type.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

The patient is a 32-year-old woman who is 8 weeks postpartum from a vaginal delivery of her first child, a 9-pound boy. She has recently taken up running again and reports a small loss of urine with every running step. She states her mother has had a continuing problem with incontinence for years and seldom leaves her home. The patient is worried that this problem is genetic and will only get worse with time. She is also worried that if surgery is needed to correct the problem, she will have to stop breast-feeding her infant.

1. What other information should you obtain from this patient?
2. What type or types of incontinence is she most likely to have from the information she has provided thus far?
3. Is this problem likely to be genetic? Why or why not?
4. What will you tell her regarding surgery and her concern about being separated from her infant?
5. What measures can you recommend to help reduce her incontinence?

Community-Based Care

Community-based care for the patient with urinary incontinence considers his or her personal, physical, emotional, and social resources. Important personal resources for self-care include mobility, vision, and manual dexterity. When planning care, consider who will be the primary caregiver and what factors may influence the effectiveness of the plan.

Home Care Management

Assess the home environment for barriers that limit access to the bathroom. Eliminate hazards that might slow walking or lead to a fall. Such hazards include throw rugs, furniture with legs that extend into the walking area, slippery waxed or polished floors, and poor lighting.

If the patient must climb stairs to reach a bathroom, handrails should be installed and stairs kept free of obstacles. Toilet seat extenders may help provide the right level of seating so that maximal abdominal pressure may be applied for voiding. Portable commodes may be obtained when ambulatory access to toilets is impractical or impossible. Physical and occupational therapists are valuable resources for assisting with home care management.

Teaching for Self-Management

Teach the patient and family about the cause of the specific type of incontinence, and discuss available treatment options for its management. The teaching plan addresses the prescribed drugs (purpose, dosage, method and route of administration, and expected and potential side effects). Instruct the patient and family about the importance of weight reduction and dietary modification to help control urinary incontinence. Remind the patient who smokes that nicotine can contribute to bladder irritation and that smoker's cough can cause urine leakage.

When external devices or protective pads are needed, describe the possible options, discuss the advantages and disadvantages of each, and help the patient make a selection best for his or her lifestyle and resources. For patients who will use intermittent catheterization or those with artificial urinary sphincters, demonstrate the correct technique to the patient or caregiver. Evaluate return demonstrations for correct technique. [Chart 69-10](#) also addresses teaching.

Psychosocial Preparation

The embarrassment of incontinence can be devastating to a patient's self-esteem, body image, and relationships. Sexual intimacy is often adversely affected by incontinence. The unpredictable nature of incontinence creates anxiety. Patients are often embarrassed to seek help, and even when resources are identified, they may need help to feel comfortable in using the resources. Buying supplies at a local store may threaten privacy.

Accept and acknowledge the personal concerns of the patient and caregiver. Never make their concerns seem trivial. Help the patient learn methods of managing the fear or anxiety. As he or she learns the specifics of the plan that will allow control of urinary incontinence, the confidence to resume social interactions should return.

Health Care Resources

Referral to home care agencies for help with personal care and to continence clinics that specialize in evaluation and treatment may be helpful. In many continence clinics, nurses

CHART 69-10 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Urinary Incontinence

- Maintain a normal body weight to reduce the pressure on your bladder.
- Do not try to control your incontinence by limiting your fluid intake. Adequate fluid intake is necessary for kidney function and health maintenance.
- If you have a catheter in your bladder, follow the instructions given to you about maintaining the sterile drainage system.
- If you are discharged with a suprapubic catheter in your bladder, inspect the entry site for the tube daily, clean the skin around the opening gently with warm soap and water, and place a sterile gauze dressing on the skin around the tube. Report any redness, swelling, drainage, or fever to your physician.
- Do not put anything into your vagina, such as tampons, drugs, hygiene products, or exercise weights, until you check with your physician at your 6-week checkup after surgery.
- Do not have sexual intercourse until after your 6-week postoperative checkup.
- Do not lift or carry anything heavier than 5 pounds or participate in any strenuous exercise until your physician gives you postoperative clearance. In some cases, this could be as long as 3 months.
- Avoid exercises, such as running, jogging, step or dance aerobic classes, rowing, cross-country ski or stair-climber machines, and mountain biking. Brisk walking without any additional hand, leg, or body weights is allowed. Swimming is allowed after all drains and catheters have been removed and your incision is completely healed.
- If Kegel exercises are recommended, ask your nurse for specific instructions.

collaborate with physicians and other health care professionals to evaluate and manage patients. The treatment plan is specific for each patient; supplies and products are custom selected.

Patients may benefit from education and from the support of others who experience similar concerns. The National Association for Continence (NAFC) (www.nafc.org), Access to Continence Care and Treatment (www.wellweb.com/INCONT/acct/contents.htm), and the Wound, Ostomy, and Continence Nurses (www.wocn.org) publish newsletters and educational materials written with simple, easy-to-understand explanations. The American Foundation for Urologic Disease (www.afud.com) provides information on many areas of bladder dysfunction. The Agency for Healthcare Research and Quality (AHRQ) has also published a caregiver guide (AHCPR Publication No. 96-0683) for the public that is available on the Internet or by calling (800) 358-9295. Local hospitals often have local NAFC-approved support groups.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

- For which client living at home is intermittent self-catheterization an inappropriate method for incontinence management?
- 36-year-old woman who is blind
 - 46-year-old man who has paraplegia
 - 56-year-old woman who has diabetes
 - 66-year-old man who has severe osteoarthritis

EVALUATION: OUTCOMES

Evaluate the care of the patient with urinary incontinence based on the identified priority patient problems. The expected outcomes are that the patient will:

- Describe the type of urinary incontinence experienced
- Demonstrate knowledge of proper use of drugs and correct procedures for self-catheterization, use of the artificial sphincter, or care of an indwelling urinary catheter
- Demonstrate effective use of the selected exercise or bladder-training program
- Select and use incontinence devices and products
- Have a reduction in the number of incontinence episodes

Specific indicators for these outcomes are listed for each priority patient problem under the Planning and Implementation section (see earlier).

UROLITHIASIS

Pathophysiology

Urolithiasis is the presence of *calculi* (stones) in the urinary tract. Stones often do not cause symptoms until they pass into the urinary tract, where they can cause excruciating pain. **Nephrolithiasis** is the formation of stones in the kidney. Formation of stones in the ureter is **ureterolithiasis**.

Urologic stones are caused by many disorders. However, the exact mechanism of stone formation is not entirely understood. Everyone excretes crystals in the urine at some time, but fewer than 10% of people form stones. Most stones contain calcium (calcium oxalate or calcium phosphate) as one part of the stone complex. Struvite (15%), uric acid (8%), and cystine (3%) are more rare compositions of stones. Formation of stones involves three conditions:

- Slow urine flow, resulting in supersaturation of the urine with the particular element (e.g., calcium) that first becomes crystallized and later becomes the stone
- Damage to the lining of the urinary tract (e.g., abrasion from crystals)
- Decreased amounts of inhibitor substances in the urine that would otherwise prevent supersaturation and crystal aggregation

High urine acidity (as with uric acid and cystine stones) or alkalinity (as with calcium phosphate and struvite stones) and drugs (as with triamterene, indinavir, and acetazolamide) contribute to stone formation.

One example of a metabolic problem causing stone formation begins when excessive amounts of calcium are absorbed through the intestinal tract (the most common cause of hypercalciuria). As blood circulates through the kidneys, the excess calcium is filtered into the urine, causing supersaturation of calcium in the urine. If fluid intake is poor, such as when a patient is dehydrated, supersaturation is more likely to occur and the risk for calcium combining with another compound to form a larger molecule increases. Calcium complexes often serve as a center for other deposits, and eventually a stone forms.

Stones that form in the kidney and then pass into the ureter often lodge in areas where the ureter bends or slightly changes shape. When the stone occludes the ureter and blocks

the flow of urine, the ureter dilates. Enlargement of the ureter is called **hydroureter**.

The pain associated with ureteral spasm is excruciating and may cause the patient to go into shock from stimulation of nearby nerves. In addition, **hematuria** (bloody urine) may result from damage to the urothelial lining. If the obstruction is not removed, urinary stasis can cause infection and impair kidney function on the side of the blockage. As the blockage persists, **hydronephrosis** (enlargement of the kidney caused by blockage of urine lower in the tract and filling of the kidney with urine) and permanent kidney damage may develop.

Etiology and Genetic Risk

The cause of urolithiasis is unknown. At least 90% of patients who form stones have a metabolic risk factor. Table 69-5 lists some metabolic problems that often cause stone formation.

A diet high in calcium is not believed to cause stones unless a metabolic problem or kidney tubule defect already exists. Data suggest that a normal-calcium diet that is relatively low in animal protein, sodium, or both may help prevent stone formation. A low-calcium diet does not prevent stone formation (Brenner, 2008). Urinary stasis, urinary retention, immobility, and dehydration all increase the risk for stones to form. Except for the use of the thiazides for calcium oxalate stones, diuretics can cause volume depletion and thus may promote the formation of stones. Generally, fluid intake sufficient to cause a urine output of 2 to 2.5 L daily is recommended.

TABLE 69-5 METABOLIC DEFECTS THAT COMMONLY CAUSE CALCULI

METABOLIC DEFICIT	ETIOLOGY
Hypercalcemia	
Primary	Absorptive: increased intestinal calcium absorption Renal: decreased kidney tubular excretion of calcium
Secondary	Resorptive: hyperparathyroidism, vitamin D intoxication, kidney tubular acidosis, prolonged immobilization
Hyperoxaluria	
Primary	Genetic: autosomal recessive trait resulting in high oxalate production
Secondary	Dietary: excess oxalate from foods such as spinach, rhubarb, Swiss chard, cocoa, beets, wheat germ, pecans, peanuts, okra, chocolate, and lime peel
Hyperuricemia	
Primary	Gout is an inherited disorder of purine metabolism (20% of patients with gout have uric acid calculi)
Secondary	Increased production or decreased clearance of purine from myeloproliferative disorders, thiazide diuretics, carcinoma
Struvite	Made of magnesium ammonium phosphate and carbonate apatite; formed by urea splitting by bacteria, most commonly, <i>Proteus mirabilis</i> ; needs an alkaline urine to form
Cystinuria	Autosomal recessive defect of amino acid metabolism that precipitates insoluble cystine crystals in the urine

GENETIC/GENOMIC CONSIDERATIONS

More than 30 genetic variations are associated with the formation of kidney stones. Single gene disorders are rare. More commonly, nephrolithiasis is a complex disease, with genetic variation in intestinal calcium absorption, kidney calcium transport, or kidney phosphate transport all associated with stone formation (Brenner, 2008). Always ask a patient with a kidney or ureteral stone whether other family members have also had this problem.

Incidence/Prevalence

The incidence of stone disease is high and varies with geographic location, race, and family history. About 12% of adults will have at least one episode of kidney stone disease. The incidence is higher in men; however, struvite stones are twice as common in women. Recurrence rates vary depending on the type of treatment. The recurrence rate of untreated calcium oxalate stones is 35% to 50% in 5 to 10 years. A higher recurrence of stones occurs in patients with a family history of stone disease and in those who had their first occurrence by age 25 years.

CULTURAL AWARENESS

The incidence of stone disease is most common in the southeastern United States, Japan, and Western Europe. Calcium stone disease is more common in men than in women and tends to occur in young adults or during early middle adulthood. Kidney stone disease occurs more often in younger adults than older adults and more commonly among white people (Brenner, 2008). For patients in these higher-risk groups, nursing care includes teaching family members, as well as patients, about the manifestations of a stone and interventions to reduce stone formation.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Ask the patient about a personal or family history of urologic stones. Obtain a diet history, including fluid intake patterns. If he or she has a history of stone formation, ask about past treatment, whether chemical analysis of the stone was performed, and what preventive measures are followed.

The major manifestation of stones is severe pain, commonly called **renal colic**. Flank pain suggests that the stone is in the kidney or upper ureter. Flank pain that extends toward the abdomen or to the scrotum and testes or the vulva suggests that stones are in the ureters or bladder. Pain is most intense when the stone is moving or when the ureter is obstructed.

Renal colic begins suddenly and is often described as “unbearable.” Nausea, vomiting, pallor, and diaphoresis often accompany the pain. A large stationary stone in the kidney (staghorn calculus), however, rarely causes much pain because it is not moving. Frequency and dysuria occur when a stone reaches the bladder. **Oliguria** (scant urine output) or **anuria** (absence of urine output) suggests obstruction, possibly at the bladder neck or urethra. *Urinary tract obstruction is an emergency and must be treated immediately to preserve kidney function.*

Examine the patient to detect bladder distention. The patient may appear pale, ashen, and diaphoretic and may suffer from excruciating pain. Vital signs may be moderately

elevated with pain; body temperature and pulse are elevated with infection. Blood pressure may decrease if the severe pain causes shock.

Urinalysis is performed in patients with suspected stones. Hematuria is common, and blood may make the urine appear smoky or rusty. The presence of RBCs is usually caused by stone-induced trauma on the lining of the ureter, bladder, or urethra. WBCs and bacteria may be present as a result of urinary stasis. Increased *turbidity* (cloudiness) and odor indicate that infection may also be present. Microscopic examination of the urine may identify crystals from which stones could form. Urinary pH is measured to determine acidity or alkalinity.

The serum WBC count is elevated with infection. Increases in the serum calcium, serum phosphate, or serum uric acid levels indicate excess minerals are present and may contribute to stone formation.

Stones are easily seen on x-rays of the kidneys, ureters, and bladder (KUB) (Fig. 69-2); IV urograms; or computed tomography (CT). Noncontrast CT is the most sensitive test to identify urinary tract stones. These procedures confirm the presence and location of the stones.

IV urography is useful for identifying whether the urinary tract is obstructed. However, because of the risk for acute kidney injury (AKI) induced by contrast dye, other diagnostic tests may be chosen for high-risk patients (older adults and patients with diabetes mellitus, multiple myeloma, or elevated serum creatinine levels).

Renal ultrasonography creates images from sound waves hitting structures of different densities. Solid structures, such as stones, are extremely dense, and the images of stones are clear. Small stones are harder to identify and locate. Ultrasound is the main method used to identify hydronephrosis from any cause.

INTERVENTIONS

Nursing interventions focus on pain management and prevention of infection and urinary obstruction. Most patients can expel the stone without invasive procedures. The most important factors regarding whether a stone will pass on its

own are its composition, size, and location. The larger the stone and the higher up in the urinary tract it is, the less likely it is to be passed. When the stone is passed, it should be captured and sent to the laboratory for analysis. Other interventions are needed when the patient does not pass the stone spontaneously (Fig. 69-3).

Managing Pain

Nonsurgical and surgical approaches are used to assist the patient with a kidney stone achieve an acceptable degree of pain relief.

Nonsurgical Management. Nonsurgical measures to relieve pain include strategies to enhance stone passing, as well as direct pain management.

- Open ureterolithotomy

FIG. 69-3 Treatment options for ureteral stones. ESWL, Extracorporeal shock wave lithotripsy.

Drug therapy is needed most in the first 24 to 36 hours when pain is most severe. Opioid analgesics are often needed to control the severe pain caused by stones in the urinary tract. Opioid agents, such as morphine (Statex ) , are often given IV for rapid pain relief. NSAIDs such as ketorolac (Toradol) in the acute phase may be quite effective. When NSAIDs are used, the risk for bleeding is increased and the use of extracorporeal shock wave lithotripsy is delayed.

Control of pain is more effective when drugs are given at regularly scheduled intervals or by a constant delivery system (e.g., skin patch) instead of PRN. Spasmolytic drugs, such as oxybutynin chloride (Ditropan) and propantheline bromide (Pro-Banthine, Propanthel ) , are important for control of pain (see [Chart 69-8](#)). Give the drugs, and assess the response by asking the patient to rate the discomfort on a pain-rating scale.

Complementary and alternative therapy with relaxation techniques, such as hypnosis and imagery, therapeutic or healing touch, and acupuncture, can reduce pain. Patients often have difficulty finding a comfortable position. Thus assisting the patient with positioning can often aid in pain reduction. Breathing techniques, such as those used in childbirth, can also help him or her relax.

Other management techniques include avoiding overhydration and underhydration in the acute phase to help make the passage of a stone less painful. Strain the urine and teach the patient to strain it to monitor for stone passage. Send any stone passed to the laboratory for analysis, because preventive therapy is based on stone composition.

Lithotripsy, also known as *extracorporeal shock wave lithotripsy (ESWL)*, is the use of sound, laser, or dry shock waves to break the stone into small fragments. The patient receives moderate sedation and lies on a flat table with the lithotripter aimed at the stone, which is located by fluoroscopy. A local anesthetic cream is applied to the skin site over the stone 45 minutes before the procedure. During the procedure, cardiac rhythm is monitored by electrocardiography (ECG) and the shock waves are delivered in synchrony with the R wave. About 500 to 1500 shock waves are applied in 30 to 45 minutes. Continuous ECG monitoring for dysrhythmia and fluoroscopic observation for stone destruction are maintained.

After lithotripsy, strain the urine to monitor the passage of stone fragments. Bruising may occur on the flank of the affected side. Occasionally a stent is placed in the ureter before ESWL to ease passage of the stone fragments. Cystine stones are often resistant to ESWL.

Surgical Management. Minimally invasive surgical and open surgical procedures are used if urinary obstruction occurs or if the stone is too large to be passed.

Minimally Invasive Surgical Procedures. Minimally invasive surgical (MIS) procedures include stenting, retrograde ureteroscopy, percutaneous ureterolithotomy, and percutaneous nephrolithotomy.

Stenting is performed with a **stent**—a small tube that is placed in the ureter by ureteroscopy. The stent dilates the ureter and enlarges the passageway for the stone or stone fragments. This totally internal procedure prevents the passing stone from coming in contact with the ureteral mucosa, thereby reducing pain, bleeding, and infection risk, all of which could block the ureter. A Foley catheter may be placed to facilitate passage of the stone through the urethra.

Retrograde ureteroscopy is an endoscopic procedure. The ureteroscope is passed through the urethra and bladder into the ureter. Once the stone is seen, it is removed using grasping baskets, forceps, or loops. Lithotripsy also can be performed through the ureteroscope. A Foley catheter may be placed to facilitate passage of the stone fragments through the urethra.

Percutaneous ureterolithotomy or nephrolithotomy is the removal of a stone in the kidney or ureter through the skin. The patient lies prone or on the side and receives local or general anesthesia. The physician identifies the ideal entry point with fluoroscopy and then passes a needle into the collecting system of the kidney. Once a tract has been made in the kidney, other equipment, such as an **intracorporeal** (inside the body) ultrasonic or laser lithotripter, can be used to break up and remove the stone. An endoscope with a special attachment to grasp and extract the stone can be used. Often a nephrostomy tube is left in place at first to prevent the stone fragments from passing through the urinary tract.

Provide routine nephrostomy tube care and monitor the patient for complications after the procedure. Complications include bleeding at the site or through the tube, pneumothorax, and infection.

Open Surgical Procedures. When other stone removal attempts have failed or when risk for a lasting injury to the ureter or kidney is possible, an *open ureterolithotomy* (into the ureter), *pyelolithotomy* (into the kidney pelvis), or *nephrolithotomy* (into the kidney) procedure may be performed. These procedures are used for a large or impacted stone.

Preoperative Care. Prepare the patient for the selected procedure by explaining how, when, and where the procedure will be performed. Describe what he or she can expect to see, hear, and feel before and after the procedure. The patient is given nothing by mouth and also receives a bowel preparation before the procedure. (See [Chapter 16](#) for routine care before surgery.)

Operative Procedures. The retroperitoneal area is entered through a large flank incision, as for nephrectomy (see [Chapter 70](#)), pyelolithotomy, or nephrolithotomy, and through a lower abdominal incision for ureterolithotomy. The urinary tract is entered surgically, and the stone is removed. Before closure, tubes and drains may be placed (e.g., nephrostomy tube, ureteral stent, Penrose or other wound drainage device, and Foley catheter).

Postoperative Care. Follow routine procedures for assessment of the patient who has received anesthesia. (See [Chapter 18](#) for routine care after surgery.) Monitor the amount of bleeding from incisions and in the urine. Maintain adequate fluid intake. Strain the urine to monitor the passage of stone fragments. Teach the patient how to prevent future stones through dietary changes, including consistent daily fluid intake to avoid dehydration and supersaturation.

Preventing Infection

Control of infections before invasive procedures is critical for the prevention of urosepsis. Interventions include giving appropriate antibiotics, either to eliminate an existing infection or to prevent new infections, and maintaining adequate nutrition and fluid intake. Because infection always occurs with struvite stone formation, the health care team plans for long-term infection prevention.

Drug therapy is the most common intervention. Broad-spectrum antibiotics, such as the aminoglycosides (e.g.,

gentamicin [Garamycin]) and cephalosporins (e.g., cephalexin [Keflex, Novo-Lexin ]), are first prescribed for infections occurring with stone disease. The broad coverage is effective against gram-negative organisms. After the results of the culture and sensitivity (C&S) studies are obtained, more specific antibiotics may be prescribed. C&S studies are often done 48 hours after the start of antibiotic therapy and again 48 hours after completion of the prescribed course of therapy.

Blood levels of antibiotics may be measured to ensure that adequate levels have been reached. If the desired blood level of these antibiotics is exceeded, toxic effects and kidney damage may result. If the blood level of the antibiotic is not adequate, organisms may not be completely eliminated. Evidence of a new infection (e.g., chills, fever, altered mental status) warrants the collection of a urine sample for repeat C&S tests.

For the patient with struvite stones, periodic and long-term monitoring of the urine for infection is needed. Urine cultures are checked monthly for 3 months and then quarterly for 1 year. Drugs that prevent bacteria from splitting urea, such as acetohydroxamic acid (Lithostat) and hydroxyurea (Hydrea), are often prescribed long-term for patients with struvite stones. Serum creatinine levels are monitored in patients receiving acetohydroxamic acid. This drug is stopped if creatinine levels are above 2 mg/dL. Review interventions aimed at preventing urinary tract infection (UTI). (See Interventions discussion on p. 1494 in the Cystitis section.)

Nutrition therapy ideally includes adequate calorie intake with a balance of all food groups. Encourage a fluid intake sufficient to dilute urine to a light color throughout the 24-hour day (typically 2 to 3 L/day) unless another health problem requires fluid restriction.

Preventing Obstruction

Measures to prevent urinary obstruction by stones include a high intake of fluids (3 L/day or more) and careful measures of intake and output. Fluid intake sufficient to provide a diluted urine helps prevent dehydration, promotes the flow of urine, and decreases the chance of crystals forming a stone. Interventions also depend on the type of stone the patient has

formed. Drugs, diet modification, and fluid intake are the major strategies used to prevent future stones.

Drug therapy to prevent obstruction depends on what is causing stone formation and the type of stone formed. Teach the patient the reason for the drug, and assess for side effects or adverse drug reactions. Some drugs may need to be avoided because they may contribute to stone formation.

Drugs to treat *hypercalciuria* (high levels of calcium in the urine) include thiazide diuretics (e.g., chlorothiazide [Diuril] or hydrochlorothiazide [HydroDIURIL, Urozide ]), orthophosphate, and sodium cellulose phosphate. Thiazide diuretics promote calcium resorption from the kidney tubules back into the body, thereby reducing urine calcium loads. Orthophosphates alter calcium-phosphorus metabolism, resulting in decreased urine saturation of calcium oxalate. Sodium cellulose phosphate reduces intestinal absorption of calcium.

For patients with *hyperoxaluria* (high levels of oxalic acid in the urine), allopurinol (Zyloprim) and vitamin B₆ (pyridoxine) are used.

For patients with chronic gout, allopurinol helps prevent the formation of urate (uric acid) stones. To alkalize the urine, drugs such as potassium citrate, 50% sodium citrate, and sodium bicarbonate are used. The desired urine pH is 6 to 6.5. Because the normal urine pH averages 5 to 6, the desired values are termed *alkaline*.

For patients with *cystinuria* (high levels of cystine in the urine), both alpha-mercaptopyrionylglycine (AMPG) and captopril (Capoten) lower urine cystine levels. They are used when hydration and urine alkalization have not been successful.

Nutrition therapy depends on the type of stone formed (Table 69-6). Collaborate with the dietitian to plan for and teach the appropriate diet to the patient.

Other measures can help the patient pass the stone more quickly. Encourage the patient to walk as often as possible. Walking promotes passage of stones and reduces bone calcium resorption. Check the urine pH daily, and strain all urine with filter paper to collect passed stones and fragments.

TABLE 69-6 DIETARY TREATMENT FOR KIDNEY AND URINARY STONES

STONE TYPE	DIETARY INTERVENTIONS	RATIONALES
Calcium oxalate	Avoid oxalate sources, such as spinach, black tea, and rhubarb. Decrease sodium intake.	Reduction of urinary oxalate content may help prevent these stones from forming. Urinary pH is not a factor. High sodium intake reduces kidney tubular calcium reabsorption.
Calcium phosphate	Limit intake of foods high in animal protein to 5-7 servings per week and never more than 2 per day. Some patients may benefit from a reduced calcium intake (milk, other dairy products). Decrease sodium intake.	Reduction of protein intake reduces acidic urine and prevents calcium precipitation. Reduction of urine calcium concentration may prevent calcium precipitation and crystallization. High sodium intake reduces kidney tubular calcium reabsorption.
Struvite (magnesium ammonium phosphate)	Limit high-phosphate foods, such as dairy products, organ meats, and whole grains.	Reduction of urinary phosphate content may help prevent these stones from forming.
Uric acid (urate)	Decrease intake of purine sources, such as organ meats, poultry, fish, gravies, red wines, and sardines.	Reduction of urinary purine content may help prevent these stones from forming.
Cystine	Limit animal protein intake (as above). Encourage oral fluid intake (500 mL every 4 hours while awake and 750 mL at night).	Reduces urinary uric acid. Increased fluid helps dilute the urine and prevents the cystine crystals from forming.

CHART 69-11 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Urinary Calculi

- Finish your entire prescription of antibiotics to ensure that you will not get a urinary tract infection.
- You may resume your usual daily activities.
- Remember to balance regular exercise with sleep and rest.
- You may return to work 2 days to 6 weeks after surgery, depending on the type of intervention, your personal tolerance, and your physician's directives.
- Depending on the type of stone you had, your diet may be restricted to prevent further stone formation.
- Remember to drink at least 3 L of fluid a day to dilute potential stone-forming crystals, prevent dehydration, and promote urine flow.
- Monitor urine pH as directed (possibly up to three times per day).
- Expect bruising after lithotripsy. The bruising may be quite extensive and may take several weeks to resolve.
- Your urine may be bloody for several days after surgery.
- Pain in the region of the kidneys or bladder may signal the beginning of an infection or the formation of another stone. Report any pain, fever, chills, or difficulty with urination immediately to your physician or nurse.
- Keep follow-up appointments to check on infection, and have repeat cultures done.

Teaching for self-management includes the key points listed in [Chart 69-11](#). Follow-up care to evaluate effects of intervention includes a 24-hour urine collection and serum chemical analysis. The patient often has great anxiety and fear that a stone and its pain may recur. In addition to anxiety about the pain, the risk for repeated surgical interventions or permanent and serious kidney damage is of major concern. Psychosocial preparation is enhanced when patients know what to expect and what actions to take if problems develop. Reassure the patient that preventive and health promotion activities help prevent recurrence.

UROTHELIAL CANCER

Pathophysiology

Urothelial cancers are malignant tumors of the *urothelium*—the lining of transitional cells in the kidney, renal pelvis, ureters, urinary bladder, and urethra. Most urothelial cancers occur in the bladder. Thus the term *bladder cancer* is often used to describe this condition.

In the United States, about 73% of urinary tract cancers are transitional cell carcinomas of the bladder ([American Cancer Society \[ACS\], 2011](#)). The second most common site of urinary tract cancer is the kidney and renal pelvis. Urothelial cancers are usually low grade, have multiple points of origin (*multifocal*), and are recurrent. Once the cancer spreads beyond the transitional cell layer, it is highly invasive and can spread beyond the bladder. Because of the nature of this cancer, patients may have recurrence up to 10 years after being cancer-free ([ACS, 2011](#)).

Tumors confined to the bladder mucosa are treated by simple excision, whereas those that are deeper but not into the muscle layer are treated with excision plus **intravesical** (inside the bladder) chemotherapy. Cancer that has spread deeper into the bladder muscle layer is treated with more extensive surgery, often a **radical cystectomy** (removal of the

bladder and surrounding tissue) with urinary diversion. Chemotherapy and radiation therapy are used in addition to surgery. If untreated, the tumor invades surrounding tissues, spreads to distant sites (liver, lung, and bone), and ultimately leads to death.

Exposure to toxins, especially chemicals used in the hair-dressing, rubber, paint, electric cable, and textile industries, increases the risk for bladder cancer. The greatest risk factor for bladder cancer is tobacco use. Other risks include *Schistosoma haematobium* (a parasite) infection, excessive use of drugs containing phenacetin, and long-term use of cyclophosphamide (Cytoxan, Procytox .

About 67,000 new cases of bladder cancer are diagnosed each year in the United States, and about 13,000 deaths occur each year from the disease ([ACS, 2011](#)). This cancer is rare in adults younger than 40 years and is most common after 60 years of age.

Health Promotion and Maintenance

Many people believe that tobacco use is associated with cancers only of organs that come into direct contact with it, such as the lungs. However, many compounds in tobacco enter the bloodstream and affect distant organs, such as the bladder. Therefore encourage everyone who smokes to quit and nonsmokers to not start. Just as important, encourage anyone who comes into contact with dry, liquid, or gaseous chemicals to take precautions. Some people work with chemicals, and others may come into contact with them while engaging in hobbies, such as refinishing furniture. Many chemicals and fumes can enter the body through contact with skin and with mucous membranes in the respiratory tract. Use of personal protective equipment, such as gloves and masks, can reduce this contact. Also encourage anyone who works with chemicals to shower or bathe and change clothing as soon as contact is completed.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

Ask about the patient's perception of his or her general health. Document the gender and age of the patient. Ask about active and passive exposure to cigarette smoke. To detect exposure to harmful environmental agents, ask the patient to describe his or her occupation and hobbies in detail. Also ask the patient to describe any change in the color, frequency, or amount of urine and any abdominal discomfort.

Observe the overall appearance of the patient, especially skin color and general nutritional status. Inspect, percuss, and palpate the abdomen for asymmetry, tenderness, and bladder distention.

Examine the urine for color and clarity. Blood in the urine is often the first major sign of bladder cancer. It may be gross or microscopic and is usually painless and intermittent. Dysuria, frequency, and urgency occur when infection or obstruction is also present.

Psychosocial Assessment

Assess the patient's emotions, including his or her response to a tentative diagnosis of bladder cancer, and note anxiety, fear, sadness, anger, or guilt. Early manifestations are painless,

and many patients ignore the blood in the urine because it is intermittent. They also may be reluctant to seek treatment because they suspect a sexually transmitted disease (STD). As a result, they may have guilt or anger about their own delays in seeking medical attention.

Assess the patient's methods of coping and the degree of support from family members. Social support may provide motivation and improve coping during recovery from treatment.

Diagnostic Assessment

The only significant finding on a routine urinalysis is gross or microscopic hematuria. Cytologic testing on voided urine specimens is not usually helpful. Bladder-wash specimens and bladder biopsies are the most specific tests for cancer.

Cystoscopy with retrograde urography is usually performed to evaluate painless hematuria. A biopsy of a visible bladder tumor can be performed during cystoscopy. This is essential for staging and is usually performed in a day-surgery unit before admission to the hospital for treatment. IV urography may be used when there is blood in the urine. Excretory urography is useful in identifying obstructions, especially where the ureter joins the bladder. Computed tomography (CT) scans show tumor invasion of surrounding tissues. Ultrasonography shows masses but is less valuable for tumor staging. Magnetic resonance imaging (MRI) may help assess deep, invasive tumors.

INTERVENTIONS

Therapy for the patient with bladder cancer usually begins with surgical removal of the tumor for diagnosis and staging of disease. For tumors extending beyond the mucosa, surgery is followed by intravesical chemotherapy or immunotherapy. High-grade or recurrent tumors are treated with more radical surgery plus intravesical chemotherapy, radiotherapy, or both. Systemic chemotherapy is reserved for patients with distant metastases. (See [Chapter 24](#) for general care of the patient receiving chemotherapy or radiation therapy.)

Nonsurgical Management

Prophylactic immunotherapy with intravesical instillation of bacille Calmette-Guérin (BCG), a live virus compound, is used to prevent tumor recurrence of superficial cancers. This procedure is more effective than single-agent chemotherapy. Usually the agent is instilled in an outpatient clinic and allowed to dwell in the bladder for a specified length of time, usually 2 hours. When the patient urinates, live virus is excreted with the urine.

Teach patients receiving this treatment to prevent contact of the live virus with other members of the household by not sharing a toilet with others for at least 24 hours after instillation. Instruct men to urinate while sitting down to avoid splashing the urine. After 24 hours, the toilet should be completely cleaned using a solution of 10% liquid bleach. If only one toilet is available in the household, teach the patient to flush the toilet after use and follow this by adding one cup of undiluted bleach to the bowl water. The bowl is then flushed after 15 minutes and the seat and flat surfaces of the toilet wiped with a cloth containing a solution of 10% liquid bleach. Teach the patient to wear gloves during the cleaning and to dispose of the cloth after sealing it in a plastic bag.

Underwear or other clothing that has come into contact with the urine during the 24 hours after instillation should

be washed separately from other clothing in a solution of 10% liquid bleach. Sexual intercourse is avoided for 24 hours after the instillation.

Multiagent chemotherapy is successful in prolonging life after distant metastasis has occurred but rarely results in a cure. Radiation therapy is also useful in prolonging life.

Surgical Management

The type of surgery for bladder cancer depends on the type and stage of the cancer and the patient's general health. Complete bladder removal (*cystectomy*) with additional removal of surrounding muscle and tissue offers the best chance of a cure for large, invasive bladder cancers. Four alternatives are used after cystectomy: ileal conduit; continent pouch; bladder reconstruction, also known as *neobladder*; and ureterosigmoidostomy.

Preoperative Care. Specific patient education depends on the type and extent of the planned surgical procedure. Coordinate education before surgery with the patient, surgeon, and enterostomal therapist (ET). Discuss the type of planned urinary diversion and the selection of a site for the stoma. Including the patient in this planning improves the chances for the patient to have a positive attitude about body image and a positive self-image. Use educational counseling to ensure understanding about self-care practices, methods of pouching, control of urine drainage, and management of odor.

The site selected for the stoma should be visible and avoid folds of skin, bones, and scar tissue. When possible, the patient's waistline or belt area is avoided. Prepare the patient for the number and type of drains that will be present after surgery. General care before surgery is discussed in [Chapter 16](#).

Operative Procedures. Transurethral resection of the bladder tumor (TURBT) or partial cystectomy is performed for small, early, superficial tumors. In a partial (segmental) cystectomy, a portion of the bladder is removed. This procedure is used when there is only a single isolated bladder tumor.

When the entire bladder must be removed (complete cystectomy), the ureters are diverted into a collecting reservoir. Techniques for urinary diversion are shown in [Fig. 69-4](#). With an ileal conduit, the ureters are surgically placed in the ileum and urine is collected in a pouch on the skin around the stoma. More often, continent reservoirs or "neobladders" are created from an intestinal graft. With cutaneous ureterosomy or ureteroureterostomy, the ureter opening is brought out onto the skin. The cutaneous ureterostomies may be located on either side of the abdomen or side by side.

Postoperative Care. After cutaneous ureterosomy, an external pouch covers the ostomy to collect urine. Work with the ET to focus care on the wound, the skin, and urinary drainage. (See [Chapters 59 and 60](#) for ostomy care.)

The patient with a Kock's pouch, a continent reservoir, may have a Penrose drain and a plastic Medena catheter in the stoma. The drain removes lymphatic fluid or other secretions; the catheter ensures urine drainage so that suture lines can heal. The patient with a neobladder usually requires 2 to 4 days in the intensive care unit (ICU) and will have a drain at first in the event the neobladder requires irrigation. Later, irrigation can be performed with intermittent catheterization. Irrigation is performed to ensure patency. There is no sensation of bladder fullness with a neobladder because sensory nerves are not attached. As a result, the patient will need to learn new cues to void, such as prescribed times or

Ureterostomies divert urine directly to the skin surface through a ureteral skin opening (stoma). After ureterostomy, the patient must wear a pouch.

Cutaneous ureterostomy

Cutaneous ureteroureterostomy

Bilateral cutaneous ureterostomy

Conduits collect urine in a portion of the intestine, which is then opened onto the skin surface as a stoma. After the creation of a conduit, the patient must wear a pouch.

Ileal (Bricker's) conduit

Colon conduit

Ileal reservoirs divert urine into a surgically created pouch, or pocket, that functions as a bladder. The stoma is continent, and the patient removes urine by regular self-catheterization.

Continent internal ileal reservoir (Kock's pouch)

Sigmoidostomies divert urine to the large intestine, so no stoma is required. The patient excretes urine with bowel movements, and bowel incontinence may result.

Ureterosigmoidostomy

Ureteroileosigmoidostomy

FIG. 69-4 Urinary diversion procedures used in the treatment of bladder cancer.

noticing a feeling of neobladder pressure. General care after surgery is discussed in [Chapter 18](#).

Different types of drains and nephrostomy catheters are used, sometimes on a temporary basis, to drain urine from the kidney. Some are totally internal, with no drainage to the outside. Others may drain exclusively to the outside and urine is collected in a pouch or bag. For this type of drainage system, urine output remains constant. A decrease in amount or no drainage is cause for concern and must be reported to the surgeon or nephrologist, as is leakage around the catheter.

Some nephrostomy tubes are connected both to the new bladder (internal drainage) and to an external drainage system. With this type of system, urine output from the external portion of the catheter is variable. With any drainage system, intervention is needed if the external catheter is accidentally partially or completely pulled out. Immediately notify the surgeon or nephrologist. If the catheter remains partially in place, secure it from further movement. This action may result in a re-insertion process rather than a total replacement.

Community-Based Care

Teaching for Self-Management

Teach the patient and family about drugs, diet and fluid therapy, the use of external pouching systems, and the technique for catheterizing a continent reservoir.

With some procedures, the patient may need electrolyte replacement to prevent long-term deficits. Teach him or her to avoid foods that are known to produce gas if the urinary diversion uses the intestinal tract. When intestinal production of gas is excessive, flatus can induce incontinence.

Patients who have a neobladder created often have extreme weight loss during the first few weeks after surgery. Collaborate with a dietitian to develop a diet plan specific to the patient to meet his or her caloric needs.

! NURSING SAFETY PRIORITY

Action Alert

Infection is common in patients who have a neobladder. Teach patients and family members the manifestations of infection and the importance of reporting the infection immediately to the surgeon.

Instruct the patient and family about any changes in self-care activities related to the urinary diversion. In collaboration with the enterostomal therapist, demonstrate external pouch application, local skin care, pouch care, methods of adhesion, and drainage mechanisms. If a Kock's pouch has been created, teach the patient how to use a catheter to drain the pouch. For all instruction, observe at least one return demonstration by the patient or the caregiver. Ideally, the patient assumes responsibility for self-care before discharge.

Assist the patient to prepare for the impact of urinary diversion on self-image, body image, sexual functioning, and self-esteem. Counseling provides information and support to reduce feelings of powerlessness.

Through discussions with the patient about usual social situations, help him or her gain control over new toileting practices. Men with a urinary diversion into the sigmoid colon need to learn the habit of sitting to urinate. For patients of either gender, promote confidence in social situations by encouraging frequent emptying of urinary collection devices before traveling or attending social functions. Resumption of sexual activity is a major concern for many, regardless of age, and may remain problematic for many years after surgery (Gemmill et al., 2010) (see the Evidence-Based Practice Box at right). Address this topic openly and with sensitivity. Cystectomy causes impotence in men, but treatment is available (see Chapter 75).

Health Care Resources

The United Ostomy Association and the American Cancer Society have educational materials that may be useful to patients. Refer patients and family members to local chapters or units of these organizations. In some areas, local support groups have meetings to assist others and to send visitors to provide peer counseling and support. Home care personnel may assist with follow-up, easing the transition from hospital to home. The Wound, Ostomy, and Continence Nurses Society has educational programs and a journal for the care of patients with ostomies.

EVIDENCE-BASED PRACTICE

How Does Urinary Diversion for Bladder Cancer Affect Sexual Expression and Quality of Life?

Gemmill, R., Ferrell, B., Krouse, R., & Grant, M. (2010). Going with the flow: Quality-of-life outcomes of cancer survivors with urinary diversion. *Journal of the Wound, Ostomy and Continence Nurses*, 37(1), 65-72.

Urinary diversion (UD) is a common outcome after treatment of bladder cancer and requires continued daily personal attention. In addition, the urinary system is anatomically associated with many of the physical aspects of sexual expression and behavior for both men and women. As survival rates from bladder cancer increase, more individuals are long-term with UD. One purpose of this descriptive study was to describe health-related quality of life (HRQOL) concerns among cancer survivors with different types of UD (continent or incontinent).

The study methods involved distribution of a HRQOL questionnaire that had been developed, tested, revised, and retested over many years at multiple sites for its utility in assessing the four dimensions of physical well-being, psychological well-being, social well-being, and spiritual well-being among cancer patients. This highly valid questionnaire was revised to include issues that were specifically ostomy-related. The revised tool had acceptable levels of reliability and validity as indicated by a subscale Cronbach alpha ranging between 0.77 to 0.90 and an overall Cronbach alpha of $r = 0.95$.

Data obtained from a total of 307 respondents meeting study criteria were analyzed using univariate logistical regression and multivariate logistical regression methods. The median time of having a UD in this sample was 9.5 years (range of 3 to 13 years). Only one third of respondents reported having an overall "excellent" HRQOL. Common areas of dissatisfaction were related to reduced sexual activity, daily time involved with care related to the UD, peristomal irritation, bowel changes, urine leakage, fear of disease recurrence, and embarrassment related to urine leakage or body image. A major finding of this study was that these issues were not limited to the immediate postoperative period but persisted for years.

Level of Evidence: 4

Although very large, the study was descriptive in nature without randomization of subject selection or assignment. The information collected relied on subject self-report. The methods of statistical analysis were appropriate for the research questions posed. A major strength of the study was the collection of data from long-term recipients of UD.

Commentary: Implications for Practice and Research

The results of this study indicate that adjustment of patients to UD requires considerable time and that quality of life is affected for years. The problems associated with sexuality were experienced by both men and women. Many of the issues identified by the respondents could be made easier by nursing interventions that include adequate patient teaching, long-term support, and continued access to wound and ostomy care nurses.

? NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which statement made by the client who is receiving intravesicular instillations of BCG for bladder cancer indicates to the nurse that more teaching is needed?

- "Holding my urine for at least 8 hours after the treatment keeps the drug in contact with my bladder."
- "Drinking plenty of fluids during the evening after the treatment helps get the drug out of my system."
- "Sitting to urinate for 24 hours after treatment prevents exposure of other people to the drug."
- "Avoiding intercourse for 24 hours after treatment reduces my wife's exposure to the drug."

BLADDER TRAUMA

Pathophysiology

Bladder trauma can be caused by penetrating or blunt injury to the lower abdomen. Penetrating injury may occur by stabbing, gunshot wound, or other trauma in which objects pierce the abdominal wall. A fractured pelvis with puncture of the bladder by bone fragments is the most common cause of bladder trauma. Bladder trauma may also be a result of sexual assault.

Blunt trauma compresses the abdominal wall and the bladder. A seat belt may compress the bladder hard enough to cause injury, especially if the bladder is full or distended.

PATIENT-CENTERED COLLABORATIVE CARE

Patients with a penetrating bladder wound often have anuria or hematuria. In the emergency department, initial assessment includes inspection of the urinary meatus for blood.

Diagnostic tests include cystography and voiding cystourethrography (VCUG). If kidney or ureteral trauma is suspected, IV urography is scheduled before cystography so that any leakage of bladder contrast medium does not mask the outlines of the kidneys or ureters. The cystogram shows whether there is a defect in bladder filling; the voiding cystourethrogram defines bladder emptying.

Bladder trauma, other than a simple contusion, requires surgical intervention. When bone fractures are present, they are stabilized before bladder repair to prevent further bladder damage. Surgical interventions include repairing the bladder wall and peritoneal membrane. Usually, repairs of the bladder are closure procedures.

Patients with an anterior bladder wall injury usually have a Penrose drain and a Foley catheter in place after surgery. Those with a posterior bladder wall injury have a Penrose drain and Foley or suprapubic catheter after surgery. In some instances, vaginal or rectal fistulas may also require repair.

Psychosocial support is critical for patients who have sustained traumatic injuries. Refer them to counseling resources to assist in dealing with psychosocial issues.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing urinary elimination problems as a result of cystitis?

- Patient urinates frequently in small amounts.
- Patient reports pain and burning on urination.
- Patient reports suprapubic pain.
- Urine is cloudy and foul-smelling.
- Urine may be darker or smoky or have obvious blood in it.

What should you INTERPRET and how should you RESPOND to a patient experiencing urinary elimination problems as a result of a UTI?

Perform and interpret physical assessment, including:

- Ask how long manifestations have been present.
- Ask about low back pain (midline in men) or flank pain.
- Ask whether he or she has had a UTI in the past; how long ago; how it was treated; and if antibiotics were prescribed, whether the drug course was completed.
- Ask about the presence of pregnancy or any chronic health problem, especially diabetes.
- Determine fluid intake and output volumes.
- Assess for bladder distention by palpation or with a bedside bladder ultrasound scanner (see [Chapter 68](#)).

- Assess for pain over the right and left kidneys.
- Examine the meatus for irritation.
- If a Foley catheter is in place, determine why it is in use and how long it has been present.
- Interpret laboratory values:
 - Is the complete blood count within normal limits?
 - Is the urinalysis positive for bacteria, leukocyte esterase, nitrate, red blood cells, or white blood cells?

Respond by:

- Assessing the need for continuing indwelling catheter
- Teaching the patient comfort measures
- Teaching the patient the importance of completing the prescribed drug regimen

On what should you REFLECT?

- Observe patient for evidence of improved urinary output (see [Chapter 68](#)).
- Think about what may have caused this infection in a hospitalized patient (or long-term care resident) and what steps could be taken to prevent a similar episode.
- Think about what patient-teaching focus could help reduce the risk for future UTI.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use sterile technique when inserting a catheter or any other instrument into the urinary system.

- Use Contact Precautions with any drainage from the genitourinary tract.

Health Promotion and Maintenance

- Teach patients to clean the perineal area daily, after voiding, after having a bowel movement, and after sexual intercourse.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Encourage all patients to maintain an adequate fluid intake (minimum of 1.5 to 2.5 L daily unless another health problem requires fluid restriction).
- Instruct women who have stress incontinence the proper way to perform pelvic floor strengthening exercises.
- Teach patients who come into contact with chemicals in their workplaces or with leisure-time activities to avoid direct skin and mucous membrane contact with these chemicals.

Psychosocial Integrity

- Allow the patient the opportunity to express feelings or concerns regarding a potential cancer diagnosis.
- Use a nonjudgmental approach in caring for patients with urinary incontinence.
- Avoid referring to protective pads or pants as “diapers.”
- Recognize the need for the patient undergoing cystectomy and urinary diversion to grieve about the body image change.
- Assess the patient’s level of comfort in discussing issues related to elimination and the urogenital area.

- Use language and terminology during kidney and urinary assessment that the patient is comfortable using.
- Refer patients to community resources and support groups.

Physiological Integrity

- Identify hospitalized patients at risk for bacteriuria and urosepsis.
- Report immediately any condition that obstructs urine flow.
- Instruct patients with UTI to complete all prescribed antibiotic therapy even when symptoms of infection are absent.
- Evaluate daily the indications for maintaining indwelling catheters, and discontinue their use as soon as possible.
- Teach patients the expected side effects and any adverse reactions to prescribed drugs.
- Assess the patient’s manual dexterity and cognitive awareness before teaching a regimen of intermittent self-catheterization.

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Health Promotion and Maintenance

1. Encourage patients with diabetes to achieve tight glycemic control.
2. Encourage patients with hypertension to follow their treatment regimens to maintain blood pressure within the target range.
3. Teach patients at risk for urinary tract infection (UTI) to maintain a daily fluid intake of 2 L unless another health problem requires fluid restriction.
4. Teach patients on antibiotic therapy for a UTI to complete the drug regimen.
5. Teach all people strategies to prevent kidney trauma.

Psychosocial Integrity

6. Use language the patient is comfortable with during assessment of the kidney and urinary system.

7. Encourage the patient to express feelings or concerns about a change in kidney function.
8. Explain treatment procedures to patients and families.

Physiological Integrity

9. Explain the genetics of autosomal dominant polycystic kidney disease.
10. Use laboratory data and clinical manifestations to determine the effectiveness of therapy for pyelonephritis.
11. Describe the clinical manifestations of hydronephrosis.
12. Explain the relationship between hypertension and kidney disease.
13. Coordinate nursing care for the patient with pyelonephritis.
14. Coordinate nursing care for the patient during the first 24 hours after a nephrectomy.

The kidneys participate in *urinary elimination* by filtering wastes and balancing fluids, electrolytes, acids, and bases. Any problem that disrupts kidney function limits the ability to meet that need and has the potential to impair general homeostasis (Fig. 70-1). The kidneys work together with many other organ systems. Thus kidney disorders affect systemic health and can lead to life-threatening outcomes. Kidney disorders are classified as congenital, obstructive, infectious, glomerular, and degenerative. Kidney tumors and kidney trauma are also described in this chapter. Acute kidney injury and chronic kidney disease are discussed in Chapter 71.

CONGENITAL DISORDERS

POLYCYSTIC KIDNEY DISEASE

Pathophysiology

Polycystic kidney disease (PKD) is an inherited disorder in which fluid-filled cysts develop in the nephrons. In the dominant form, only a few nephrons have cysts until the person reaches his or her 30s. In the recessive form of the disease, nearly 100% of nephrons have cysts from birth. Cysts develop anywhere in the nephron as a result of abnormal kidney cell division.

FIG. 70-1 Unbalanced body water, electrolytes, and waste products as a result of kidney problems that prevent adjustments in urinary elimination.

Over time, small cysts become much larger (up to a few centimeters in diameter) and more widely distributed. The growing cysts damage the glomerular and tubular membranes. As the cysts fill with fluid and enlarge, the nephron and kidney function become less effective.

The kidney tissue is eventually replaced by nonfunctioning cysts, which look like clusters of grapes (Fig. 70-2). The kidneys become very large. Each cystic kidney may enlarge to two or three times its normal size, becoming as large as a football, and may weigh 10 pounds or more each. Other abdominal organs are displaced, and the patient has pain. The fluid-filled cysts are also at increased risk for infection, rupture, and bleeding, which increase pain.

Most patients with PKD have high blood pressure. The cause of hypertension is related to kidney ischemia from the enlarging cysts. As the vessels are compressed and blood flow to the kidneys decreases, the renin-angiotensin system is activated, raising blood pressure. Control of hypertension is a top priority because proper treatment can disrupt the process that leads to further kidney damage.

Cysts may occur also in other tissues, such as the liver and blood vessels. They may reduce liver function. In addition, the incidence of cerebral *aneurysms* (outpouching and thinning of an artery wall) is higher in patients with PKD. These aneurysms may rupture, causing bleeding and sudden death. For reasons as yet unknown, kidney stones occur in 8% to 36% of the patients with PKD. Heart valve problems (e.g., mitral valve prolapse), left ventricular hypertrophy, and colonic diverticula also are common in patients with PKD.

Etiology and Genetic Risk

PKD has several forms and can be inherited as either an autosomal dominant trait or, less commonly, as an autosomal recessive trait. People who inherit the recessive form of PKD

usually die in early childhood. The 5% to 10% incidence of PKD in patients with no family history occurs as a result of a new gene mutation.

GENETIC/GENOMIC CONSIDERATIONS

The autosomal dominant form of PKD (ADPKD) is the most common form of polycystic disease. Children of parents who have the autosomal dominant form of PKD have a 50% chance of inheriting the gene that causes the disease. Fig. 70-3 shows a typical pedigree for a family with ADPKD. Presentation of ADPKD can vary for age of onset, manifestations, and illness severity, even within one family. However, it is highly penetrant, meaning that nearly 100% of people who inherit a PKD gene will develop kidney cysts by age 30 (Nussbaum et al., 2007). Half of these people develop chronic kidney disease by age 50 years. ADPKD-1 is the most common and most severe form of the autosomal dominant disease. ADPKD-2 has a slower rate of cyst formation, so symptoms occur later in life and progression to end-stage kidney disease and other complications is delayed.

Autosomal recessive PKD is rare, and most people with the disease die in early childhood. It is caused by a gene mutation different from the dominant form. To inherit a recessive gene, both parents must carry a copy of the mutated allele and both mutated alleles must be inherited. Thus each child has a 1-in-4 chance of inheriting autosomal recessive polycystic disease.

There is no way to prevent PKD, although early detection and management of hypertension may slow the progression of kidney damage. Genetic counseling may be useful for adults who have one parent or both parents with PKD. Family history analysis is a simple assessment that can be used to help identify people at risk for PKD (see Fig. 70-3).

FIG. 70-2 External surface (A) and internal surface (B) of a polycystic kidney.

FIG. 70-3 Four-generation pedigree for autosomal dominant polycystic kidney disease (ADPKD). Colored-in symbols indicate family members with ADPKD. Slashes indicate the person has died.

Incidence/Prevalence

PKD is a common disorder, affecting 250,000 to 500,000 people in the United States. It is more common in white people than in people of other races. Men and women have an equal chance of inheriting the disease because the gene responsible for PKD is not located on the sex chromosomes (Polycystic Kidney Disease Foundation, 2011).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Explore the family history of a patient with suspected or actual PKD, and ask whether either parent was known to have PKD or whether there is any family history of kidney disease. The age at which the problem was diagnosed in the parent and any related complications are important to obtain. Ask about constipation, abdominal discomfort, a change in urine

CHART 70-1 KEY FEATURES

Polycystic Kidney Disease

- Abdominal or flank pain
- Hypertension
- Nocturia
- Increased abdominal girth
- Constipation
- Bloody or cloudy urine
- Kidney stones

color or frequency, high blood pressure, headaches, and a family history of sudden death from a stroke.

Physical Assessment/Clinical Manifestations

Chart 70-1 lists key features of PKD. Pain is often the first manifestation. Inspect the abdomen. A distended abdomen is common as the cystic kidneys swell and push the abdominal contents forward. Polycystic kidneys are easily palpated because of their increased size. Proceed with *gentle* abdominal palpation because the cystic kidneys and nearby tissues may be tender and palpation is uncomfortable.

The patient also may have flank pain as a dull ache or as sharp and intermittent discomfort. Dull, aching pain is caused by increased kidney size with distention or by infection within the cyst. Sharp, intermittent pain occurs when a cyst ruptures or a stone is present. When a cyst ruptures, the patient may have bright red or cola-colored urine. Infection is suspected if the urine is cloudy or foul smelling or if there is **dysuria** (pain on urination).

Nocturia (the need to urinate excessively at night) is an early manifestation and occurs because of decreased urine concentrating ability. As kidney function further declines, the patient has increasing hypertension, edema, and uremic manifestations such as anorexia, nausea, vomiting, pruritus, and fatigue (see Chapter 71). Because berry aneurysms often occur in patients with PKD, a severe headache with or without neurologic or vision changes requires attention.

Psychosocial Assessment

As an inherited disorder, PKD may cause psychosocial responses. The patient often has seen the effects and problems of the disease in close family members. He or she may have had a parent who died or close relatives who required dialysis or transplantation. While obtaining the family history, listen carefully for spoken and unspoken feelings of anger, resentment, futility, sadness, or anxiety. Such feelings may need further exploration. The focus of the feelings may be one or both parents or the process of diagnosis and treatment. Feelings of guilt and concern for the patient's children may also complicate the issue.

Diagnostic Assessment

Urinalysis shows **proteinuria** (protein in the urine) once the glomeruli are involved. **Hematuria** (blood in the urine) may be gross or microscopic. Bacteria in the urine indicate infection, usually in the cysts. Obtain a urine sample for culture and sensitivity testing when there is evidence of infection. As kidney function declines, serum creatinine and blood urea nitrogen (BUN) levels rise. With decreasing kidney function, creatinine clearance decreases. Changes in kidney handling of sodium may cause either sodium losses or sodium retention.

Diagnostic studies include renal sonography, computed tomography (CT), and magnetic resonance imaging (MRI). Small cysts are detected by sonography, CT, or MRI. Renal sonography shows evidence of PKD, with minimal risk.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration

The 36-year-old unaffected daughter of a 63-year-old man with PKD is visiting her two 31-year-old sisters (identical twins) who are both hospitalized with acute complications of their PKD (see Fig. 70-3). You find the unaffected sister in the hallway crying. She tells you that she feels sad that her sisters are suffering so much and guilty that she has escaped the disease. She also tells you that, although she wants to donate a kidney to the sister whose disease has already progressed to end-stage kidney disease (ESKD), she is not a blood type match. (Both parents have type A blood, the unaffected sister has type A blood, and the affected twin sisters have type O blood.) In addition, she has a 2-year-old son and a 6-week-old son, and she fears that they may either develop the disease or pass it on to their children. She also tells you that she is grateful that her father's PKD is not as severe as her sisters' disease.

1. What is the pattern of inheritance for the PKD depicted in Fig. 70-3 (and explain why it could not be another pattern of inheritance)?
2. Are the unaffected sister's fears of passing the disease on to her children or grandchildren founded or unfounded? Provide a rationale for your decision.
3. Is the unaffected sister correct in thinking that her blood type difference eliminates the possibility that she could donate a kidney to one of her sisters? Why or why not? (You may need to review blood type issues in Chapter 42 and kidney transplantation issues in Chapter 71.)
4. What comments or suggestions could you make to help the unaffected sister feel less guilty about her own good health?

INTERVENTIONS

Interventions for the patient with PKD include pain management and prevention of infection, constipation, hypertension, and chronic kidney disease. When the disease progresses

to the point that the kidneys no longer function to clear wastes, care becomes similar to that needed for the patient with end-stage kidney disease (see Chapter 71).

Managing Pain

Comfort strategies include drug therapy and complementary approaches. A combination may be most effective. NSAIDs are used cautiously because of their tendency to reduce kidney blood flow. Aspirin-containing compounds are avoided to reduce the risk for bleeding.

If cyst infection causes discomfort, antibiotics such as trimethoprim/sulfamethoxazole (Bactrim, Septra, Trimplex) or ciprofloxacin (Cipro) are prescribed. (See Chart 69-4 in Chapter 69.) These drugs enter the cyst wall. Monitor the serum creatinine levels because antibiotic therapy can be nephrotoxic. Apply dry heat to the abdomen or flank to promote comfort when kidney cysts are infected. When pain is severe, cysts can be reduced by needle aspiration and drainage; however, they usually refill.

Teach the patient methods of relaxation and comfort using deep breathing, guided imagery, or other strategies. The expected outcome is patient self-management. (See Chapter 5 for pain management.)

Preventing Constipation

Teach the patient who has adequate urine output how to prevent constipation by maintaining adequate fluid intake, increasing dietary fiber when fluid intake is more than 2500 mL/24 hr, and exercising regularly. Explain that pressure on the large intestine may occur as the polycystic kidneys increase in size. The patient should know that these recommendations for bowel management might change, particularly if end-stage kidney disease also develops. Advise him or her about the use of stool softeners and bulk agents, including the careful use of laxatives, to prevent chronic constipation.

Controlling Hypertension and Preventing End-Stage Kidney Disease

Blood pressure control is necessary to reduce cardiovascular complications and slow the progression of kidney dysfunction. Nursing interventions include education to promote self-management and understanding. When kidney impairment results in decreased urine concentration with nocturia and low urine specific gravity, urge the patient to drink at least 2 L of fluid per day to prevent dehydration, which can further reduce kidney function. Restricting sodium intake may help control blood pressure. See Chapter 38 for a detailed discussion about the causes and management of hypertension.

Drug therapy for blood pressure control includes antihypertensive agents and diuretics. Antihypertensive agents include angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers, beta blockers, and vasodilators (see Chapter 38). ACE inhibitors may help control the cell growth aspects of PKD and reduce microalbuminuria.

Teach the patient and family how to measure and record blood pressure. Help the patient establish a schedule for self-administering drugs, monitoring daily weights, and keeping blood pressure records (Chart 70-2). Explain the potential side effects of the drugs. Make available written materials, such as drug teaching cards and booklets.

A low-sodium diet is often prescribed to control the hypertension that usually occurs with PKD. However, some

CHART 70-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Polycystic Kidney Disease

- Measure and record your blood pressure daily, and notify your health care provider for consistent changes in blood pressure.
- Take your temperature if you suspect you have a fever.
- Weigh yourself every day at the same time of day and with the same amount of clothing; notify your physician or nurse if you have a sudden weight gain.
- Limit your intake of salt to help control your blood pressure.
- Notify your physician or nurse if your urine smells foul or has blood in it.
- Notify your physician or nurse if you have a headache that does not go away or if you have visual disturbances.
- Monitor bowel movements to prevent constipation.

patients may have salt wasting and should not follow a sodium-restricted diet. As the disease progresses, the protein intake may be limited to slow the development of end-stage kidney disease. Assist the patient and family in understanding the diet plan and why it was prescribed. Work closely with the dietitian to foster the patient's understanding. Also refer the patient for nutritional counseling.

Health Care Resources

The Polycystic Kidney Disease Foundation (www.pkdcure.org) and the National Kidney & Urologic Diseases Information Clearinghouse (NKUDIC) of the National Institute of Diabetes and Digestive and Kidney Diseases (www2.niddk.nih.gov) conduct research and provide education about PKD. Many pamphlets are available; there is a fee for some materials. Chapters of the National Kidney Foundation (NKF) and the American Association of Kidney Patients (AAKP) also have resources for information and support.

OBSTRUCTIVE DISORDERS

HYDRONEPHROSIS, HYDROURETER, AND URETHRAL STRICTURE

Pathophysiology

Hydronephrosis and hydroureter are problems of urine outflow obstruction. Urethral strictures also obstruct urine outflow. Prompt recognition and treatment are crucial to prevent permanent kidney damage.

In **hydronephrosis**, the kidney enlarges as urine collects in the renal pelvis and kidney tissue. Because the capacity of the renal pelvis is normally 5 to 8 mL, obstruction in the pelvis or at the point where the ureter joins the renal pelvis quickly distends the renal pelvis. Kidney pressure increases as the volume of urine increases. Over time, sometimes in only a matter of hours, the blood vessels and kidney tubules can be damaged extensively (Fig. 70-4).

In patients with **hydroureter** (enlargement of the ureter), the effects are similar but the obstruction is in the ureter rather than in the kidney. The ureter is most easily obstructed where the iliac vessels cross or where the ureters enter the bladder. Ureter dilation occurs above the obstruction and enlarges as urine collects (see Fig. 70-4).

FIG. 70-4 Hydronephrosis is caused by obstruction in the upper part of the ureter. Hydroureter is caused by obstruction in the lower part of the ureter.

In patients with a **urethral stricture**, the obstruction is very low in the urinary tract, causing bladder distention before hydroureter and hydronephrosis. The problems and kidney damage are similar without prompt treatment.

Urinary obstruction causes damage when pressure builds up directly on kidney tissue. Tubular filtrate pressure also increases in the nephron as drainage through the collecting system is impaired. With this added pressure, glomerular filtration decreases or ceases, and complete necrosis of the affected kidney can occur. Nitrogen waste products (urea, creatinine, and uric acid) and electrolytes (sodium, potassium, chloride, and phosphorus) are retained, and acid-base balance is impaired.

Causes of hydronephrosis or hydroureter include tumors, stones, trauma, structural defects, and fibrosis. In patients with cancer, obstructed ureters may result from the tumors themselves, pelvic radiation, or surgical treatment. Early treatment of the causes can prevent hydronephrosis and hydroureter and thus prevent permanent kidney damage. The specific time needed to prevent permanent damage depends on the patient's kidney health. Permanent damage can occur in less than 48 hours in some patients and after several weeks in other patients.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Obtain a history from the patient, focusing on known kidney or urologic disorders. A history of childhood urinary tract problems may indicate previously undiagnosed structural defects. Ask about his or her usual pattern of urination, especially amount, frequency, color, clarity, and odor. Ask about

recent flank or abdominal pain. Chills, fever, and malaise may be present with a urinary tract infection (UTI).

Inspect each flank to identify asymmetry, which may occur with a kidney mass, and *gently* palpate the abdomen to locate areas of tenderness. Palpate and percuss the bladder to detect distention, or use a bedside bladder scanner. Gentle pressure on the abdomen may cause urine leakage, which reflects a full bladder and possible obstruction.

Urinalysis may show bacteria or white blood cells if infection is present. When urinary tract obstruction is prolonged, microscopic examination may show tubular epithelial cells. Blood chemistries are normal unless glomerular filtration decreases. Blood creatinine and blood urea nitrogen (BUN) levels increase with a reduced glomerular filtration rate (GFR). Serum electrolyte levels may be altered with elevated blood levels of potassium, phosphorus, and calcium along with a metabolic acidosis (bicarbonate deficit).

IV urography shows ureteral or renal pelvis dilation. Urinary outflow obstruction can be seen with sonography (renal echography) or computed tomography (CT).

INTERVENTIONS

Urinary retention and potential for infection are the primary problems. Failure to treat the cause of obstruction leads to infection and end-stage kidney disease.

Urologic Interventions

If the stricture is caused by a stone, it can be located and removed using cystoscopic or retrograde urogram procedures. The urologist uses a cystoscope to guide a stone basket over the stone and removes it through the bladder. After stone removal, a plastic stent is usually left in the ureter for a few weeks to improve urine flow in the area irritated by the stone. The stent is later removed by another cystoscopic procedure.

Radiologic Interventions

When a stricture is causing hydronephrosis and cannot be corrected with urologic procedures, a **nephrostomy** is performed. This procedure diverts urine externally and prevents further damage to the kidney.

Patient Preparation. If possible, the patient is kept NPO for 4 to 6 hours before the procedure. Clotting studies (e.g., international normalized ratio [INR], prothrombin time [PT], and partial thromboplastin time [PTT]) should be normal or corrected. The patient receives moderate sedation for the procedure.

Procedure. The patient is placed in the prone position. The kidney is located under ultrasound or fluoroscopic guidance, and a local anesthetic is given. A needle is placed into the kidney, a soft-tipped guidewire is placed through the needle, and then a catheter is placed over the wire. The catheter tip remains in the renal pelvis, and the external end is connected to a drainage bag. The procedure immediately relieves the pressure and prevents further damage. The nephrostomy tube remains in place until the obstruction is resolved (with or without further intervention).

Follow-up Care. Assess the amount of drainage in the collection bag. The amount of drainage depends on whether a ureteral catheter is also being used (with a separate drainage bag). Patients with ureteral tubes may have all urine pass through to the bladder or may have urine drain into the

collection bags. The type of urine drainage expected should be clearly communicated in the chart. If urine is expected to drain into the collection bag, assess the amount of drainage hourly for the first 24 hours. If the amount of drainage decreases and the patient has back pain, the tube may be clogged or dislodged.

Monitor the nephrostomy site for leaking urine or blood. Urine drainage may be red-tinged for the first 12 to 24 hours after the procedure and should gradually clear. Assess the patient for manifestations of infection, including fever or a change in urine character.

! NURSING SAFETY PRIORITY

Critical Rescue

After nephrostomy, notify the physician immediately when the drainage decreases or stops, drainage becomes cloudy or foul-smelling, the nephrostomy site leaks blood or urine, or the patient has back pain.

? NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which laboratory test result for a client who is about to have a nephrostomy for hydronephrosis does the nurse report immediately to the physician?

- A. Serum sodium 137 mEq/L
- B. Serum potassium 4.8 mEq/L
- C. Blood urea nitrogen (BUN) 23 mg/dL
- D. International normalized ratio (INR) 4.6

INFECTIOUS DISORDERS: PYELONEPHRITIS

In the healthy person, urine is normally sterile and remains sterile if there is no obstruction to urine passage in the kidney and urinary tract. When any structural abnormality is present, the risk for damage as a result of infection is greatly increased. **Urinary tract infection (UTI)** is an infection in this normally sterile system. **Pyelonephritis** is a bacterial infection in the kidney and renal pelvis.

Pathophysiology

Pyelonephritis is either the presence of active organisms in the kidney or the effects of kidney infections. **Acute pyelonephritis** is the active bacterial infection, whereas **chronic pyelonephritis** results from repeated or continued upper urinary tract infections or the effects of such infections. Chronic pyelonephritis often occurs with a urinary tract defect, obstruction, or, most commonly, when urine refluxes from the bladder back into the ureters. The vesicoureteral junction is the point at which the ureter joins the bladder. **Reflux** is the reverse or upward flow of urine toward the renal pelvis and kidney.

In pyelonephritis, organisms move up from the urinary tract into the kidney tissue. Descending infection transmitted by organisms in the blood may occur, but not often. Bacteria trigger the inflammatory response, and local edema results.

Acute pyelonephritis involves acute tissue inflammation, tubular cell necrosis, and possible abscess formation. **Abscesses**, which are pockets of infection with pus, can occur anywhere in the kidney. The infection is scattered within the

kidney; healthy tissues can lie next to infected areas. Fibrosis and scar tissue develop from the inflammation. The calices thicken, and scars develop in the interstitial tissue.

Reflux of infected urine from the bladder into the ureters and kidney is responsible for most cases of chronic pyelonephritis. Reflux within the kidney can occur when some papillae in the kidney do not close properly. Inflammation and fibrosis lead to deformity of the renal pelvis and calices. Repeated or continuous infections create additional scar tissue, changing blood vessel, glomerular, and tubular structure. As a result, filtration, reabsorption, and secretion are impaired and kidney function is reduced (Fig. 70-5).

Etiology and Genetic Risk

Single episodes of *acute pyelonephritis* may result from the entry of bacteria, especially during pregnancy, obstruction, or reflux. *Chronic pyelonephritis* usually occurs with structural deformities or obstruction with reflux. Reflux or obstruction leading to chronic pyelonephritis is often caused by stones or neurogenic impairment of voiding. Reflux is more common in children who have acquired scarring during acute infection or as a result of anatomic anomalies. Reflux and scarring contribute to chronic pyelonephritis as an adult. Chronic pyelonephritis in adults who did not have reflux as a child usually occurs with spinal cord injury, bladder tumor, prostate enlargement, or urinary tract stones.

Acute or chronic pyelonephritis occurs often in patients who have undergone manipulation of the urinary tract (e.g., placement of a urinary catheter), those with diabetes mellitus or chronic kidney stones, or those who overuse analgesics. In those with diabetes mellitus, the reduced bladder tone increases the risk for pyelonephritis. In patients with chronic stone disease, stones may retain organisms, resulting in ongoing infection and kidney scarring. NSAID use can lead to papillary necrosis and reflux.

The most common pyelonephritis-causing organism is *Escherichia coli*. *Enterococcus faecalis* is common in hospitalized patients. Both organisms are in the intestinal tract. Other organisms that cause pyelonephritis in hospitalized patients include *Proteus mirabilis*, *Klebsiella*, and *Pseudomonas aeruginosa*. When the infection is bloodborne, common infecting organisms include *Staphylococcus aureus* and the *Candida* and *Salmonella* species.

Other causes of kidney scarring leading to kidney function impairment include antibody reactions, cell-mediated

immunity against the bacterial antigens, or autoimmune reactions.

Incidence/Prevalence

There are approximately 250,000 cases of acute pyelonephritis each year, resulting in more than 100,000 hospitalizations. Chronic pyelonephritis is commonly associated with vesico-ureteral reflux or other anatomic abnormalities and is more common in women, although exact numbers for incidence and prevalence are not available. After 65 years of age, rates of pyelonephritis for men increase greatly because of the increased incidence of prostatitis and enlarged prostate.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Ask about a history of urinary tract infections (UTIs), diabetes mellitus, stone disease, and defects of the genitourinary tract. Determine whether the UTIs occurred with pregnancy, and ask the patient about any previous episodes of pyelonephritis or similar symptoms. Ask about disease or treatment that causes immunosuppression, because they can also increase risk for pyelonephritis. Recurrences are common and may lead to a decline of kidney function.

Physical Assessment/Clinical Manifestations

Ask about specific manifestations of acute pyelonephritis (Chart 70-3). Chronic pyelonephritis has a less dramatic presentation, with manifestations related to the infection or kidney function. Ask the patient to describe any vague or nonspecific urinary symptoms or abdominal discomfort. Inquire about any history of repeated low-grade fevers. The patient with chronic pyelonephritis often has bacteruria that causes no symptoms. Chart 70-4 outlines the kidney effects of chronic pyelonephritis.

CHART 70-3 KEY FEATURES

Acute Pyelonephritis

- Fever
- Chills
- Tachycardia and tachypnea
- Flank, back, or loin pain
- Tender costovertebral angle (CVA)
- Abdominal, often colicky, discomfort
- Nausea and vomiting
- General malaise or fatigue
- Burning, urgency, or frequency of urination
- Nocturia
- Recent cystitis or treatment for urinary tract infection (UTI)

CHART 70-4 KEY FEATURES

Chronic Pyelonephritis

- Hypertension
- Inability to conserve sodium
- Decreased urine concentrating ability, resulting in nocturia
- Tendency to develop hyperkalemia and acidosis

FIG. 70-5 Pathophysiology of pyelonephritis.

Inspect the flanks, and gently palpate the costovertebral angle (CVA). Inspect both CVAs for enlargement, asymmetry, edema, or redness, all of which can indicate inflammation. If there is no tenderness to light palpation in either CVA, an advanced practice nurse firmly percusses each area. Tenderness or discomfort may indicate infection or inflammation.

Psychosocial Assessment

The patient with any problem in the genitourinary area may have feelings of anxiety, embarrassment, or guilt. Listen carefully for signs of anxiety or specific fears, and prevent embarrassment during assessment. Feelings of guilt, often associated with sexual habits or practices, may be masked through delay in seeking treatment or through vague, nonspecific responses to specific or direct questions. Encourage patients to tell their own story in familiar, comfortable language.

Laboratory Assessment

Urinalysis shows a positive leukocyte esterase and nitrite dipstick test and the presence of white blood cells and bacteria. Occasional red blood cells, white blood cell casts, and protein may be present. The urine is cultured to determine whether gram-positive or gram-negative organisms are causing the infection. The urine sample for culture and sensitivity testing, obtained by the clean-catch method, shows the bacterial species and susceptibility or resistance of the specific organism to various antibiotics. In patients with recurrent episodes of pyelonephritis or upper UTIs, more specific testing of bacterial antigens and antibodies may help determine whether the same organism is responsible for the recurrent infections.

Blood cultures are obtained for specific organisms. Other blood tests include the C-reactive protein and erythrocyte sedimentation rate to determine the presence of inflammation.

Imaging Assessment

An x-ray of the kidneys, ureters, and bladder (KUB) and IV urography are performed to diagnose stones or obstructions. A cystourethrogram is indicated for some patients. These procedures define urinary tract structures and identify any defects. Specific defects to be identified include foreign bodies, such as stones; obstruction to the outflow of urine, such as tumors, structural defects, or prostate enlargement; and urine reflux caused by incompetent bladder-ureter valve closure. (See Chapter 68 for more information on imaging assessment.)

Other Diagnostic Assessment

Other diagnostic tests include examining antibody-coated bacteria in urine, certain enzymes (e.g., lactate dehydrogenase isoenzyme 5), and radionuclide scintillation (e.g., gallium scan). Examining urine for antibody-coated bacteria helps identify patients who may need long-term antibiotic therapy. High-molecular-weight enzymes in urine, such as lactate dehydrogenase isoenzyme 5, are present with any kidney tissue deterioration problem and give trend data. The gallium scan can identify active pyelonephritis or abscesses in or around the kidney.

ANALYSIS

The priority problems for the patient with pyelonephritis are:

1. Acute Pain (flank and abdominal) related to inflammation and infection

2. Potential for chronic kidney disease and end-stage kidney disease related to infectious tissue destruction

PLANNING AND IMPLEMENTATION

Managing Pain

Planning: Expected Outcomes. With proper intervention, the patient with pyelonephritis is expected to achieve an acceptable state of comfort. Indicators include that he or she often or consistently demonstrates these behaviors:

- Uses pharmacologic relief measures
- Uses NSAIDs appropriately
- Reports pain controlled

Interventions. Interventions may be nonsurgical or surgical. The use of several techniques that crush stones, such as lithotripsy and percutaneous ultrasonic pyelolithotomy (see Chapter 69), has decreased the need for surgery.

Nonsurgical Management. Interventions include the use of drug therapy, nutrition and fluid therapy, and teaching to ensure the patient's understanding of the treatment.

Drug therapy with antibiotics is prescribed to treat the infection. At first, the antibiotics are broad spectrum. After urine and blood culture and sensitivity results are known, more specific antibiotics may be prescribed. Urinary antiseptic drugs (e.g., nitrofurantoin [Macrobid]) may also be prescribed to provide comfort.

Nutrition therapy involves ensuring that the patient's nutritional intake has adequate calories from all food groups for healing to occur. Fluid intake is recommended at 2 L/day unless another health problem requires fluid restriction.

Surgical Management. Surgical interventions can correct structural problems causing urine reflux or obstruction of urine outflow or can remove the source of infection.

Antibiotics are given, usually IV, to achieve adequate blood levels or sterile blood culture results. Teach the patient the nature and purpose of the proposed surgery, the expected outcome, and how he or she can participate.

The surgical procedures may be one of these: **pyelolithotomy** (stone removal from the kidney), **nephrectomy** (removal of the kidney), ureteral diversion, or reimplantation of ureter to restore proper bladder drainage.

A pyelolithotomy is needed for removal of a large stone in the renal pelvis that blocks urine flow and causes infection. Nephrectomy is a last resort when all other measures to clear the infection have failed. For patients with poor ureter valve closure or dilated ureters, **ureteroplasty** (ureter repair or revision) or ureteral reimplantation (through another site in the bladder wall) preserves kidney function and eliminates infections.

See Chapter 69 for nursing care after surgery for the patient undergoing urologic surgery.

Preventing End-Stage Kidney Disease

Planning: Expected Outcomes. The patient is expected to conserve existing kidney function for as long as possible and have a slow progression to end-stage kidney disease once the damage has occurred. Indicators include that he or she consistently demonstrates these behaviors:

- Describes the role of antibiotics and self-administration of drugs
- Explains and offers techniques to ensure adequate nutrition and hydration
- Describes the plan for post-treatment follow-up, including knowledge of recurrent symptoms

- Modifies prescribed regimen as directed by a health care professional

Interventions. Specific antibiotics are prescribed to treat the infection. Stress the importance of completing the drug therapy as directed. Discuss with the patient and family the importance of regular follow-up examinations and completing the recommended diagnostic tests.

Blood pressure control is needed to slow the progression of kidney dysfunction. When kidney impairment decreases concentrating ability, encourage the patient to drink at least 2 L of fluid per day to prevent dehydration (dehydration could further reduce kidney function). When dietary protein is restricted, refer the patient to the dietitian as needed. Other interventions related to the progression of chronic kidney disease are covered in [Chapter 71](#).

Community-Based Care

Pyelonephritis causes fear and anxiety in the patient and family. The severity of the acute process and its potential to develop into a chronic process are frightening. The patient and the family need reassurance that treatment and preventive measures can be successful.

Home Care Management

If no surgery is performed, the patient may need help with self-care, nutrition, and drug management at home. If surgery is performed, he or she may need help with incision care, self-care, and transportation for follow-up appointments.

Teaching for Self-Management

After assessing the patient's and family's understanding of pyelonephritis and its therapy, explain:

- Drug regimen (purpose, timing, frequency, duration, and possible side effects)
- The role of nutrition and adequate fluid intake
- The need for a balance between rest and activity, including any limitations after surgery
- The manifestations of disease recurrence
- The use of previously successful coping mechanisms

Advise the patient to complete all prescribed antibiotic regimens and to report any side effects or unusual symptoms to the physician rather than stopping the drugs. Refer the patient and family for nutritional counseling as needed, because many patients have special nutritional requirements, such as those for diabetes or pregnancy.

Health Care Resources

The patient may also briefly need a home health nurse to help with drug or nutrition therapy at home. Housekeeping services may be helpful while he or she is regaining strength.

EVALUATION: OUTCOMES

Evaluate the care of the patient with pyelonephritis based on the identified priority patient problems. Expected outcomes may include that the patient will:

- Report that pain is controlled
- Be knowledgeable about the disease, its treatment, and interventions to prevent or reduce disease progression

Specific indicators for these outcomes are listed for each priority patient problem in the Planning and Implementation section (see earlier).

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which statement made by a client who has acute pyelonephritis indicates to the nurse correct understanding of the antibiotic therapy?

- "If my temperature is normal for 3 days in a row, the infection is gone and I can stop taking the drug."
- "If my temperature goes above 100° for 2 days, I should take double the dose of the drug."
- "Even if I feel completely well, I should take the drug exactly as prescribed until it is gone."
- "I should notify my prescriber to change the medication if I develop diarrhea while taking this drug."

IMMUNOLOGIC KIDNEY DISORDERS

Glomerulonephritis (GN) is the third leading cause of end-stage kidney disease (ESKD) ([U.S. Renal Data Systems, 2010](#)). Whether the disease starts in the kidney or occurs as the result of other health problems, the glomeruli are usually injured ([Table 70-1](#)). For disease that starts in the kidney, a genetic basis and immune problem are common. In addition, systemic diseases and infections can have kidney effects and cause glomerular injury ([Table 70-2](#)). Conditions that lead to glomerular disease include systemic lupus erythematosus and diabetic nephropathy.

Each type of disease or syndrome has a specific pathophysiology and clinical manifestations. Their *glomerular* effects are caused by injury to the glomeruli and result in

TABLE 70-1 PRIMARY GLOMERULAR DISEASES AND SYNDROMES

- Acute glomerulonephritis
- Rapidly progressive glomerulonephritis (RPGN)
- Chronic glomerulonephritis
- Nephrotic syndrome
- Persistent, vague urinary abnormalities with few or no symptoms

TABLE 70-2 SECONDARY GLOMERULAR DISEASES AND SYNDROMES

- Systemic lupus erythematosus (SLE)
- Schönlein-Henoch purpura
- Goodpasture's syndrome
- Systemic necrotizing vasculitis
- Wegener's granulomatosis
- Periarthritis nodosa (also called *polyarteritis nodosa*)
- Amyloidosis
- Diabetic glomerulopathy
- HIV-associated nephropathy
- Alport's syndrome
- Multiple myeloma
- Viral hepatitis B
- Viral hepatitis C
- Cirrhosis
- Sickle-cell disease
- Nonstreptococcal postinfectious acute glomerulonephritis
- Infective endocarditis
- Hemolytic-uremic syndrome
- Thrombotic thrombocytopenic purpura

proteinuria, hematuria, decreased glomerular filtration rate (GFR), edema, and hypertension. The extent and duration of kidney injury, prognosis, and specific cause vary among these syndromes.

Immunologic changes injure the glomeruli, interstitium, or tubules, and the effects may be acute or chronic. Both antibody and cellular immune responses are involved. The resultant kidney disorder can be systemic or confined to the kidneys.

Most forms of glomerulonephritis (GN) occur with a collection of immune complexes in the glomeruli (Fig. 70-6). An immune complex is made up of antigens (foreign substances within the body) and antibodies. The antigen can be part of any normal kidney tissue, or it can be dissolved in a body fluid (e.g., blood). Bacteria and viruses are also antigens. Exposure to bacteria, viruses, drugs, or other toxins is believed to be the trigger for glomerular injury.

Antibody reaction with antigens can cause immune complexes to form and become deposited in glomerular tissue. These complexes trigger many inflammatory mediators, such as complement, white blood cells, and blood clotting proteins, which also damage the kidney tissue. Actions that cause tissue injury include damage to cell membranes, local edema, movement of white blood cells to the site of inflammation, and platelet activation.

ACUTE GLOMERULONEPHRITIS

Pathophysiology

An infection often occurs before the kidney manifestations of acute glomerulonephritis (GN). The onset of symptoms is about 10 days from the time of infection. Usually, patients recover quickly and completely from acute GN. The term *acute nephritic syndrome* also describes this disorder.

FIG. 70-6 An immune complex precipitating in the glomerulus of a patient with glomerulonephritis.

Most causes of acute GN are infectious (Table 70-3) or are related to other systemic diseases (see Table 70-2). The incidence of acute GN is unknown. GN after a systemic streptococcal infection is more common in men.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Ask about recent infections, particularly of the skin or upper respiratory tract, and about recent travel or other possible exposures to viruses, bacteria, fungi, or parasites. Recent illnesses, surgery, or other invasive procedures may suggest infections. Ask about any known systemic diseases, such as systemic lupus erythematosus (SLE), which could cause acute GN.

Physical Assessment/Clinical Manifestations

Inspect the patient's skin for lesions or recent incisions (including body piercings). Assess the face, eyelids, hands, and other areas for edema (present in about 75% of the patients with acute GN). Assess for fluid overload and circulatory congestion (which may accompany the sodium and fluid retention occurring with acute GN). Ask about any difficulty in breathing or shortness of breath. Assess for crackles in the lung fields, an S₃ heart sound (gallop rhythm), and neck vein distention.

Ask about changes in urination pattern and any change in urine color. Microscopic blood in the urine occurs most of the time, and patients often describe their urine as smoky, reddish brown, rusty, or cola colored. Ask about dysuria or oliguria. Weigh him or her to assess for fluid retention.

Take the patient's blood pressure and compare it with the baseline blood pressure. Mild to moderate hypertension often occurs with acute GN as a result of sodium and fluid retention. The patient may have fatigue, a lack of energy, anorexia, nausea, and/or vomiting if uremia from severe kidney impairment is present.

TABLE 70-3 INFECTIOUS CAUSES OF ACUTE GLOMERULONEPHRITIS

- Group A beta-hemolytic *Streptococcus*
- Staphylococcal or gram-negative bacteremia or sepsis
- Pneumococcal, *Mycoplasma*, or *Klebsiella pneumonia*
- Syphilis
- Visceral abscesses
- Infective endocarditis
- Hepatitis B
- Infectious mononucleosis
- Measles
- Mumps
- Rocky Mountain spotted fever
- Cytomegalovirus infection
- Histoplasmosis
- Toxoplasmosis
- Varicella
- *Chlamydia psittaci* infection
- Coxsackievirus infection
- Any bacterial, parasitic, fungal, or viral infection (potentially)

CONSIDERATIONS FOR OLDER ADULTS

The less common manifestations of acute GN are more likely to occur in older adults. Circulatory congestion often is present, causing acute GN to be easily confused with congestive heart failure.

Laboratory Assessment

Urinalysis shows red blood cells (*hematuria*) and protein (*proteinuria*). An early morning specimen of urine is preferred for urinalysis because the urine is most acidic and formed elements are more intact at that time. Microscopic examination often shows red blood cell casts, as well as casts from other substances. The urine sediment assay is usually positive.

The glomerular filtration rate (GFR), either estimated from a single serum and urine creatinine value or measured by the 24-hour urine test for creatinine clearance, may be decreased to 50 mL/min. Blood urea nitrogen (BUN) levels are usually increased. The older patient may have a greater decline in GFR.

A 24-hour urine collection for total protein assay is obtained. The protein excretion rate for patients with acute GN may be increased from 500 mg to 3 g/24 hr in most patients. Serum albumin levels are decreased because of the protein lost in the urine and because of fluid retention causing dilution.

Specimens from the blood, skin, or throat are obtained for culture, if indicated. Other serologic tests include antistreptolysin-O titers, C3 complement levels, cryoglobulins (immunoglobulin G [IgG]), antinuclear antibodies (ANAs), and circulating immune complexes.

Antistreptolysin-O titers are increased after group A beta-hemolytic *Streptococcus* infections. Complement levels are decreased when the complement system is activated. Type III cryoglobulins may be found during acute illness. ANAs suggest an autoimmune response, and SLE is just one possibility. Immune complexes containing IgG and C3 are often detected.

Other Diagnostic Assessment

A kidney biopsy provides a precise diagnosis of the condition, assists in determining the prognosis, and helps outline treatment (see [Chapter 68](#)). The specific tissue features are determined by light microscopy, immunofluorescent stains, and electron microscopy to identify cell type, the presence of immunoglobulins, or the type of tissue deposits.

INTERVENTIONS

Interventions focus on managing infection, preventing complications, and providing appropriate patient education.

Managing infection as a cause of acute GN begins with appropriate antibiotic therapy. Penicillin, erythromycin, or azithromycin is prescribed for GN caused by streptococcal infection. Check the patient's known allergies before giving any drug. To prevent infection spread, antibiotics for people in immediate close contact with the patient also may be prescribed. Stress personal hygiene and basic infection control principles (e.g., handwashing) to prevent spread of the organism. Teach patients the importance of completing the entire course of the prescribed antibiotic.

Preventing complications is an important nursing intervention. For patients with fluid overload, hypertension, and

edema, diuretics and a sodium and water restriction are prescribed. Antihypertensive drugs may be needed to control hypertension (see [Chapter 38](#)). The usual fluid allowance is equal to the 24-hour urine output plus 500 to 600 mL. Patients with oliguria usually have increased serum levels of potassium and blood urea nitrogen (BUN). Potassium and protein intake may be restricted to prevent hyperkalemia and uremia as a result of the elevated BUN.

Nausea, vomiting, or anorexia indicates that uremia is present. Dialysis is necessary if uremic symptoms or fluid volume excess cannot be controlled (see [Chapter 71](#)). **Plasmapheresis** (removal and filtering of the plasma to eliminate antibodies) also may be used (see [Chapter 42](#)).

To conserve the patient's energy, assist him or her in maintaining a restful environment, balancing activity and rest, and coordinating needed activities. Urge the patient to practice relaxation techniques and to participate in diversional activities to reduce emotional stress.

Preparing for self-management includes teaching the patient and family members about the purpose of prescribed drugs, the dosage and schedule, and potential adverse side effects. Ensure that they understand dietary or fluid restrictions, including methods of detecting fluid retention. Advise the patient to measure weight and blood pressure daily at the same time each day. Instruct him or her to notify the health care provider of any sudden increase in weight or blood pressure.

If short-term dialysis is required to control fluid volume or uremic symptoms, explain peritoneal or vascular access care and dialysis schedules and routines (also see [Chapter 71](#)).

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Rapidly progressive glomerulonephritis (RPGN), a type of acute nephritis, is also called *crescentic glomerulonephritis* because of the presence of crescent-shaped cells in the Bowman's capsule. RPGN develops over several weeks or months and causes loss of kidney function. Patients become quite ill quickly and have manifestations of kidney impairment (fluid volume excess, hypertension, oliguria, electrolyte imbalances, and uremic symptoms).

The patient may have had previous infection or systemic disease, such as systemic lupus erythematosus (SLE). The kidney function decline often progresses to end-stage kidney disease.

CHRONIC GLOMERULONEPHRITIS**Pathophysiology**

Chronic glomerulonephritis, or *chronic nephritic syndrome*, develops over 20 to 30 years or even longer. The exact onset of the disorder is rarely identified. Often the cause of the disease is not known because the kidneys are atrophied and tissue is not available for biopsy or diagnosis. Mild proteinuria and hematuria, hypertension, fatigue, and occasional edema are often the only manifestations.

Although the exact cause is not known, changes in the kidney tissue result from hypertension, infections and inflammation, or poor blood flow to the kidneys. Kidney tissue atrophies, and the number of functional nephrons is greatly reduced. Biopsy in the late stages of atrophy may show

glomerular changes, cell loss, protein and collagen deposits, and fibrosis of the kidney tissue. Microscopic examination shows deposits of immune complexes.

The loss of nephrons reduces glomerular filtration. Hypertension and renal arteriole sclerosis are often present. The glomerular damage allows proteins to enter the urine. Chronic glomerulonephritis always leads to end-stage kidney disease (see [Chapter 71](#)).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Ask about other health problems, including systemic diseases, kidney or urologic disorders, infectious diseases (e.g., streptococcal infections), and recent exposures to infections. Ask about overall health status and whether increasing fatigue and lethargy have occurred.

Identify the patient's voiding pattern. Ask whether the frequency of voiding has increased or the quantity of urine has decreased. Ask about changes in urine color, odor, or clarity and whether dysuria or incontinence has occurred. Nocturia also is a common symptom.

Assess the patient's general comfort, and ask whether any dyspnea at rest or with exertion has occurred, because fluid overload can occur with decreased urine output. Ask about and observe for changes in mental functioning, such as irritability or an inability to read or to perform job-related functions or other processes requiring concentration. Changes in memory and the ability to concentrate occur as waste products collect in the blood.

Physical Assessment/Clinical Manifestations

Assess for systemic circulatory overload. Auscultate lung fields for crackles, observe the respiratory rate and depth, and measure blood pressure and weight. Auscultate the heart for rate, rhythm, and the presence of an S_3 heart sound. Inspect the neck veins for venous engorgement, and check for edema of the foot and ankle, on the shin, and over the sacrum.

Assess for uremic symptoms, such as slurred speech, ataxia, tremors, or **asterixis** (flapping tremor of the fingers or the inability to maintain a fixed posture with the arms extended and wrists hyperextended). Inspect skin for a yellowish color, texture, bruises, rashes, or eruptions. Ask about itching, and document areas of dryness or any excoriation from scratching.

Diagnostic Assessment

Urine output decreases, but the urine appears normal unless a urinary tract infection (UTI) also is present. Urinalysis shows protein, usually less than 2 g in a 24-hour collection. The specific gravity is fixed at a constant level of dilution (around 1.010). Red blood cells and casts may be in the urine.

The glomerular filtration rate (GFR), measured by creatinine clearance, is low. The serum creatinine level is elevated, usually greater than 6 mg/dL but may be as high as 30 mg/dL or more. The BUN is increased, often as high as 100 to 200 mg/dL.

Decreased kidney function causes abnormal serum electrolyte levels. Sodium retention is common, but dilution of

the plasma from excess fluid can result in a falsely normal serum sodium level (135 to 145 mEq/L) or a low sodium level (less than 135 mEq/L). When oliguria develops, potassium is not excreted and hyperkalemia occurs when levels exceed 5.4 mEq/L.

Hyperphosphatemia develops with serum levels greater than 4.7 mg/dL. Serum calcium levels are usually at the lower end of the normal range or are slightly below normal.

Acidosis develops from hydrogen ion retention and loss of bicarbonate. However, there may be a decrease in serum carbon dioxide (CO_2) levels as patients breathe more rapidly to compensate for the acidosis. If respiratory compensation is present, the pH of arterial blood is between 7.35 and 7.45. A pH of less than 7.35 means that the patient's respiratory system is not completely compensating for the acidosis (see [Chapter 14](#)).

The kidneys are abnormally small on x-ray and on IV urography and when measured by sonography or computed tomography (CT).

A kidney biopsy is important in the early stages of glomerulonephritis, when protein or blood is first present in the urine. Tissue changes include a variety of cells infiltrating the glomerular tissue, deposits of immune complexes, and blood vessel sclerosis. In advanced disease, when the kidneys are small, biopsy is not usually performed.

INTERVENTIONS

Interventions focus on slowing the progression of the disease and preventing complications. Management consists of diet changes, fluid intake sufficient to prevent reduced blood flow volume to the kidneys, and drug therapy to control the problems from uremia. Eventually, the patient requires dialysis or transplantation to prevent death from uremia. (Care for the patient with ESKD requiring dialysis or transplantation is discussed in [Chapter 71](#).)

NEPHROTIC SYNDROME

Pathophysiology

Nephrotic syndrome (NS) is a condition of increased glomerular permeability that allows larger molecules to pass through the membrane into the urine and then be excreted. This process causes massive loss of protein into the urine, edema formation, and decreased plasma albumin levels. Many agents and disorders are possible causes of NS.

The most common cause of glomerular membrane changes is an immune or inflammatory process. Defects in glomerular filtration can also occur as a result of genetic defects of the glomerular filtering system, such as Fabry disease. Altered liver activity may occur with nephrotic syndrome, resulting in increased lipid production and hyperlipidemia.

PATIENT-CENTERED COLLABORATIVE CARE

The main feature of nephrotic syndrome (NS) is severe proteinuria (more than 3.5 g of protein in 24 hours). Patients also have low serum albumin levels (serum albumin is less than 3 g/dL), high serum lipid levels, fats in the urine, edema, and hypertension ([Chart 70-5](#)). Renal vein thrombosis often occurs at the same time as NS, either as a cause of the problem

CHART 70-5 KEY FEATURES

Nephrotic Syndrome

Sudden onset of these manifestations:

- Massive proteinuria
- Hypoalbuminemia
- Edema (especially facial and periorbital)
- Lipiduria
- Hyperlipidemia
- Increased coagulation
- Reduced kidney function

or as an effect. NS may progress to ESKD, but this can be prevented with treatment.

Management varies depending on what process is causing the disorder (identified by kidney biopsy). Immunologic processes may improve with suppressive therapy using steroids and cytotoxic or immunosuppressive agents. Angiotensin-converting enzyme (ACE) inhibitors can decrease protein loss in the urine, and cholesterol-lowering drugs can improve blood lipid levels. Heparin may reduce urine protein loss and improve kidney function. Diet changes are often prescribed. If the glomerular filtration rate (GFR) is normal, dietary intake of complete proteins is needed. If the GFR is decreased, dietary protein intake must be decreased. Mild diuretics and sodium restriction may be needed to control edema and hypertension. Assess the patient's hydration status, because vascular dehydration is common. If the plasma volume is depleted, kidney problems worsen. Acute kidney injury (AKI) may be avoided if good blood flow to the kidney is maintained.

IMMUNOLOGIC INTERSTITIAL AND TUBULOINTERSTITIAL DISORDERS

Problems can arise in the kidney tissues around the nephrons, as well as in the nephron tissues. These interstitial and tubulointerstitial disorders in the kidney are usually caused by immune problems. The kidney changes may be acute or chronic. The acute effects often occur with drugs such as penicillins, cephalosporins, sulfonamides, or NSAIDs. Chronic interstitial nephritis has many causes, including analgesic use, complement activation, cyclosporin use, polycystic kidney disease, autoimmune disorders, multiple myeloma, sickle cell disease, obstructive disorders, and radiation nephritis. Drug-induced problems often occur with a rash or an elevated eosinophil count. Fever is common in interstitial nephritis of unknown cause. Progression to ESKD occurs unless the cause is identified and removed.

DEGENERATIVE DISORDERS

Degenerative disorders that change kidney function often occur with a multisystem disorder. Many of these degenerative disorders result from changes in kidney blood vessels.

NEPHROSCLEROSIS

Pathophysiology

Nephrosclerosis is a problem of thickening in the nephron blood vessels, resulting in narrowing of the vessel lumens. This change decreases kidney blood flow, and the tissue

is chronically hypoxic. Ischemia and fibrosis develop over time.

Nephrosclerosis occurs with all types of hypertension, atherosclerosis, and diabetes mellitus. The more severe the hypertension, the greater the risk for severe kidney damage. Nephrosclerosis is rarely seen when blood pressure is consistently below 160/110 mm Hg. The changes caused by hypertension may be reversible or may progress to end-stage kidney disease (ESKD) within months or years.

Hypertension is the second leading cause of ESKD, with about 30% of patients requiring kidney replacement therapy (e.g., dialysis or transplantation).

CULTURAL CONSIDERATIONS

Hypertension is more common in African Americans and American Indians, and the risks for ESKD from hypertension are also greater for these ethnic groups ([U.S. Renal Data Systems, 2010](#)). Between 25 and 45 years of age, the ratio of African Americans to Caucasians at risk for ESKD from hypertension is nearly 20:1. At any health care encounter with an African-American patient or an American Indian patient, blood pressure should always be assessed. If hypertension is present, treatment and patient education can help reduce the risk for development of ESKD.

PATIENT-CENTERED COLLABORATIVE CARE

Management focuses on controlling high blood pressure and reducing albuminuria to preserve kidney function. Although many antihypertensive drugs may lower blood pressure, the patient's response is important in ensuring long-term adherence to the prescribed therapy. Factors that promote adherence include once-a-day dosing, low cost, and minimal side effects.

Lack of knowledge or misinformation about hypertension poses many challenges to health care providers working with patients who have hypertension. When kidney disease occurs, adherence to therapy is even more important for preserving health.

Many drugs can control high blood pressure (see [Chapter 38](#)), and more than one agent may be needed for best control. Angiotensin-converting enzyme (ACE) inhibitors are very useful in reducing hypertension and preserving kidney function. Diuretics can maintain fluid and electrolyte balance in the presence of kidney function insufficiency. Hyperkalemia needs to be prevented when potassium-sparing diuretics, alone or in combination, are used to treat hypertensive patients with known kidney disease.

RENOVASCULAR DISEASE

Pathophysiology

Processes affecting the renal arteries may severely narrow the lumen and greatly reduce blood flow to the kidney tissues. Uncorrected renovascular disease, such as renal artery stenosis, atherosclerosis, or thrombosis, causes ischemia and atrophy of kidney tissue ([Russell, 2008](#)).

Patients with renovascular disease often have a sudden onset of hypertension, particularly in patients older than 50 years. Patients with high blood pressure but with no family history of hypertension also may potentially have renal artery stenosis (RAS). RAS from atherosclerosis or blood vessel

hyperplasia is the main cause of renovascular disease. Other causes include thrombosis and renal vessel aneurysms.

Atherosclerotic changes in the renal artery often occur along with sclerosis in the aorta and other major vessels. Changes in the renal artery are often located where the renal artery and aorta meet. Fibrotic changes of the blood vessel wall occur throughout the length of the renal artery.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Key features of renovascular disease are listed in [Chart 70-6](#). Hypertension usually first occurs after 40 to 50 years of age, and often the patient does not have a family history of hypertension. Diagnosis is made by magnetic resonance angiography (MRA), renal duplex ultrasonography, radionuclide imaging, renal arteriography, and renal vein renin levels. MRA provides an excellent image of the renal vasculature and kidney anatomy. Radionuclide imaging is a noninvasive way of evaluating kidney blood flow and excretory function. Combining radionuclide imaging with ingestion of an angiotensin-converting enzyme (ACE) inhibitor such as captopril improves the accuracy of the test. A renal arteriogram makes the features of the renal blood vessels visible. The comparison of renal vein renin levels *may* reveal which kidney is producing more renin.

INTERVENTIONS

Identifying the type of defect, extent of narrowing, and condition of the surrounding blood vessels is critical for treatment choice. The patient's overall health and the size of the atrophied kidney also affect management decisions. Many patients with renovascular disease also have cardiovascular disease, and both conditions require treatment.

RAS may be managed by drugs to control high blood pressure and by procedures to restore the blood supply to the kidney. Drugs may control high blood pressure but may not lead to long-term preservation of kidney function. In young and middle-aged adults, a lifetime of treatment with many drugs for high blood pressure makes treatment difficult and the outcomes uncertain.

Balloon angioplasty with or without stent placement to open renal vessels is less risky and requires less time for recovery than does renal artery bypass surgery (see [Chapter 38](#)). Renal artery bypass surgery is a major procedure and requires 2 or more months for recovery. A bypass may be performed for either one or both renal arteries.

Renal angioplasty with metal stent placement is one safe and effective method to repair RAS. After the procedure, the patient usually remains in ICU for 24 hours to monitor for sudden blood pressure fluctuations as the kidneys adjust to increased blood flow.

CHART 70-6 KEY FEATURES

Renovascular Disease

- Significant, difficult-to-control high blood pressure
- Poorly controlled diabetes or sustained hyperglycemia
- Elevated serum creatinine
- Decreased creatinine clearance

A synthetic blood vessel graft is inserted to redirect blood flow from the abdominal aorta into the renal artery, beyond the area of narrowing. A splenorenal bypass can also restore blood flow to the kidney. The process is similar to other arterial bypass procedures (see [Chapter 37](#)).

DIABETIC NEPHROPATHY

Pathophysiology

Diabetes mellitus is the leading cause of end-stage kidney disease (ESKD) among white people in North America. About 36% of patients requiring dialysis or kidney transplantation have diabetes mellitus ([U.S. Renal Data Systems, 2010](#)). Diabetic nephropathy occurs with either type 1 or type 2 diabetes mellitus. Severity of diabetic kidney disease is related to the degree of hyperglycemia the patient generally experiences. With poor control of hyperglycemia, the complicating problems of atherosclerosis, hypertension, and neuropathy (which promotes loss of bladder tone, urinary stasis, and urinary tract infection) are more severe and more likely to cause kidney damage.

PATIENT-CENTERED COLLABORATIVE CARE

Diabetic nephropathy is a vascular complication of diabetes. Its first manifestation is persistent albuminuria (as shown by dipstick or a urinary albumin excretion rate above 0.3 g/dL), without evidence of other kidney disease. Diabetic kidney disease is progressive ([Table 70-4](#)).

Structural and functional changes occur in the kidneys of diabetic patients. Initially, kidney size is slightly increased and glomerular filtration rates (GFRs) are higher than normal. Microlevels of albumin are first detected in the urine. Progressive kidney damage occurs before dipstick procedures can detect protein in the urine. For most patients, proteinuria (albuminuria) indicates the need for follow-up and possibly a kidney biopsy for further diagnosis. See [Chapter 67](#) for a detailed discussion of kidney issues in patients with diabetes.

Proteinuria may be mild, moderate, or severe. Patients with diabetes are always considered to be at risk for end-stage

TABLE 70-4 THE STAGES OF PROGRESSION OF TYPE 1 DIABETIC KIDNEY DISEASE

Stage I, at the time diabetes is diagnosed. Kidney size and glomerular filtration rate are increased. Blood sugar control can reverse the changes.
Stage II, 2 to 3 years after diagnosis. Glomerular and tubular capillary basement membrane changes result in microscopic changes, with loss of filtration surface area and scar formation. Glomerular changes are referred to as <i>glomerulosclerosis</i> .
Stage III, 7 to 15 years after diagnosis. Microalbuminuria is present. The glomerular filtration rate (GFR) may still be normal or may be increased.
Stage IV. Albuminuria is detectable by dipstick. GFR is decreased. Blood pressure is increased, and retinopathy is present.
Stage V. GFR decreases at an average rate of 10 mL/min/yr.
NOTE: Progression of chronic kidney disease related to type 1 diabetes mellitus can be delayed by maintaining glycemic control with HbA _{1c} levels below 8%.

kidney disease (ESKD). If possible, nephrotoxic agents (e.g., radiopaque contrast media or aminoglycosides) and dehydration are avoided. Patients with worsening kidney function may begin to have frequent hypoglycemic episodes and a reduced need for insulin or antidiabetic agents. Explain that the kidneys metabolize and excrete insulin. When kidney function is reduced, the insulin is available for a longer time and thus less of it is needed. Unfortunately, many patients believe this means their diabetes is improving. The result is a more rapid progression to ESKD. (See [Chapter 67](#) for specific information on diabetic nephropathy.)

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

The client with diabetes who also has persistent proteinuria asks what he could do to prevent eventual kidney failure. What is the nurse's best response?

- A. "Wear pads and other protective gear around your lower back when engaging in contact sports."
- B. "Drink at least 3 L of water daily and avoid carbonated beverages."
- C. "Limit your intake of proteins to less than 100 g daily."
- D. "Keep your blood glucose levels in the target range."

RENAL CELL CARCINOMA

Pathophysiology

Renal cell carcinoma (RCC) is the most common type of kidney cancer and is also known as *adenocarcinoma of the kidney*. As with other cancers, the healthy tissue of the kidney is damaged and replaced by cancer cells.

Systemic effects occurring with this cancer type are called *paraneoplastic syndromes* and include anemia, erythrocytosis, hypercalcemia, liver dysfunction with elevated liver enzymes, hormonal effects, increased sedimentation rate, and hypertension.

Anemia and erythrocytosis may seem confusing; however, most patients with this cancer have *either* anemia or erythrocytosis, not both at the same time. There is some blood loss from hematuria, but the small amount lost does not cause anemia. The cause of the anemia and the erythrocytosis is related to kidney cell production of erythropoietin. At times, the tumor cells produce large amounts of erythropoietin, causing erythrocytosis. Other times, the tumor cells destroy the erythropoietin-producing kidney cells and anemia results. Hypertension may result from increased blood levels of renin.

Parathyroid hormone produced by tumor cells can cause hypercalcemia. Other hormone changes include increased renin levels (causing hypertension) and increased human chorionic gonadotropin (hCG) levels, which decrease libido and change secondary sex features.

RCC has four distinct cell types. Genetic differences cause a predisposition to develop tumors of each of these types. The most well known genetic familial syndrome that includes kidney cancer is von Hippel-Lindau syndrome. These cancers are highly vascular and may occur with cancers of the pancreas, central nervous system, and adrenal glands.

Kidney tumors are classified into four stages ([Table 70-5](#)). Complications include metastasis and urinary tract obstruction. The cancer usually spreads to the adrenal gland, liver, lungs, long bones, or the other kidney ([Moldawer & Figlin](#),

TABLE 70-5 STAGING KIDNEY TUMORS

Stage I. Tumors up to 2.5 cm are situated within the capsule of the kidney. The renal vein, perinephric fat, and adjacent lymph nodes have no tumor.

Stage II. Tumors are larger than 2.5 cm and extend beyond the capsule but are within Gerota's fascia. The renal vein and lymph nodes are not involved.

Stage III. Tumors extend into the renal vein, lymph nodes, or both.

Stage IV. Tumors include invasion of adjacent organs beyond Gerota's fascia or metastasize to distant tissues.

Data from American Cancer Society. (2011). *Cancer facts and figures 2011*. Report No. 00-300M-No. 5008.11. Atlanta: Author.

2008). When the cancer surrounds a ureter, hydroureter and obstruction may result.

The exact cause of RCC is unknown, but the risk is slightly higher for people who use tobacco or are exposed to lead, phosphate, and cadmium.

Kidney cancers account for about 51,190 new cases and 12,890 deaths annually in the United States. The 5-year survival rate is 60% in the United States. Renal cell carcinoma occurs most often in patients between 55 and 60 years of age (Jemal et al., 2007).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Ask the patient about age, known risk factors (e.g., smoking or chemical exposures), weight loss, changes in urine color, abdominal or flank discomfort, and fever. Also ask whether any other family member has ever been diagnosed with cancer of the kidney, bladder, ureter, prostate gland, uterus, or ovary.

Physical Assessment/Clinical Manifestations

Only about 5% to 10% of patients with renal cell cancer have flank pain, obvious blood in the urine, and a kidney mass that can be palpated. Ask about the nature of the flank or abdominal discomfort. Patients often describe the pain as dull and aching. The pain may be more intense if bleeding into the tumor or kidney occurs. Inspect the flank area, checking for asymmetry or an obvious bulge. An abdominal mass may be felt through *gentle* palpation. A renal bruit may be heard on auscultation.

Bloody urine is a *late* common sign. Blood may be visible as bright red flecks or clots, or the urine may appear smoky or cola colored. Without gross hematuria, microscopic examination may or may not reveal red cells.

Inspect the skin for pallor, darkening of the nipples, and, in men, breast enlargement (*gynecomastia*) caused by changing hormone levels. Other findings may include muscle wasting, weakness, poor nutritional status, and weight loss. All tend to occur late in the disease.

Diagnostic Assessment

Urinalysis may show red blood cells. Hematologic studies show decreased hemoglobin and hematocrit values, hypercalcemia, increased erythrocyte sedimentation rate, and

increased levels of adrenocorticotrophic hormone, human chorionic gonadotropin (hCG), cortisol, renin, and parathyroid hormone.

Kidney masses may be detected by surgical exploration, IV urogram with nephrograms, or sonography. The mass and surrounding tissues may be outlined by CT with contrast or by magnetic resonance imaging (MRI). Complete diagnosis requires a biopsy of the tumor.

INTERVENTIONS

Interventions focus on controlling the cancer and preventing metastasis.

Nonsurgical Management

Radiofrequency ablation can slow tumor growth. It is a minimally invasive procedure carried out after MRI has precisely located the tumor. The procedure is used most commonly for patients who have only one kidney or who are poor surgical candidates.

Chemotherapy has limited effectiveness against this cancer type. Use of biological response modifiers (BRMs) such as interleukin-2 (IL-2), interferon (INF), and tumor necrosis factor (TNF) has lengthened survival time (see [Chapters 19 and 24](#)). Newer targeted therapy agents, sorafenib (Nexavar) and temsirolimus (Torisel), were approved as treatment for patients with advanced renal cell carcinoma. Sorafenib, an oral drug taken daily, is a multikinase inhibitor that slows cancer cell division and inhibits blood vessel growth in the tumor. Temsirolimus is a weekly IV infusion and works by inhibiting cell division. These drugs have increased survival time of patients with advanced cancer.

Surgical Management

Renal cell carcinoma is usually treated surgically by *nephrectomy* (kidney removal). Renal cell tumors are highly vascular, and blood loss during surgery is a major concern. Before surgery, the arteries supplying the kidney may be occluded (embolized) by radiation to reduce bleeding during nephrectomy.

Preoperative Care. Instruct the patient about surgical routines (see [Chapters 16, 17, and 18](#)). Explain the probable site of incision and the presence of dressings, drains, or other equipment after surgery. Reassure the patient about pain relief. Care before surgery may include giving blood and fluids IV to prevent shock.

Operative Procedures. The patient is placed on his or her side with the kidney to be removed uppermost. The trunk area is flexed to increase exposure of the kidney area. Removal of the eleventh or twelfth rib may be needed to provide better access to the kidney. The surgeon removes the entire kidney and all visible tumor, renal artery and vein, and fascia after tying off the ureter. The adrenal gland is left intact. A drain may be placed in the wound before closure.

When a *radical* nephrectomy is performed, local and regional lymph nodes are also removed. The surgical approach may be transthoracic (as discussed in the previous paragraph), lumbar, or through the abdomen, depending on the size and location of the tumor. Radiation therapy may follow a radical nephrectomy.

Postoperative Care. Refer to [Chapter 18](#) for care of the patient after surgery. Nursing priorities are focused on assessing kidney function to determine effectiveness of the

remaining kidney, pain management, and preventing complications.

Monitoring includes assessing for hemorrhage and adrenal insufficiency. Inspect the patient's abdomen for distention from bleeding. Check the bed linens under the patient, because blood may pool there. Hemorrhage or adrenal insufficiency causes hypotension, decreased urine output, and an altered level of consciousness.

A decrease in blood pressure is an early sign of both hemorrhage and adrenal insufficiency. With hypotension, urine output also decreases immediately. Large water and sodium losses in the urine occur in patients with adrenal insufficiency. As a result, a large urine output is followed by hypotension and oliguria (less than 400 mL/24 hr or less than 25 mL/hr). IV replacement of fluids and packed red blood cells may be needed.

The second kidney is expected to provide adequate function, but this may take days or weeks. Assess urine output hourly for the first 24 hours after surgery (urine output of 0.5 mL/kg/hr or about 30 to 50 mL/hr is acceptable). Output of less than 25 to 30 mL/hr suggests decreased blood flow to the kidney and the onset or worsening of acute kidney injury. The hemoglobin level, hematocrit values, and white blood cell count may be measured every 6 to 12 hours for the first day or two after surgery.

Monitor the patient's temperature, pulse rate, and respiratory rate at least every 4 hours. Accurately measure and record fluid intake and output. Weigh the patient daily.

The patient may be in a special care unit for 24 to 48 hours after surgery for monitoring of bleeding and adrenal insufficiency. A drain placed near the site of incision removes residual fluid. Because of the discomfort of deep breathing, the patient is at risk for atelectasis. Fever, chills, thick sputum, or decreased breath sounds suggest pneumonia.

Managing pain after surgery usually requires opioid analgesics (e.g., hydromorphone [Dilaudid] and morphine [Statex ) given intravenously. The incision was made through major muscle groups used with breathing and movement. Liberal use of analgesics is needed for 3 to 5 days after surgery to manage pain. Oral agents may be tried when the patient can eat and drink.

Preventing complications focuses on infection and management of adrenal insufficiency. Antibiotics may be prescribed during and after surgery to prevent infection. The need for additional antibiotics is based on evidence of infection. Assess the patient at least every 8 hours for manifestations of systemic infection or local wound infection.

Adrenal insufficiency is possible as a complication of kidney and adrenal gland removal. Although only one adrenal gland may be affected, the remaining gland may not be able to secrete sufficient glucocorticoids immediately after surgery. Steroid replacements may be needed in some patients. [Chapter 65](#) discusses the manifestations of acute adrenal insufficiency in detail along with specific nursing interventions.

KIDNEY TRAUMA

Pathophysiology

Trauma to one or both kidneys is always a concern in penetrating wounds or blunt injuries to the back, flank, or abdomen. Blunt trauma to the back, flank, or abdomen

MINOR TRAUMA

PEDICLE INJURY

MAJOR TRAUMA

FIG. 70-7 Common types and locations of kidney trauma.

CHART 70-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Preventing Kidney and Genitourinary Trauma

- Wear a seat belt.
- Practice safe walking habits.
- Use caution when riding bicycles and motorcycles.
- Wear appropriate protective clothing when participating in contact sports.
- Avoid all contact sports and high-risk activities if you have only one kidney.

accounts for most kidney injuries. Injury can be minor, major, or pedicle (Fig. 70-7). Anyone can suffer kidney trauma. Strategies to prevent trauma are reviewed in Chart 70-7.

Minor injuries include contusions, small lacerations, and tearing of the parenchyma and the calyx (forniceal disruption) caused by falls, contact sports, and blows to the back

and torso. With a contusion, one or both kidneys are bruised because of impact. Small blood vessels may be damaged, causing some hematuria. Small lacerations may result in small, local hematomas. A small hematoma also may occur at the site of forniceal disruption.

Major injuries include lacerations to the cortex, medulla, or branches of the renal artery or vein. Deep tissue injuries may extend throughout the kidney and cause hematomas within or through the capsule. Injuries involving the cortex can cause tissue shattering. The capsule may remain intact or be ruptured.

A major injury often follows penetrating abdominal, flank, or back wounds (e.g., as is seen with gunshot wounds, knife wounds, or motor vehicle crashes). Bleeding is extensive, and surgical exploration is often needed. Because of the hemorrhage, decreased blood flow to the kidney can produce short-term or long-term renin-induced hypertension.

Pedicle injuries are lacerations or breaks in the renal artery or renal vein. Hemorrhage is extensive and rapid, and death may occur unless diagnosis and intervention are prompt.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Obtain a history of the patient's usual health and the events involved in the trauma from the patient, a witness, or emergency personnel. Critical information to know is a history of kidney or urologic disease, surgical intervention, or health problems such as diabetes mellitus or hypertension.

Ureteral or renal pelvic injury often causes diffuse abdominal pain, local collections of urine, and infection. Ask the patient about pain in the flank or abdominal pain. Is the pain dull? Sharp? Constant? Intermittent? Made worse by coughing?

Take the patient's blood pressure, apical and peripheral pulses, respiratory rate, and temperature. Inspect both flanks for asymmetry or penetrating injuries of the lower chest or back. Also inspect the abdomen for bruising or penetrating wounds. Percuss the abdomen for distention. Inspect the urethra for gross bleeding.

Urinalysis usually shows hemoglobin or red blood cells from renal blood vessel rupture. Microscopic examination may also show red blood cell casts, which suggest tubular damage. Hemoglobin and hematocrit values decrease with blood loss. If inflammation or infection is present, the white blood cell count is elevated.

Diagnostic procedures include IV urography and computed tomography (CT). CT scan shows the location of the injury and blood vessel and tissue integrity. Hematomas within or through the kidney capsule are seen with CT scan. A urogram reveals the integrity and patency of the collecting system. Sonography can be used instead if there is a need to avoid contrast dye, especially in patients with elevated serum creatinine levels.

INTERVENTIONS

Nonsurgical Management

Drug therapy is used for bleeding prevention or control. The need for clotting factors such as vitamin K and platelets is assessed, and they are given as needed.

Fluid therapy is given to restore circulating blood volume and ensure adequate blood flow to the kidneys. *Crystalloid solutions* replace water and some electrolytes and include 0.9% sodium chloride (normal saline solution [NSS]), 5% dextrose in 0.45% sodium chloride, and lactated Ringer's solution. When bleeding is extensive, whole blood or packed red cell replacement restores hemoglobin and promotes oxygenation. *Plasma volume expanders*, such as dextran or albumin, help restore plasma oncotic pressure and reduce fluid shift to the interstitial fluid space.

During fluid restoration, give fluids at the prescribed rate and monitor the patient for shock. Take vital signs as often as every 5 to 15 minutes. Measure and record urine output hourly. Output should be greater than 0.5 mL/kg/hr.

! NURSING SAFETY PRIORITY

Action Alert

If the urethral opening is bleeding, consult with the physician before attempting urinary catheterization.

Surgical Management

Nephrectomy or partial nephrectomy may be needed. When major blood vessels are torn, the kidney may be removed, repaired outside of the patient, and then reimplanted, a process known as "bench surgery."

Community-Based Care

Teach the patient and family about the effects of the injury and how to assess for infection or other complications, such as the onset of bleeding or urinary retention. Instruct the patient to check the pattern and frequency of urination and to note whether the color, clarity, and amount appear normal. Also instruct the patient to seek medical attention if anything appears abnormal or if bladder distention or inadequate bladder emptying occurs, which suggests an obstruction. Chills, fever, lethargy, or cloudy, foul-smelling urine indicates a urinary tract infection. Warn the patient to not ignore these manifestations and to seek medical care promptly if they occur.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing problems with urinary elimination as a result of acute pyelonephritis?

- Patient urinates frequently in small amounts.
- Patient reports pain and burning on urination.
- Patient reports back or flank pain.
- Urine is cloudy and foul smelling.
- Urine may be darker or smoky or have obvious blood in it.

What should you INTERPRET and how should you RESPOND to a patient experiencing problems with urinary elimination as a result of acute pyelonephritis?

Perform and interpret physical assessment, including:

- Ask how long manifestations have been present.
- Ask about low back pain (midline in men) or flank pain.

- Ask whether he or she has had a UTI in the past; how long ago; how it was treated; and if antibiotics were prescribed, whether the drug course was completed.
- Ask about the presence of pregnancy or any chronic health problem, especially diabetes.
- Ask about any nausea or vomiting and its duration.
- Determine fluid intake and output volumes.
- Assess for pain over the right and left kidneys.
- Weigh the patient, and ask whether this weight is more or less than his or her usual weight.
- Assess for fever and chills.
- Assess for tachycardia.
- Interpret laboratory values:
 - Is the complete blood count with differential elevated?

NURSING CONCEPT REVIEW—cont'd

- Are the BUN and serum creatinine levels elevated?
- Is the urinalysis positive for bacteria, leukocyte esterase, nitrate, red blood cells, white blood cells, or casts?

Respond by:

- Providing for pain control
- Teaching the patient the importance of completing the prescribed antibiotic drug regimen

On what should you REFLECT?

- Observe patient for evidence of improved urinary output (see [Chapter 68](#)).
- Think about what may have caused this infection and what steps could be taken to prevent a similar episode.
- Think about what patient teaching focus could help reduce the risk for future pyelonephritis and its complications.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Health Promotion and Maintenance

- Encourage all patients to maintain an adequate fluid intake (2-3 L/day unless another condition requires fluid restriction).
- Encourage patients with diabetes to adhere to regimens for glucose control and blood pressure control to prevent kidney disease.

Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety regarding the potential for chronic kidney disease and end-stage kidney disease.
- Assess the patient's level of comfort in discussing issues related to elimination and the genitourinary area.
- Refer patients with polycystic kidney disease to a geneticist or a genetic counselor.
- During kidney/urinary assessment, use language and terminology that is comfortable for the patient.
- Refer patients to community resources, support groups, and information organizations such as the National

Kidney Foundation, the Polycystic Kidney Disease Foundation, and the American Association of Kidney Patients.

Physiological Integrity

- Report immediately any condition that obstructs urine flow.
- Instruct patients with UTI to complete all prescribed antibiotic therapy even when symptoms of infection are absent.
- Check the blood pressure and urine output frequently in patients who have any type of kidney problem.
- Report immediately to the health care provider any sudden decrease of urine output in a patient with kidney disease or kidney trauma. In general, adult urine output expectations are 0.5-1 mL/kg/hr.
- Instruct patients with any type of kidney problem to weigh daily and to notify their health care provider if there is a sudden weight gain.
- Teach patients the expected side effects and any adverse reactions to prescribed drugs.
- Teach patients the manifestations of disease recurrence and when to seek medical help.

Care of Patients with Acute Kidney Injury and Chronic Kidney Disease

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Evaluate patient risk for dehydration, shock, and acute kidney injury.
2. Collaborate with members of the health care team to reduce patient exposure to nephrotoxins in the acute care setting.
3. Prevent injury in the patient who has bone density loss or skin changes from kidney disease.
4. Apply principles of infection control to prevent infection in patients receiving immunosuppressive therapy.

Health Promotion and Maintenance

5. Teach everyone to drink fluids to prevent dehydration during hot weather and when engaging in heavy work or exercise.
6. Assess intake and output for anyone at risk for or with hypovolemia.
7. Teach transplant recipients and their families about the importance of adhering to anti-rejection therapy.

Psychosocial Integrity

8. Encourage patients and families to express any concerns about the risk for death and the disruption of lifestyle as a result of treatment for kidney dysfunction.

9. Assess the patient for depression and nonacceptance of the diagnosis or treatment plan.
10. Refer patients to community resources and support groups.

Physiological Integrity

11. Compare the pathophysiology and causes of acute kidney injury (AKI) with those of chronic kidney disease (CKD).
12. Use laboratory data and clinical assessment to determine the effectiveness of therapy for kidney dysfunction.
13. Discuss interventions to prevent AKI.
14. Discuss the mechanisms of peritoneal dialysis (PD) and hemodialysis (HD) as renal replacement therapies.
15. Coordinate nursing care for the patient with severe CKD or end-stage kidney disease (ESKD).
16. Plan prevention strategies for the complications of PD.
17. Coordinate nursing care for the patient during the first 24 hours after kidney transplantation.

Severe kidney disease leading to renal failure is common in North America. Acute kidney injury (AKI) is most common in the acute care setting, and chronic kidney disease (CKD), which may take years to develop, is more common in the community. Both types of kidney dysfunction cause problems

by interfering with urinary elimination and disrupting homeostasis of fluid volume, blood pressure, electrolytes, wastes, and acid-base balance (see [Fig. 70-1](#) in [Chapter 70](#)). These problems can reduce general function, shorten life, and decrease quality of life. Diabetes, hypertension, and

TABLE 71-1 CHARACTERISTICS OF ACUTE KIDNEY INJURY AND CHRONIC KIDNEY DISEASE

CHARACTERISTIC	ACUTE KIDNEY INJURY	CHRONIC KIDNEY DISEASE
Onset	Sudden (hours to days)	Gradual (months to years)
% of nephron involvement	≈50%	90%-95%
Duration	2-4 wks; less than 3 months	Permanent
Prognosis	Good for return of kidney function with supportive care; high mortality in some situations	Fatal without a renal replacement therapy such as dialysis or transplantation

cardiovascular disease are much more common in people with CKD, and their incidence increases as the stage of CKD worsens (U.S. Renal Data Systems [USRDS], 2010). Between 2003 and 2006, the number of patients with stage 3 CKD rose by 1.8% (USRDS, 2010). Thus overall, the incidence has increased only slightly and is most likely related to the use of kidney protective therapy with antihypertensive drugs such as angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blocker (ARB) drugs, as well as the benefits associated with use of beta-blocker drugs in the treatment of heart failure. The incidence is expected to continue to rise as a result of the aging population and the huge increase in the incidence of type 2 diabetes. In the United States, about half a million people with end-stage-kidney disease (ESKD) are treated yearly with dialysis or kidney transplantation (Okusa et al., 2009). Kidney dysfunction has many causes. CKD is most commonly caused by hypertension (HTN) and diabetes.

As described in [Chapter 68](#), kidney functions include excretion of waste, water and salt balance, acid-base balance, and hormone secretion. When kidney function declines gradually, as occurs most often with CKD (also known as *chronic renal failure [CRF]*), 90% to 95% of the nephrons must be destroyed before kidney dysfunction is obvious. The patient may have many years of reduced kidney function (*renal insufficiency*) before the uremia of ESKD develops. During this time of decreased kidney function, the patient is at increased risk for acute kidney injury because of the stress on remaining nephrons.

When kidney decline is sudden, the functioning nephrons are overworked and kidney dysfunction may develop with the loss of only 50% of functioning nephrons. Acute kidney injury and chronic kidney disease are compared in [Table 71-1](#). Acute kidney injury affects *many* body systems. Chronic kidney disease affects *every* body system. The problems that occur with loss of kidney function are related to fluid overload, electrolyte and acid-base abnormalities, buildup of nitrogen-based wastes, and loss of kidney hormone function.

When kidney function declines to the point that the kidneys can no longer maintain homeostasis by urine elimination, renal replacement therapy is needed to prevent death.

ACUTE KIDNEY INJURY

Pathophysiology

Acute kidney injury (AKI), which used to be known as **acute renal failure (ARF)** is a rapid decrease in kidney function, leading to the collection of metabolic wastes in the body. AKI can result from conditions that reduce blood flow to the kidneys (**prerenal acute kidney injury**); damage to the glomeruli, interstitial tissue, or tubules (**intrarenal/intrinsic acute kidney injury**); or obstruction of urine flow (**postrenal acute kidney injury**). When AKI occurs in patients who already have reduced kidney function, it may lead to **end-stage kidney disease (ESKD)** or it may resolve to nearly the pre-AKI level of kidney function. Many factors contribute to kidney insults in AKI, but the acute syndrome may be reversible, especially with prompt intervention.

The pathologic process of AKI is related to the cause of the sudden decrease in kidney function and to the affected kidney site(s). Reduced blood flow (poor perfusion), toxins, tubular ischemia, infections, and obstruction have different effects on the kidney and its function. Any of these processes can reduce glomerular filtration rate (GFR), damage nephron cells, and obstruct urine flow in the kidney tubules.

With shock or other problems causing an acute reduction in blood flow to the kidney (*hypoperfusion*), the kidney compensates by constricting renal blood vessels, activating the renin-angiotensin-aldosterone pathway, and releasing antidiuretic hormone (ADH). These responses increase blood volume and improve kidney perfusion. However, these same responses reduce urine volume, resulting in **oliguria** (urine output less than 400 mL/day) and **azotemia** (the retention and buildup of nitrogenous wastes in the blood). Nephron cell injury is more likely to occur from the lack of oxygen (*ischemia*) related to reduced blood flow (McCance et al., 2010). Toxins can cause blood vessel constriction in the kidney, leading to reduced kidney blood flow and kidney ischemia.

Kidney tissue inflammation caused by infection, drugs, or cancer results in immune-mediated changes in kidney tissue. With extensive tubular damage, tubular cells slough and combine with other formed elements (e.g., red blood cell [RBC] casts), which then obstruct tubular lumens and prevent urine outflow. *Obstruction anywhere within the urinary tract may result in reduced urine formation and full or partial obstruction to urine outflow.*

When pressure in the kidney tubules (*intrarenal pressure*) exceeds glomerular pressure, glomerular filtration stops. This problem allows nitrogen-based wastes to collect in the blood, increasing the blood urea nitrogen (BUN) and serum creatinine levels. When the BUN rises faster than the serum creatinine level, the cause is usually related to protein breakdown or dehydration. When both the BUN and the creatinine levels rise and the ratio between the two remains constant, this indicates kidney dysfunction.

Classification of Acute Kidney Injury Risk

The recent change in terminology from *acute renal failure* to *acute kidney injury* resulted in the development of standardized criteria to recognize the changes associated with the problem earlier, when interventions are more likely to reverse the process and prevent permanent kidney damage (Dirkes, 2011; Martin, 2010). This change was aimed at preventing

TABLE 71-2 THE RIFLE CLASSIFICATION SYSTEM FOR DIAGNOSIS AND SEVERITY OF ACUTE KIDNEY INJURY

RIFLE CLASSIFICATION	SERUM CREATININE LEVEL	GLOMERULAR FILTRATION RATE (GFR)	URINE OUTPUT
Severity Level			
Risk	Increased 1.5 times above normal (or the patient's normal when chronic kidney disease is known to exist) OR	Decreased by at least 25% of the standard normal or the patient's normal	<0.5 mL/kg hourly for 6 hours
Injury	Increased 2.5 times standard normal or the patient's normal OR	Decreased by at least 50% of the standard normal or the patient's normal	<0.5 mL/kg hourly for 12 hours
Failure	Increased 3 times standard normal or the patient's normal OR	Decreased by more than 50% of the standard normal or the patient's normal	<0.5 mL/kg hourly for 24 hours or no urine output (anuria) for 12 hours
Outcome Level			
Loss	Complete loss of kidney function that persists for more than 4 weeks		None without renal replacement therapy
End-stage kidney disease	Complete loss of kidney function that persists for more than 3 months		None without renal replacement therapy

kidney damage both in people who had healthy kidneys before a specific precipitating event and in those who already had some degree of chronic kidney disease (CKD). (An acute kidney injury occurring in a person with CKD can greatly increase the rate of progression to end-stage kidney disease.)

Table 71-2 lists the criteria for classification of acute kidney injury based on the five RIFLE categories of changes in glomerular filtration, serum creatinine levels, and reduction of hourly urine output. (RIFLE stands for **R**isk, **I**njury, **F**ailure, **L**oss, and **E**nd-stage kidney disease.) These criteria apply to patients with no known kidney problems and to patients with CKD. The first three criteria (R,I,F), are injury severity levels. Identification of AKI at these levels and proper management can prevent progression to more serious injury that may not be reversible. The last two criteria (L,E) indicate serious injury that requires renal replacement therapy at least on a temporary basis. Even at level L, some people have return of kidney function. It is the responsibility of all health care professionals to be alert to the possibility of AKI, implement prevention strategies, and identify the need to implement appropriate interventions to prevent permanent impairment of kidney function.

Types of Acute Kidney Injury

The types of AKI are described by their causes. These include prerenal azotemia, intrarenal (*intrinsic*) AKI, and postrenal azotemia. Table 71-3 lists causes of AKI.

Prerenal azotemia is kidney injury caused by poor blood flow to the kidneys. The most common problems leading to AKI are hypovolemic shock and heart failure (Ali & Gray-Vickrey, 2011). Early AKI (levels R and I) often can be reversed by correcting blood volume, increasing blood pressure, and improving cardiac output. When the reduced blood flow is prolonged, the kidneys are severely damaged and intrarenal kidney injury results.

The term *intrarenal AKI* is often referred to as *oliguric AKI* in the clinical setting. Other terms include *acute tubular necrosis (ATN)* and *lower nephron nephrosis*. Infections (bacteria, viral, fungal), drugs (especially aminoglycoside antibiotics and NSAIDs), and invading tumors (e.g., lymphomas or leukemias) can cause acute interstitial nephritis. Other

TABLE 71-3 CAUSES OF THE THREE TYPES OF ACUTE KIDNEY INJURY

Prerenal Acute Kidney Injury

Any condition decreasing blood flow to the kidneys and leading to ischemia in the nephrons, such as:

- Shock (hypovolemia, hemorrhage, distributive, obstructive)
- Heart failure
- Pulmonary embolism
- Anaphylaxis
- Sepsis
- Pericardial tamponade

Intrarenal (Intrinsic) Acute Kidney Injury

Actual physical, chemical, hypoxic, or immunologic damage directly to the kidney tissue, such as:

- Acute interstitial nephritis
- Exposure to nephrotoxins
- Acute glomerular nephritis
- Vasculitis
- Acute tubular necrosis
- Renal artery or vein stenosis
- Renal artery or vein thrombosis
- Formation of crystals or precipitates in the nephron tubules

Postrenal Acute Kidney Injury

Obstruction of the urine collecting system anywhere from the calyces to the urethral meatus (obstruction of the ureter must be bilateral to cause postrenal failure unless only one kidney is functional), such as:

- Ureter, bladder, or urethral cancer
- Kidney, ureter, or bladder stones
- Bladder atony
- Prostatic hyperplasia or cancer
- Urethral stricture
- Cervical cancer

causes of intrarenal AKI include inflammation of the glomeruli (*glomerulonephritis*) or of the small vessels of the kidneys (*vasculitis*) or an obstruction of blood flow to the kidneys.

Postrenal azotemia develops from obstruction to the outflow of formed urine anywhere within the kidney or urinary tract.

TABLE 71-4 THE PHASES OF OLIGURIC ACUTE KIDNEY INJURY

PHASE	DESCRIPTION	CHARACTERISTICS
Onset phase	Begins with the precipitating event and continues until oliguria develops. Lasts hours to days.	The gradual accumulation of nitrogenous wastes, such as increasing serum creatinine and BUN, may be noted.
Oliguric phase	Characterized by a urine output of 100-400 mL/24 hr that does not respond to fluid challenges or diuretics. Lasts 1-3 weeks.	Laboratory data include increasing serum creatinine and BUN levels, hyperkalemia, bicarbonate deficit (metabolic acidosis), hyperphosphatemia, hypocalcemia, and hypermagnesemia. Sodium retention occurs, but this is masked by the dilutional effects of water retention. Urinary indices are typically low and fixed; regulation of water balance by the kidneys is impaired, so urine specific gravity and urine osmolality do not vary as plasma osmolality changes.
Diuretic phase (high-output phase)	Often has a sudden onset within 2-6 wk after oliguric stage. Urine flow increases rapidly over a period of several days. The diuresis can result in an output of up to 10 L/day of dilute urine.	Electrolyte losses typically precede clearance of nitrogenous wastes. Later in the diuretic phase, the BUN level starts to fall and continues to fall until the level reaches normal limits or reaches a plateau. Normal kidney tubular function is re-established during this phase.
Recovery phase (convalescent phase)	In this phase, the patient begins to return to normal levels of activity. Complete recovery may take up to 12 months.	The patient functions at a lower energy level and has less stamina than before the illness. Residual kidney dysfunction may be noted through regular monitoring of kidney function. Kidney function may never return to pre-illness levels, but function sufficient for a long and healthy life is likely.

BUN, Blood urea nitrogen.

When kidney function declines, the oliguric phases of AKI begin (Table 71-4). Some patients have a *nonoliguric* form of AKI in which urine output remains near normal but serum creatinine levels rise. Ideally, interventions to restore circulating volume, improve cardiac output, and increase blood pressure prevent progression to a more severe level of kidney injury.

Etiology

Many types of problems can reduce kidney function. Severe hypotension from shock or dehydration reduces kidney blood flow and can lead to prerenal AKI. Cardiac disease or heart failure also can reduce kidney blood flow. The patient may be oliguric or even **anuric** (less than 100 mL/24 hr) if kidney blood flow reduction is severe. Conditions causing AKI are listed in Table 71-3.

Incidence/Prevalence

Health care–acquired AKI occurs in as many as 4% of hospital admissions and 20% of critical care admissions (Peacock & Sinert, 2010). Most AKI episodes are due to events that lead to hypotension with poor kidney perfusion and worsening of chronic kidney problems. For patients who survive the precipitating event, the chance for return of kidney function is good. However, complications during the course of AKI can greatly increase the risk for death. Bloodstream infections from IV line contamination are frequent complications that lead to death. However, the highest death rate occurs with trauma (70%) and surgery. AKI caused by **nephrotoxic** (kidney damaging) substances (Table 71-5) has the lowest rates of recovery. The prognosis for AKI caused by obstruction or glomerulonephritis is much better.

Health Promotion and Maintenance

Keep in mind that severe blood volume depletion can lead to kidney injury even in people who have no known kidney problems. Urge all people to avoid dehydration by drinking at least

TABLE 71-5 SOME POTENTIALLY NEPHROTOXIC SUBSTANCES

Drugs Antibiotics/Anti-infectives - Amphotericin B - Colistimethate - Methicillin - Polymyxin B - Rifampin - Sulfonamides - Tetracycline hydrochloride - Vancomycin	Other Drugs - Acetaminophen - Captopril - Cyclosporine - Fluorinate anesthetics - Metformin - D-Penicillamine - Phenazopyridine hydrochloride - Quinine
Aminoglycoside Antibiotics - Gentamicin - Kanamycin - Neomycin - Netilmicin sulfate - Tobramycin	Other Substances Organic Solvents - Carbon tetrachloride - Ethylene glycol
Chemotherapy agents - Cisplatin - Cyclophosphamide - Methotrexate	Non-drug Chemical Agents - Radiographic contrast dye - Pesticides - Fungicides - Myoglobin (from breakdown of skeletal muscle)
Nonsteroidal Anti-inflammatory Drugs (NSAIDs) - Celecoxib - Flurbiprofen - Ibuprofen - Indomethacin - Ketorolac - Meclofenamate - Meloxicam - Nabumetone - Naproxen - Oxaprozin - Rofecoxib - Tolmetin	Heavy Metals and Ions - Arsenic - Bismuth - Copper sulfate - Gold salts - Lead - Mercuric chloride

2 to 3 L of fluids daily. This is especially important for athletes or any person who performs strenuous exercise or work and sweats heavily.

Nurses have an essential role in the prevention of acute kidney injury in hospitalized patients. Always be on the lookout for signs of reduced kidney function through careful physical assessment (especially of urine output and weight), close monitoring of laboratory values, and evaluation of fluid status. Early recognition and correction of problems causing reduced kidney blood flow usually restore function before tissue damage can occur. Evaluate the patient's fluid status. Accurately measure intake and output and check body weight to identify changes in fluid balance.

! NURSING SAFETY PRIORITY

Critical Rescue

In any acute care setting, preventing volume depletion is a nursing priority because this is the most common cause of AKI. Recognizing the manifestations of volume depletion (low urine output, decreased systolic blood pressure, decreased pulse pressure, orthostatic hypotension, thirst, rising blood osmolality) and intervening early to restore volume can reverse AKI and prevent permanent kidney damage.

Also monitor laboratory values for any changes that reflect poor kidney function. Decreased urine specific gravity indicates a loss of urine-concentrating ability and is the earliest sign of kidney tubular damage. Other laboratory values that are helpful in monitoring kidney function include serum creatinine, urine and serum electrolytes, and blood urea nitrogen (BUN).

Be aware of nephrotoxic substances that the patient may ingest or be exposed to (see [Table 71-5](#)). Question any prescription for potentially nephrotoxic drugs, and validate the dose before the patient receives the drug. Antibiotics are common drugs that have nephrotoxic side effects. NSAIDs can cause or increase the risk for AKI. Combining two or more nephrotoxic drugs dramatically increases the risk for AKI. If a patient must receive a known nephrotoxic drug, closely monitor laboratory values, including BUN, creatinine, and drug peak and trough levels, for indications of reduced kidney function.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

The accurate diagnosis of AKI, including its type and its cause, depends on a detailed history of potential causes of AKI. Ask the patient about exposure to nephrotoxins, recent surgery or trauma, transfusions, or other factors that might lead to reduced kidney blood flow. Obtain a drug history, especially treatment with antibiotics, ACE inhibitors, and NSAIDs. Ask about recent imaging procedures requiring injection of a contrast dye. These dyes can cause AKI, especially in older patients with reduced kidney function. AKI must be differentiated from chronic kidney disease (CKD). Ask the patient about diseases that impair kidney function, such as diabetes mellitus, long-term hypertension, systemic lupus erythematosus, and other connective tissue diseases.

To identify possible acute glomerulonephritis, ask about acute illnesses such as influenza, colds, gastroenteritis, and sore throats. Ask whether urine color is darker or appears smoky.

Reversible prerenal azotemia may occur after any episode of acute hypotension, hemorrhage or shock, burns, heart failure, or any problem in which the blood volume is depleted. Extensive bowel preparations, being NPO before surgery without fluid replacement, and fluid loss during surgery can cause prerenal AKI in some patients.

Postrenal kidney injury is identified by focusing on urinary obstructive problems. Ask the patient about any difficulty in starting the urine stream, changes in the amount or appearance of the urine, narrowing of the urine stream, nocturia, urgency, or symptoms of kidney stones. Also ask about any cancer history that may cause urinary obstruction.

Physical Assessment/Clinical Manifestations

The manifestations of AKI are related to the buildup of nitrogenous wastes ([azotemia](#)), as well as to the underlying cause ([Chart 71-1](#)). Manifestations of *prerenal* azotemia are hypotension, tachycardia, decreased urine output, decreased cardiac output, decreased central venous pressure (CVP), and

CHART 71-1 KEY FEATURES

Acute Kidney Injury

Prerenal Azotemia

- Hypotension
- Tachycardia
- Decreased cardiac output
- Decreased central venous pressure
- Decreased urine output
- Lethargy

Intrarenal (Intrinsic) AKI and Postrenal Azotemia

- Renal manifestations:
 - Oliguria or anuria
 - Increased urine specific gravity
- Cardiac manifestations:
 - Hypertension
 - Tachycardia
 - Jugular venous distention
 - Increased central venous pressure
 - ECG changes: tall T waves
- Respiratory manifestations:
 - Shortness of breath
 - Orthopnea
 - Crackles
 - Pulmonary edema
 - Friction rub
- Gastrointestinal manifestations:
 - Anorexia
 - Nausea
 - Vomiting
 - Flank pain
- Neurologic manifestations:
 - Lethargy
 - Headache
 - Tremors
 - Confusion
- General manifestations:
 - Generalized edema
 - Weight gain

AKI, Acute kidney injury; ECG, electrocardiogram.

lethargy. The appearance of a patient with prerenal azotemia is similar to that of a patient with heart failure or dehydration, depending on the cause of the poor kidney blood flow.

Intrarenal (intrinsic) AKI usually occurs with damage to the glomeruli, interstitial tissue, or tubules. Manifestations are related to the retention of fluid and nitrogenous wastes. These include **oliguria** (decreased urine output) or **anuria** (absence of urine), edema, hypertension, tachycardia, shortness of breath, distended neck veins, elevated CVP, weight gain, respiratory crackles, anorexia, nausea, vomiting, and lethargy or changes in levels of consciousness. Manifestations of electrolyte imbalances (particularly elevated potassium levels and low calcium levels), such as electrocardiographic (ECG) changes, may also be present.

In patients with *postrenal* AKI, monitor for oliguria or intermittent anuria, symptoms of uremia, and lethargy. Report changes in the urine stream, difficulty starting urination, and the presence of blood or particles in the urine.

Laboratory Assessment

The many changes in laboratory values in the patient with AKI are similar to those occurring in chronic kidney disease (CKD) (Chart 71-2; see also p. 1552 in the discussion of Laboratory Assessment in the **Chronic Kidney Disease** section). Expect to see rising BUN and serum creatinine levels and abnormal blood electrolyte values. Patients with AKI, however, usually do *not* have the anemia associated with CKD unless there is hemorrhagic blood loss or unless blood urea levels are high enough to break (lyse) red blood cells.

In early AKI, urine tests provide important information. Urine sodium levels are often less than 10 to 20 mEq/L in patients with prerenal azotemia. The urine is concentrated, with a specific gravity greater than 1.030. The presence of urine sediment (e.g., red blood cells [RBCs], RBC casts, and tubular cells), myoglobin, or hemoglobin; a urine sodium level lower than 40 mEq/L; and a specific gravity of less than 1.010 indicate intrarenal kidney injury. In postrenal AKI,

CHART 71-2 LABORATORY PROFILE

Kidney Disease

TEST	NORMAL RANGE FOR ADULTS	VALUES IN KIDNEY DISEASE
Serum creatinine	Male: 0.6-1.2 mg/dL Female: 0.5-1.1 mg/dL Older adults: Decreased	In Chronic Kidney Disease May increase by 0.5-1.0 mg/dL every 1-2 yr May be as high as 15-30 mg/dL <i>before</i> symptoms of severe CKD are present In Acute Kidney Injury Gradual increase of 1-2 mg/dL every 24-48 hr May increase 1-6 mg/dL in 1 wk or less
Blood urea nitrogen	10-20 mg/dL Older adults: May be slightly increased	In Chronic Kidney Disease May reach 180-200 mg/dL <i>before</i> symptoms develop In Acute Kidney Injury Often increases by 10-20 mg/dL at same pace as serum creatinine level May reach 80-100 mg/dL within 1 wk
Serum sodium	136-145 mEq/L; 136-145 mmol/L (SI units)	Normal, increased, or decreased
Serum potassium	3.5-5.0 mEq/L; 3.5-5.0 mmol/L (SI units)	Increased
Serum phosphorus (phosphate)	3.0-4.5 mg/dL; 0.97-1.45 mmol/L (SI units) Older adults: May be slightly decreased	Increased
Serum calcium	Total calcium: 9.0-10.5 mg/dL; 2.25-2.75 mmol/L (SI units) Ionized calcium: 4.5-5.6 mg/dL; 1.05-1.3 mmol/L (SI units) Older adults: Slightly decreased	Decreased
Serum magnesium	1.3-2.1 mEq/L; 0.65-1.05 mmol/L	Increased
Serum carbon dioxide combining power (bicarbonate)	23-30 mEq/L (venous); 23-30 mmol/L (SI units)	Decreased
Arterial blood pH	7.35-7.45	Decreased (in metabolic acidosis) or normal
Arterial blood bicarbonate (HCO ₃ ⁻)	21-28 mEq/L	Decreased
Arterial blood PaCO ₂	35-45 mm Hg	Decreased
Hemoglobin	Female: 12-16 g/dL; 7.4-9.9 mmol/L (SI units) Male: 14-18 g/dL; 8.7-11.2 mmol/L (SI units) Older adults: Slightly decreased	Decreased
Hematocrit	Female: 37%-47% Male: 42%-52% Older adults: May be slightly decreased	Decreased to 20%
Blood osmolarity	285-295 mOsm/kg or mmol/kg (SI)	Elevated in volume-depleted states, increasing the risk for acute tubular necrosis.

CKD, Chronic kidney disease; SI, International System of Units.

urine sodium levels may be normal (about 40 mEq/L), with a specific gravity of 1.000 to 1.010.

Imaging Assessment

X-rays help determine the cause of AKI. An abdominal x-ray is used to check the size of the kidneys. Enlarged kidneys, possibly due to obstruction, may result from hydronephrosis. X-rays may show stones obstructing the renal pelvis, ureters, or bladder.

Renal ultrasonography is a noninvasive procedure using high-energy sound waves. It is useful in the diagnosis of urinary tract obstruction. Dilation of the renal calyces and collecting ducts, as well as stones, can be detected. Ultrasonography can show kidney size and patency of the ureters.

CT scans without contrast dye can identify obstruction or tumors. Contrast dyes are usually avoided to prevent further kidney damage. A nuclear medicine study called MAG3 may be used to determine the nature of the renal failure, GFR, or tubular function and its severity. A renal scan can determine whether blood flow to the kidneys is sufficient. Cystoscopy or retrograde pyelography may be needed to identify obstructions of the lower urinary tract.

Other Diagnostic Assessment

Kidney biopsy is performed if the cause of AKI is uncertain, an immunologic disease is suspected, or the reversibility of the kidney dysfunction needs to be determined after AKI has persisted for an extended period. Prepare the patient before the test, and provide follow-up care. Be aware of all test results and understand how they might affect the treatment regimen. (See Chapter 68 for a detailed discussion of renal diagnostic tests.)

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The client admitted to the emergency department 1 hour after a motorcycle crash has all of the following laboratory test results. Which result does the nurse report to the health care provider immediately?

- A. Blood glucose level of 138 mg/dL
- B. Blood urea nitrogen of 22 mg/dL
- C. Blood osmolarity of 330 mOsm
- D. Serum potassium of 4.9 mEq/L

INTERVENTIONS

The patient with AKI may move from the oliguric phase (in which fluid and electrolytes are retained) to the diuretic phase. In the oliguric phase, the plan of care focuses on close monitoring for life-threatening electrolyte changes and nitrogen retention that may require intervention. During the diuretic phase, hypovolemia and electrolyte loss are the main problems. The patient in the diuretic phase of AKI needs a plan of care that focuses on fluid and electrolyte replacement and monitoring.

These examples of output variation reflect the continually changing nature of AKI and the need for the plan of care to be constantly updated to reflect the stages of the disease process. Drug therapy, nutrition therapy, and renal replacement therapy (peritoneal dialysis [PD], hemodialysis [HD], or hemofiltration) are commonly used to manage AKI.

Drug Therapy

Patients with AKI receive many drugs. As kidney function changes, drug dosages are changed. It is important to be knowledgeable about the site of drug metabolism and especially careful when giving drugs. Constantly monitor for possible side effects and interactions of the drugs that the patient with AKI is receiving (Chart 71-3; see also the discussion of drug therapy on pp. 1553, 1556, and 1557 in the [Chronic Kidney Disease](#) section). Diuretics may be used to increase urine output.

In patients with prerenal azotemia, fluid challenges and diuretics are often used to promote kidney blood flow. In the patient without fluid overload, 500 to 1000 mL of normal saline may be infused over 1 hour. In prerenal azotemia, the patient responds to the fluid challenge by producing urine soon after the initial bolus. Diuretics such as furosemide (Lasix) also may be prescribed along with a fluid bolus. If oliguric kidney injury is diagnosed, the fluid challenges and diuretics are discontinued. Patients often require central venous pressure (CVP) monitoring or measurement of pulmonary arterial pressure by means of a pulmonary artery catheter for accurate evaluation of their hemodynamic status. They also require constant nursing supervision for assessment of the response to fluid and drug therapy. Carefully monitor for signs of possible fluid overload.

Calcium channel blockers may be used to treat AKI resulting from nephrotoxic acute tubular necrosis (ATN). These drugs prevent the movement of calcium into the kidney cells, maintain kidney cell integrity, and improve the glomerular filtration rate (GFR) by improving kidney blood flow.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice; Quality Improvement

The patient is a 67-year-old woman who has type 2 diabetes (for which she takes metformin) and had a CT scan with contrast material 3 days ago for a pulmonary problem. Today she is sent to the emergency department by her primary care physician because she has gained 8 pounds since the scan and has symptoms of heart failure. She describes her urine output for the past 24 hours as being "about a teacup full." Her admitting diagnosis is possible acute kidney injury. Her vital signs are as follows: temperature 100° F; pulse 108 and irregular; respirations 32; blood pressure 166/110.

1. What additional assessment data should you obtain? Provide a rationale for your choices.
2. What risk factors does she have for acute kidney injury?
3. Is her risk greatest for prerenal acute kidney injury, intrarenal azotemia, or postrenal acute kidney injury? Explain your answer.
4. What questions will you ask her about her urine output?
5. What resources or changes in policy could have helped prevent this problem and future problems?

Nutrition Therapy

Patients who have AKI often have a high rate of protein breakdown. The exact cause for this state is not known. Increases in metabolism and protein breakdown may be related to the stress of a critical illness, causing an increase in blood levels of catecholamines, cortisol, and glucagon. The rate of protein breakdown correlates with the severity of uremia and azotemia. This state causes the breakdown of muscle for protein, which leads to an increase in azotemia and an even more elevated blood urea nitrogen (BUN) level.

CHART 71-3 COMMON EXAMPLES OF DRUG THERAPY

Kidney Disease

DRUG/DOSAGE	ACTION/PURPOSE	NURSING INTERVENTIONS	RATIONALES
Cardiac Glycosides			
Digoxin (Digitek, Lanoxicaps, Lanoxin, Novodigoxin ) 0.125-0.25 mg orally or IV daily or every other day <i>Older adults:</i> 0.0625-0.125 mg orally or IV daily or every other day	Used when heart failure induces kidney injury/disease or makes it worse. Improves ventricular contraction, increasing stroke volume and cardiac output.	Teach patients to take pulse daily before taking the drug and to notify the prescriber if it is below 60. Instruct patients to notify prescriber if any of these manifestations occur: changes in color vision (more yellow color), blurred vision, eyes sensitive to light, light flashes, or halos around bright lights; changes in behavior, mood, or mental ability; chest pain or palpitations. Teach patients to not take antacids within 2 hours of taking this drug.	Drug slows the heart rate and can cause severe bradycardia. These are manifestations of drug toxicity and require the drug be stopped or the dose decreased temporarily. Antacids prevent drug absorption and may delay or inhibit drug effectiveness.
Vitamins and Minerals			
Folic acid (vitamin B ₉ , Folvite, Novofolacid ) 1 mg orally daily Ferrous sulfate (Feosol, Novoferrosulfa ) 325 mg orally three or four times daily	When the patient is receiving dialysis, many essential vitamins and minerals are removed from the blood. Replacement is needed to prevent severe deficiencies.	Teach patients to take the drugs after dialysis. Teach patients to take iron supplements (ferrous sulfate) with meals. Teach patients to take stool softeners daily while taking iron supplements. Remind patients that iron supplements change the color of the stool.	Dialysis removes the drug from the blood. Food reduces nausea and abdominal discomfort. Oral iron preparations cause constipation, and most patients with kidney disease failure must reduce their fluid intake, further increasing the risk for constipation. Knowing the expected side effects decreases anxiety when they appear.
Synthetic Erythropoietin			
Epoetin alfa (Epogen, Procrit) 50-100 units/kg subcutaneously or IV three times a week for patients on dialysis Darbepoetin alfa (Aranesp) 0.45 mcg/kg subcutaneously or IV once weekly for patients on dialysis	Drug prevents anemia by stimulating red blood cell growth and maturation in the bone marrow.	Teach patients to report any of these side effects to the prescriber as soon as possible: chest pain, difficulty breathing, high blood pressure, rapid weight gain, seizures, skin rash or hives, swelling of feet or ankles. Reinforce to patients that they must have hemoglobin levels monitored weekly.	Drug can induce serious cardiovascular problems, such as myocardial infarction (MI). Drug can raise hemoglobin and hematocrit levels to the point that blood viscosity increases, raising blood pressure and increasing the risk for MI. Drug dosage is reduced to prevent hemoglobin levels higher than 10 to 12 mg/dL.
Phosphate Binders			
Aluminum hydroxide gel (Amphojel, AlternaGEL, Alu-Cap, Nephrox) 300-600 mg orally two to four times daily Aluminum carbonate gel (Basaljel) 500 mg-2 g orally two to four times daily	High blood phosphate levels cause hypocalcemia and osteodystrophy. Drugs lower serum phosphate levels by binding phosphorus present in food.	Teach patients to take drugs with meals. Remind patients taking digoxin to separate the drugs by at least 2 hours. Teach patients to take stool softeners daily while taking these drugs. Teach patients to report muscle weakness, slow or irregular pulse, or confusion to the prescriber.	Drug action is to bind phosphate in food, preventing its absorption. These drugs reduce digoxin absorption and effects. These drugs cause constipation, and most patients with severe kidney disease must reduce their fluid intake, further increasing the risk for constipation. These are manifestations of hypophosphatemia, which require dosage adjustment.

If the patient with AKI has a good dietary intake (see discussion of [Enhancing Nutrition](#) on pp. 1555-1556 in the [Chronic Kidney Disease](#) section), nutritional support may not be needed. A dietary consult with a dietitian, who will calculate the patient's caloric needs, may be prescribed. Work with the dietitian to provide a diet with specified amounts of protein, sodium, and fluids. For the patient who does not require dialysis, 0.6 g/kg of body weight or 40 g/day of protein is usually prescribed. For patients who do require dialysis, the protein level needed will range from 1 to 1.5 g/kg. The amount of dietary sodium ranges from 60 to 90 mEq. If high blood potassium levels are present, dietary potassium is restricted to 60 to 70 mEq. The amount of fluid permitted is generally calculated to be equal to the urine volume plus 500 mL. Assess food intake every shift to ensure that caloric intake is adequate.

Many patients with AKI are too ill or their appetite is too poor to eat enough food. For these patients, some form of nutritional support (e.g., total parenteral nutrition [TPN] or hyperalimentation) is needed. The purposes of nutritional support in AKI are to provide sufficient nutrients to maintain or improve nutritional status, to preserve lean body mass, to restore or maintain fluid balance, and to preserve kidney function.

If TPN is used, the solutions are mixed to meet the patient's specific needs. Because kidney function is unstable in AKI, constantly monitor the serum electrolyte levels to indicate when the TPN solution needs to be changed. IV fat emulsion (Intralipid) infusions can provide a nonprotein source of calories. In uremic patients, fat emulsions are used in place of glucose to avoid the problems of excessive sugars.

Dialysis Therapies

Hemodialysis (HD) and peritoneal dialysis (PD) are used for patients with L and E levels of AKI. Indications for dialysis use include the presence of uremia, persistent high potassium levels, metabolic acidosis, continued fluid overload, uremic pericarditis, and encephalopathy.

Immediate vascular access for HD in patients with AKI is made by placement of a dual- or triple-lumen catheter specific for HD. When HD is expected to be used for several weeks, the catheter is usually placed in the subclavian or internal jugular vein. If only one or two HD treatments are needed, as for removal of drugs or toxins, a femoral site may be selected. Longer use of the femoral site is avoided because the patient's mobility is restricted and complications, such as hematomas and infection, are common. Repeatedly accessing the femoral site increases the risk for hematoma formation and makes repeated use of the vein impossible.

The subclavian vein is used, when possible, instead of the femoral site because the catheter can be left in place between dialysis treatments. However, the longer the catheter is left in this place, the greater the chance for infection. The subclavian dialysis catheter ([Fig. 71-1](#)) is inserted at the bedside. A physician or nurse practitioner performs the sterile procedure, and then the catheter is covered with a sterile dressing. Monitor for manifestations of procedure complications such as pneumothorax (reduced breath sounds, tracheal deviation away from midline, prominence and poor movement of one side of the chest) or subcutaneous emphysema (crackling and swelling of tissue around the site). Catheter placement is checked by chest x-ray before its use.

FIG. 71-1 Subclavian dialysis catheters. These catheters are radiopaque tubes that can be used for hemodialysis access. The Y-shaped tubing allows arterial outflow and venous return through a single catheter. **A**, Mahurkar catheters, made of polyurethane and used for short-term access. **B**, A PermCath catheter, made of silicone and used for long-term access.

If hemodialysis is needed for more than a few days, a long-term dialysis catheter may be used. Most of these catheters are placed in the radiology department using a tunneling technique. The patient receives moderate sedation. Under sonographic or fluoroscopic guidance, the physician makes a small incision where the internal jugular vein passes behind the clavicle. A 6- to 8-cm tunnel is created out from the side of the incision. A long-term hemodialysis catheter is inserted through the tunnel and into the jugular vein. Keeping a segment of the catheter within the subcutaneous tissues before entering the jugular vein reduces the risk for infection.

Hemodialysis catheters have two lumens, one for outflow and one for inflow. This allows the outflow of blood for dialysis to be separated from the dialyzed blood returned through the inflow lumen. A triple-lumen catheter for HD is available. The third lumen is an access for drawing venous blood or giving drugs and fluid without interrupting dialysis.

Peritoneal dialysis (PD) may also be used in the treatment of AKI, although some patients, such as those being mechanically ventilated, may not be able to tolerate the abdominal distention that occurs with PD. PD uses the peritoneum as the dialyzing membrane. The dialysate is infused through a

catheter implanted in the peritoneum. A complete discussion of PD is provided in the [Chronic Kidney Disease](#) section, pp. 1564-1567.

Continuous Renal Replacement Therapy

Continuous renal replacement therapies (CRRTs) are the standard treatment for AKI levels L and E. Renal replacement therapies in the form of hemofiltration are often better tolerated than HD for critically ill patients because this method avoids rapid shifts of fluids and electrolytes.

Continuous venovenous hemofiltration (CVVH), continuous venovenous hemodiafiltration (CVVHD), continuous arteriovenous hemofiltration (CAVH), and continuous arteriovenous hemofiltration with dialysis (CAVHD) are the renal replacement therapies most commonly used for patients with AKI. The venovenous methods are being used more often than the arteriovenous methods. These procedures are similar to HD but their use is temporary.

Continuous venovenous hemofiltration (CVVH) is often used with critically ill patients. CVVH uses only a double-lumen venous catheter for access and is powered by a pump, making the rate of filtration more reliable than methods using mean arterial pressure. The pump increases the risk for an air embolus, but most pumps have alarms that detect air. These systems also require the use of anticoagulants but at lower doses than needed for AV systems. These procedures are used in critical care units, and patients require continuous nursing care.

The technique of CVVHD is a very common method of renal replacement therapy. It uses an infusion pump, hemodialysis membrane, and dialysate solution, as well as the same type of blood access as the CVVH technique. Similar to the CAVHD system, CVVHD adds the dialysis membrane and the dialysate solution instead of just filtering the blood and, as a result, increases the efficiency of removing waste products from the blood. CVVHD is somewhat less effective than CAVHD because the lower pressure in the venous system compared with the arterial system does not filter as much blood in the same amount of time. Thus CVVHD needs to be performed for longer periods to achieve the same effects as CAVHD. However, because the removal is slower, fewer adverse changes in blood volume and blood pressure are likely to occur.

CAVH is used for patients who have fluid volume overload, are resistant to diuretics, and have unstable blood pressures and cardiac output. The use of CAVH requires placement of both arterial and venous catheters and that the patient have a mean arterial pressure (MAP) of at least 60 mm Hg. ([Mean arterial pressure](#) is a person's average arterial pressure and is based on cardiac output and systemic vascular resistance. The normal adult MAP is 100 mm Hg.) CAVH continuously removes large amounts of plasma water, wastes, and electrolytes. Electrolytes are replaced through prescribed amounts of IV electrolyte solutions. A major disadvantage of arteriovenous (AV) filtration is the risk for bleeding caused by anticoagulants used to prevent membrane clotting.

A double-lumen dialysis catheter is inserted into a large vein (subclavian, jugular) for CAVHD. A [dialysate](#) (a solution composed of water, glucose, sodium chloride, potassium, magnesium, calcium, and bicarbonate) delivery system is used to remove waste products in addition to plasma water in patients with limited cardiac output, those with severe

hypotension, or those who do not respond to diuretic therapy. These patients cannot tolerate HD, and PD could not remove the large amount of excess fluid.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

When performing an hourly assessment of a client who had a subclavian catheter placed 6 hours ago for continuous arteriovenous hemofiltration with dialysis (CAVHD), the nurse observes these findings. For which finding does the nurse stop the CAVHD?

- A. The right foot and ankle appear slightly more edematous than the left foot and ankle.
- B. Blood pressure has decreased from 148/90 to 90/60.
- C. Pulse oximetry is increased from 89% to 91%.
- D. The trachea is in a midline position.

Posthospital Care

The care for a patient with AKI after discharge from the hospital varies, depending on the status of the disorder when the patient is discharged. The course of AKI varies, with recovery lasting up to several months. If the kidney injury is resolving, follow-up care may be provided by a nephrologist or by the family physician in consultation with the nephrologist. However, AKI may result in permanent kidney damage and CKD with the need for chronic dialysis or even transplantation. In these cases, follow-up care is similar to that needed for patients with chronic kidney disease (see [Community-Based Care](#), pp. 1571-1572).

If the AKI is beginning to resolve, the follow-up care may involve many services. Frequent medical visits are necessary, as are scheduled laboratory blood and urine tests to monitor kidney function. A dietitian is needed to modify the patient's diet according to the degree of kidney function and ongoing nutritional needs. Teach patients continuing dialysis after discharge to limit foods high in potassium, sodium, and phosphorus and to observe protein restrictions. Also teach about any needed fluid intake limitation. Instruct patients to weigh themselves daily, keep a daily log, and report any daily weight gain of 2 pounds or more immediately to the health care provider.

Some patients may need temporary dialysis until their kidneys can eliminate fluid and waste products. The dialysis started while the patient was an inpatient can be continued at an outpatient dialysis center. Teaching about the type of dialysis, how to care for vascular access sites, dietary restrictions, fluid restrictions, and prevention of complications is ongoing throughout the recovery phase. Depending on their level of independence and family support, some patients may also need home care nursing or social work assistance.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

What is the most important precaution for the nurse to teach the client with continuing kidney impairment on discharge after treatment for acute kidney injury?

- A. Avoid fluids that contain either alcohol or caffeine.
- B. Weigh yourself daily and report any rapid weight gain.
- C. Drink at least 3 liters of fluid daily to prevent dehydration.
- D. Use a dipstick to check for glucose in your urine at least once daily.

CHART 71-4 KEY FEATURES

Uremia

- Metallic taste in the mouth
- Anorexia
- Nausea
- Vomiting
- Muscle cramps
- Uremic “frost” on skin
- Itching
- Fatigue and lethargy
- Hiccups
- Edema
- Dyspnea
- Muscle cramps
- Paresthesias

TABLE 71-6 PROGRESSION OF CHRONIC KIDNEY DISEASE

STAGE OF CHRONIC KIDNEY DISEASE (CKD)	ESTIMATED GLOMERULAR FILTRATION RATE	INTERVENTION
Stage 1 At risk; normal kidney function (early kidney disease may or may not be present)	>90 mL/min	Screening for risk factors Uncontrolled hypertension Diabetes mellitus Chronic kidney or urinary tract infection Presence of genetic kidney diseases Exposure to nephrotoxic substances
Stage 2 Mild CKD	60-89 mL/min	Focus on reduction of risk factors
Stage 3 Moderate CKD	30-59 mL/min	Implement strategies to slow disease progression
Stage 4 Severe CKD	15-29 mL/min	Manage complications, and prepare for eventual renal replacement therapy
Stage 5 End-stage kidney disease (ESKD)	<15 mL/min	Implement renal replacement therapy/kidney transplantation

CHRONIC KIDNEY DISEASE

Pathophysiology

Unlike acute kidney injury (AKI), chronic kidney disease (CKD) is a progressive, irreversible disorder and kidney function does *not* recover. When kidney function is too poor to sustain life, CKD becomes **end-stage kidney disease (ESKD)**. Terms used with kidney dysfunction include **azotemia** (buildup of nitrogen-based wastes in the blood), **uremia** (azotemia with clinical symptoms [Chart 71-4]), and **uremic syndrome**. Table 71-1 compares AKI and CKD.

Stages of Chronic Kidney Disease

The kidneys lose function (fail) in an organized fashion involving five stages based on estimated glomerular filtration rate (GFR). Progression toward ESKD usually starts with a gradual decrease in GFR (Table 71-6). In this first stage, the person may have a normal GFR (greater than 90 mL/min) with normal kidney function and no obvious kidney disease. However, there may be a *reduced renal reserve* in which

reduced kidney function occurs *without* buildup of wastes in the blood because the unaffected nephrons overwork to compensate for the diseased nephrons. Although no manifestations of kidney dysfunction are usually present at this stage, if the patient is stressed with infection, fluid overload, pregnancy, or dehydration, kidney function at this stage can appear reduced.

In the next stage, *mild CKD*, GFR is reduced, ranging between 60 and 89 mL/min. Kidney nephron damage has occurred, and there may be slight elevations of metabolic wastes in the blood because not enough healthy nephrons remain to compensate completely for the damaged nephrons. Levels of blood urea nitrogen (BUN), serum creatinine, uric acid, and phosphorus are not sensitive enough to define this stage, however, and reduced GFR is the best measure of CKD. Increased output of dilute urine may occur at this stage of CKD and, if the problem is untreated at this stage, can cause severe dehydration.

! NURSING SAFETY PRIORITY

Action Alert

Teach patients with mild CKD that carefully managing fluid volume, blood pressure, electrolytes, and other kidney-damaging diseases (e.g., hypertension, diabetes mellitus) by following prescribed drug and nutrition therapies can prevent damage and slow the progression to ESKD.

In *moderate CKD*, GFR reduction continues and ranges between 30 and 59 mL/min. Nephron damage has continued, and the remaining nephrons cannot manage metabolic wastes, fluid balance, and electrolyte balance. Restriction of fluids, proteins, and electrolytes is needed.

Over time, patients progress to *severe CKD* (the fourth stage) and *end-stage kidney disease (ESKD)* (the fifth stage). Excessive amounts of urea and creatinine build up in the blood, and the kidneys cannot maintain homeostasis. Severe fluid, electrolyte, and acid-base imbalances occur (Pradeep & Verrelli, 2010). Without renal replacement therapy, fatal complications occur.

Kidney Changes

Kidney dysfunction with greatly reduced GFR causes many problems, including abnormal urine production, poor water excretion, electrolyte imbalances, and metabolic abnormalities. Because the healthy nephrons become larger and work harder, the GFR is effective until about three fourths of kidney function is lost. Homeostasis of electrolytes, acid-base, and nitrogenous wastes is maintained until late in the course of kidney disease.

As the disease progresses, the ability to produce dilute urine is reduced, resulting in urine with a fixed osmolarity (**isosthenuria**). As kidney function continues to decline, the BUN increases and urine output decreases. At this point, the patient is at risk for fluid overload.

Metabolic Changes

Urea and creatinine excretion are disrupted by kidney dysfunction. Creatinine comes from proteins present in skeletal muscle. The rate of creatinine excretion depends on muscle mass, physical activity, and diet. Without major changes in diet or physical activity, the serum creatinine level is constant.

Creatinine is partially excreted by the kidney tubules, and a decrease in kidney function leads to a buildup of serum creatinine. Urea is made from protein metabolism and is excreted by the kidneys. The BUN level normally varies directly with protein intake and hydration status.

The method for assessing the GFR is the use of a formula that considers the serum creatinine level, age, gender, race, and body size. The most common formula is the Cockcroft-Gault equation.

Sodium excretion changes are common. Early in CKD, the patient is at risk for *hyponatremia* (sodium depletion) because there are fewer healthy nephrons to reabsorb sodium. Thus sodium is lost in the urine. The polyuria of early kidney dysfunction also causes sodium loss.

In the later stages of CKD, kidney excretion of sodium is reduced as urine production decreases. Then sodium retention and high serum sodium levels (*hypernatremia*) can occur with only modest increases in dietary sodium intake. This problem leads to severe fluid and electrolyte imbalances (see Chapter 13). Sodium retention causes hypertension and edema.

Even with sodium retention, the serum sodium level may appear normal because plasma water is retained at the same time. If fluid retention occurs at a greater rate than sodium retention, the serum sodium level is falsely low because of dilution (see Chart 71-2).

Potassium excretion occurs mainly through the kidney. Any increase in potassium load during the later stages of CKD can lead to *hyperkalemia* (high serum potassium levels). Normal serum potassium levels of 3.5 to 5 mEq/L are maintained until the 24-hour urine output falls below 500 mL. High potassium levels then develop quickly, reaching 7 to 8 mEq/L or greater. Severe ECG changes result from this elevation, and fatal dysrhythmias can occur. Other factors contribute to high potassium levels in CKD, including the ingestion of potassium in drugs, failure to restrict dietary potassium, tissue breakdown, blood transfusions, and bleeding or hemorrhage. (See Chapter 13 for discussion of potassium problems.)

Acid-base balance is affected by CKD. In the early stages, blood pH changes little because the remaining healthy nephrons increase their rate of acid excretion. As more nephrons are lost, acid excretion is reduced and metabolic acidosis results (see Chapter 14).

Many factors lead to acidosis in CKD. First, the kidneys cannot excrete excessive hydrogen ions (acids). Normally, tubular cells move hydrogen ions into the urine for excretion, but ammonium and bicarbonate are needed for this movement to occur. In patients with CKD, ammonium production is decreased and reabsorption of bicarbonate does not occur. This process leads to a buildup of hydrogen ions and reduced levels of bicarbonate (*base deficit*). High potassium levels further reduce kidney ammonium production and excretion.

As CKD worsens and acid retention increases, increased respiratory action is needed to keep blood pH normal. The respiratory system adjusts or compensates for the increased blood hydrogen ion levels (decreased pH) by increasing the rate and depth of breathing to excrete carbon dioxide through the lungs. This breathing pattern, called *Kussmaul respiration*, increases with worsening kidney disease. Although hydrogen ions (acids) can leave the body this way, when too

much carbon dioxide is “blown off,” respiratory alkalosis results. Serum bicarbonate measures the extent of metabolic acidosis (bicarbonate deficit). Patients with CKD usually need alkali replacement to counteract acidosis.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

The wife of a client with severe chronic kidney disease who has a Kussmaul pattern of respiration asks the nurse about giving the client oxygen to ease his respirations. What is the nurse's best response?

- “That is a good idea and I will check with the physician right away.”
- “The oxygen mask or tube may increase his risk for skin breakdown.”
- “He will probably need a high flow of oxygen because he is also anemic.”
- “Oxygen will not help his respirations and could make his acidosis worse.”

Calcium and phosphorus balance is disrupted by CKD. A complex, balanced normal relationship exists between calcium and phosphate and is influenced by vitamin D (see Chapter 13). The kidney produces calcitriol, the active form of vitamin D, which then enhances intestinal absorption of calcium.

In CKD, phosphate retention and a deficiency of active vitamin D disrupt the calcium and phosphate balance. Normally, excessive dietary phosphate is excreted by the kidneys in the urine. Parathyroid hormone (PTH) controls the amount of phosphate in the blood by causing tubular excretion of phosphate when there is an excess. An early effect of CKD is reduced phosphate excretion (Fig. 71-2). As plasma

FIG. 71-2 The effects of kidney dysfunction on phosphate and calcium balance. PTH, Parathyroid hormone.

phosphate levels increase (*hyperphosphatemia*), calcium levels decrease (*hypocalcemia*). Chronic low blood calcium levels stimulate the parathyroid glands to release more PTH. Under the influence of additional PTH, calcium is released from storage areas in bones (**bone resorption**), which results in bone density loss. The extra calcium from the bone is needed to balance the excess plasma phosphate level. The problem of low blood calcium levels is made worse with severe CKD because kidney cell damage also reduces production of active vitamin D. Thus less calcium is absorbed through the intestinal tract in the absence of sufficient vitamin D.

The problems in bone metabolism and structure caused by CKD-induced low calcium levels and high phosphorus levels are called **renal osteodystrophy**. Bone mineral loss causes bone pain, spinal sclerosis, fractures, bone density loss, osteomalacia, and tooth calcium loss.

Crystals formed from excessive calcium phosphate are called *metastatic calcifications* and may precipitate in many body areas. When the plasma level of the calcium-phosphate product (serum calcium level multiplied by the serum phosphate level) exceeds 70 mg/dL, the crystals may lodge in the kidneys, heart, lungs, major blood vessels, joints, eyes (causing conjunctivitis), and brain. Skin itching increases with calcium-phosphate imbalances.

Cardiac Changes

Hypertension is common in most patients with CKD. This problem may be either the cause or the result of CKD. In patients who have other causes of hypertension such as atherosclerosis, the increased blood pressure damages the delicate capillaries in the glomerulus, and eventually ESKD results.

CKD itself elevates blood pressure by causing fluid and sodium overload and dysfunction of the renin-angiotensin-aldosterone system. The retention of sodium and water causes circulatory overload, which elevates blood pressure. The kidneys respond to a decrease in kidney blood flow or to low serum sodium levels by trying to improve blood flow to the kidney. The release of renin triggers the production of more angiotensin and aldosterone. Angiotensin causes blood vessel constriction and increases blood pressure. Aldosterone, a hormone released by the adrenal glands, stimulates kidney tubules to reabsorb sodium and water. These actions increase plasma volume and raise blood pressure. The damaged kidneys do not recognize the increase in blood pressure and continue to produce renin. The result is severe hypertension that is difficult to treat and worsens kidney function. Many patients with CKD also have heart damage and heart enlargement from the long-term hypertension.

Hyperlipidemia occurs in CKD from changes in fat metabolism that increase triglyceride, total cholesterol, and low-density lipoprotein (LDL) levels. These changes increase the patient's risk for coronary artery disease and acute cardiac events. Problems with lipids and atherosclerosis are increased for the patient CKD and diabetes (Brites et al., 2007).

Heart failure may occur in CKD because it increases the workload on the heart as a result of anemia, hypertension, and fluid overload. Left ventricular enlargement and heart failure are common in ESKD. Uremia may cause *uremic cardiomyopathy*, the uremic toxin effect on the myocardium. Heart failure also may occur in these patients because of hypertension and coronary artery disease. Cardiac disease

continues to be the leading cause of death in patients with ESKD (USRDS, 2010).

Pericarditis also occurs in patients with CKD. The pericardial sac becomes inflamed by uremic toxins or infection. If it is not treated, this problem leads to pericardial effusion, cardiac tamponade, and death. Manifestations include severe chest pain, increased pulse rate, low-grade fever, and a pericardial friction rub that can be heard with a stethoscope placed over the left sternal border.

As the pericarditis continues and the pericardial effusion worsens, dysrhythmias may develop. The fluid around the heart makes heart tones softer and harder to hear. Blood pressure decreases, and the patient may have shortness of breath. If left untreated, pericardial effusion causes cardiac tamponade, an emergency in which pulse pressure decreases and bradycardia results. Treatment of tamponade requires removal of pericardial fluid by placement of a needle, catheter, or drainage tube into the pericardium.

Hematologic Changes

Anemia is a common problem in patients in the later stages of CKD, and it worsens the CKD manifestations. The causes of anemia include a decreased erythropoietin level that decreases red blood cell (RBC) production, decreased RBC survival time resulting from uremia, iron and folic acid deficiencies, and increased bleeding as a result of impaired platelet function.

Gastrointestinal Changes
